ENCYCLOPÆDIA BRITANNICA.

MENA, JUAN DE, one of the Italianizing Spanish poets of the 15th century, was born at Cordova about 1411. We are informed by Romero, to whom we are indebted for almost all we know about his life, that he had ıttained the age of twenty-three before he began to give himself to "the sweet labour of good learning," pursuing a regular course of study at Salamanca and afterwards at Rome. It was at the latter city that he first became ıcquainted with the writings of Dante and Petrarch, which ıfterwards so powerfully influenced his own style. Having returned to Spain, he became a "veinticuatro," or magis-rate, of his native town, and was received as a poet with great favour at the court of John II., being made Latin secre-ary to the king and historiographer of Castile. He died uddenly, in consequence of a fall from his mule, in 1456, ıt Torrelaguna, where the marquis of Santillana, his friend ınd patron, erected his monument and wrote his epitaph. De Mena's principal work, *El Laberinto* ("The Labyrinth"), ometimes called *Las Trescientas* ("The Three Hundred") rom the original number of its stanzas, is a didactic llegory on the duties and destinies of man, obviously con-tructed on the lines of the *Divina Commedia* of Dante. The poet, while wandering in a wood and exposed to the ıttacks of various beasts of prey, is met by Providence in he guise of a beautiful woman, who offers to guide him afely through the dangers which surround him, and at the ame time to explain—"as far as they may be grasped by uman understanding"—the dark mysteries of life that veigh upon his spirit. He is then led to the spherical entre of the five zones, where he sees the three wheels of estiny, the past, the future, and the present, and the men elonging to each, arranged in the seven circles of planetary nfluence. Opportunity is thus afforded for a vast quan-ity of mythological and historical portraiture; the best ketches are those of the poet's own contemporaries, but he work in general is much disfigured with all sorts of edantry, and hardly ever attains to mediocrity as a poem. The *Laberinto* was first printed at Seville in 1496; Nuñez nd Sanchez accompanied it with commentaries in 1499 nd 1582 respectively; and it is still regarded with a good eal of reverence by the Spaniards as the "magnum opus" f their "Ennius." De Mena was the author of a number f minor poems or "vers de société," written merely for court circles, and having neither general interest nor per-manent value; most of them are to be found in the *Cancionero General*. He also wrote a poem entitled *La Coronacion*, the subject being the "crowning" of the marquis of Santillana by the Muses and the Virtues on Mount Parnassus. Finally, his *Siete Pecados Mortales* ("Seven Deadly Sins") is a dull allegory on the antagonism between reason and the will of man. Complete editions of the poems of De Mena appeared in 1528, 1804, and 1840.

MÉNAGE, GILLES (1613-1692), described by Bayle as "one of the most learned men of his time, and the Varro of the 17th century," was the son of Guillaume Ménage, king's advocate at Angers, and was born in that city on August 15, 1613. A tenacious memory and an early developed enthusiasm for learning carried him speedily through his literary and professional studies, and we read of him practising at the bar at Angers as early as 1632. In the same year he pleaded several causes before the parlement of Paris, and soon afterwards he attended the "Grand Tours" at Poitiers, but after having been laid aside by a severe illness he abandoned the legal profession and declared his intention of entering the church. He succeeded in obtaining some sinecure benefices, and lived for some years in the household of Cardinal De Retz (then only coadjutor to the archbishop of Paris), where he had ample leisure for his favourite literary pursuits. Some time after 1648 he withdrew to a house of his own in the cloister of Notre Dame, where his remarkable conversational powers enabled him to gather round him on Wednesday evenings those much frequented literary assemblies which he called "Mercuriales." His learning procured for him admission to the Della Cruscan Academy of Florence, but his irrepressible tendency to caustic sarcasm led to his remorseless exclusion from the French Academy. He died at Paris on July 23, 1692. Of the voluminous works of Ménage (fully enumerated in the *Dictionnaire* of Chauffepié) the following may be mentioned:—*Origines de la Langue Françoise* (1650; greatly enlarged in 1694); *Diogenes Laertius Græce et Latine, cum Commentario* (1663, and again much improved in 1692); *Poemata Latina, Gallica, Græca, et Italica* (1656; 8th ed., 1687); *Origini della Lingua Italiana* (1669); and *Anti-Baillet* (1690).

er his death a volume of *Menagiana* was published; it ; afterwards expanded into two, and, with great addi- ıs, into four in the Paris edition of 1715.

IENANDER, the most famous Greek poet of the v Comedy, which prevailed from about the death of xander the Great (323 B.C.) to 250. He was born at ıens in 342, and died, it was said, by drowning in the bour of that city (Piræus) in 291. His social tastes uced him to write plays rather for the upper classes, to raise comedy to a gentility which it had hardly ;essed in the hands of the preceding comic poets. He the associate, if not the pupil, of Theophrastus, who self had been a disciple of Plato and Aristotle, and he the intimate friend and admirer of Epicurus; but he enjoyed the more distinguished patronage of Demetrius lereus (who was likewise a pupil of Theophrastus), and tolemy the son of Lagus.[1] His principal rival in the art Philemon, who appears to have been more popular with multitude, and for that reason probably more successful. said that out of a hundred comedies Menander gained prize with but eight. All the extant plays of Terence, the exception of the *Phormio*, are avowedly taken Menander; but some of them appear to have been tations and combinations of more than one plot, ›ugh Terence himself says in the prologue to the *phi* (11) that he copied the Greek model closely, bum de verbo expressum extulit." Julius Cæsar d Terence *dimidiatus Menander*, as if two halves of rent plays had been fitted into one.[2]

ıe Attic New Comedy, says Dr Wagner,[3] "may be nated as essentially domestic," *i.e.*, as opposed to free discussion of the politics of the day which gave e Old Comedy the place which is held by the "leading es" of a modern newspaper. "The stock characters such as the stern or weak father, the son whose ; are seconded by a slave or a hungry parasite, the ogger, active in stirring up law suits, and the gascon- soldier of fortune."[4] These and cognate subjects, ı formed the stock-in-trade of Menander's plays, are ıed up in two well-known lines of Ovid—

> "Dum fallax servus, durus pater, improba lena
> Vivet, dum meretrix blanda, Menandros erit."

, good remark of Dr Wagner's[5] that the last-mentioned ıese, the *meretrix blanda* (which probably refers ally to the *Thais*), "holds the most important and icuous part in the New Attic Comedy, while married are continually represented as the plague and bore eir husbands' lives." Intrigues with these, generally gh the medium of a clever confidential slave, are for ıost part the very point or pivot on which the plot

› more literary Romans greatly admired Menander ɔoet. Pliny (*N. H.*, xxx. 1, § 7) speaks of him as ander litterarum subtilitati sine æmulo genitus." rtius, contemplating a visit to Athens,[6] anticipates easure of reading Menander in his native city—

> "Persequar aut studium linguæ, Demosthenis arma,
> Libaboque tuos, scite Menandre, sales."

He elsewhere speaks of him as "mundus Menander," neat, terse, and urbane; and his skill in depicting the character of a fascinating Thais is alluded to here and in ii. 6, 3:—

> "Turba Menandreæ fuerat nec Thaidos olim
> Tanta, in qua populus lusit Erichthonius."

Of this comedy, the *Thais*, Professor Mahaffy remarks[7] that perhaps it was the most brilliant of Menander's plays, "the manners and characters of the personage being painted with thorough experience as well as genius." Nevertheless, only five verses of this play have been preserved to us, one of which is that quoted by St Paul (1 Cor. xv. 33), "Evil communications corrupt good manners." The same critic, in praising Menander's style as the purest model of the New Attic, observes that a remarkable feature of the New Comedy was "its utter avoidance of rhetoric" (p. 489). The influence which this art had on Euripides is well known. Sophocles was not wholly exempt from a kind of rhetorical pedantry, and the speeches in Thucydides are so many exercises of the author in that art. But, as rhetoric pertained essentially to public life, it was likely to have a much less scope in scenes borrowed almost solely from social and domestic experiences.

Menander, however, did not neglect the other branch of a liberal Attic education,—philosophy. A follower and a friend of Epicurus, whose *summum bonum* was the greatest amount of enjoyment to be got out of life, he carried out in practice what he advocated by precept; for he was essentially the well-to-do gentleman,[8] and moved in the upper circles of Athenian society. "The philosophers of the day" (*i.e.*, the schools and universities in our modern systems of teaching) "were still," says Professor Mahaffy,[9] viz., even during the period of the New Comedy, "the constant butt of the dramatists." He adds that, "what is still stranger, political attacks on living personages, not excepting Alexander the Great, were freely and boldly made."

On the whole, our estimate of the spirit and object of Menander must be formed rather from his imitator and copyist Terence than from the fragments which remain, about 2400 verses in all, as collected by Meineke in his *Fragmenta Comicorum Græcorum*. For, as Professor Mahaffy well observes,[10] the extracts made by Athenæus, our principal authority, have reference chiefly to "the archæology of cooks and cookery," while Stobæus was a collector of γνῶμαι or wise maxims,—"a most unfortunate and worthless kind of citation." It follows that no sound conclusions as to dramatic genius, or of the knowledge of human nature, can be drawn from detached verses preserved without the least reference to these particular points. The extraordinary popularity of Menander must have been due to literary merit, if not to great originality. Mr Mahaffy observes on this[11] that "there is so much of a calm gentlemanly morality about his fragments, he is so excellent a teacher of the ordinary world-wisdom—resignation, good temper, moderation, friendliness—that we can well understand this popularity. Copies of his plays continued long in existence, and were certainly known to Suidas and Eustathius as late as the 11th and 12th centuries, if they did not survive to a yet later period.[12]

In respect of language, Menander occupies the same position in poetry which his contemporary Demosthenes does in prose. In both the New Attic is elaborated with great finish, and with much greater grammatical precision than we find in writers of the Old Attic, such as Sophocles and Thucydides. A considerable addition to the vocabulary of every-day life had now been made, as was indeed inevitable from the versatile character of the language and the genius of the people who used it. Many new verb-forms, especially the perfect active,[13] now occur, and indeed form a characteristic innovation of the style of Plato. The earlier prose was in its general vocabulary to a considerable extent poetical, and such a concurrence of short syllables as in the Platonic ἀποδεδοκιμακότες

ıllusion to this Pliny writes (*N. H.*, vii. 30, § 111), "Magnum andro in comico socco testimonium regum Ægypti et Mace- ›ontigit classe et per legatos petito; majus ex ipso, regiæ prælata litterarum conscientia." This seems to say that er had been invited to the courts of Alexander and Ptolemy, ɔides had been to that of Archelaus, king of Macedonia, but ferred to write comedies for the Attic stage.

ıs the *Andria*, *Heautontimorumenos*, and *Hecyra* are described ; in the *tituli* prefixed as *Græca* or *tota Græca Menandru*. *nuch* and *Timorumenos* are each based on two plays of er, and the *Adelphi* was compiled partly from Menander and rom Diphilus.

13 A curious example is ἀπεκτάγκασι, the transitive perfect of ἀποκτείνειν. Similarly we have the unusual forms κέχρηκα (frag. 559), εὕδφηκα (727), συγκέχυκα (810).

(ἀποδοκιμάζειν) is ill-suited even to choral metre. The Old Comedy was worked by men of real genius, who "were indeed giants, while the men of Menander's day only showed how strong and thorough was the culture which in art and literature outlived the decadence of the nation."[1]

In all, we have, as collected by Meineke, 1045 fragments of Menander, of which 515 can be referred to known plays, the titles of those quoted from amounting to ninety, and including the Terentian *Andria, Adelphi, Eunuchus, Heautontimorumenos*. These fragments contain about 1650 verses or parts of verses, not including a considerable number of words quoted expressly as from Menander by the old lexicographers. Besides all these there are not fewer than 758 monostich verses separately preserved in MSS., though some of these are met with in the other and longer fragments. Many of the fragments are obscure, some corrupt; and they have been a fertile field for critical acumen from the time of Bentley. Not unfrequently we come upon the shrewd or original remark of an observer. Thus (frag. 7) "A poor man has no relations, for no one acknowledges him, lest he should beg." Frag. 145, "Everything that takes place is brought about by law, necessity, or fashion." 237, "The gods do not save men through any human means (prayer or sacrifices); if they did, the human would have more power than the divine." 275, "Poverty is the most easily cured of all evils; any friend can do it by merely putting his hand in his pocket." 397, "A poor man who lives in a large town makes himself more wretched than he need; for he cannot help comparing with his own the luxurious lives of the rich." 435, "No man realizes the extent of a sin when he commits it; it is afterwards that he sees it." 460, "A man is convinced not so much by what is said as by the manner of saying it." 474, "There is one thing only that hides vulgarity, villainy, and every other fault,—wealth. Everything but that is carped at and criticized." 517, "People who have no merit of their own generally boast of their birth and their ancestors. But every living man has ancestors, or he would not be a living man." 578, "Wealth acts on a man as wind does on a ship,—it often forces him out of his proper course." 663, "Many a young lady says a great deal in her own favour by saying nothing at all." 688, "A man who abuses his own father is practising blasphemy against the gods." In fact, Menander is characteristically a sententious writer, like Euripides, with whom in the general style of his writings, though not, of course, in his somewhat loose and irregular versification, he is sometimes compared. (F. A. P.)

MENCIUS, the Latinized form of Măng-tsze, "Mr Măng," or "Măng the philosopher," a name in China only second as a moral teacher to that of Confucius. His statue or spirit-tablet (as the case may be) has occupied, in the temples of the sage, since our 11th century, a place among "the four assessors"; and since 1530 A.D. his title has been "the philosopher Măng, sage of the second degree."

The Măngs or Măng-suns had been in the time of Confucius one of the three great clans of Lû (all descended from the marquis Hwan, 711–694 B.C.), which he had endeavoured to curb. Their power had subsequently been broken, and the branch to which Mencius belonged had settled in Tsâu, a small adjacent principality, the name of which still remains in Tsâu hsien, a district of Yenchâu Shan-tung. A magnificent temple to Mencius is the chief attraction of the district city. The present writer visited it in 1873, and was struck by a large marble statue of him in the courtyard in front. It shows much artistic skill, and gives the impression of a man strong in body and mind, thoughtful and fearless. His lineal representative lives in the city, and thousands of Măngs are to be found in the neighbourhood.

The dates of some of the principal events in Mencius's life are fixed by a combination of evidence, and his death is referred by common consent to the year 289 B.C. He had lived to a great age,—some say to his eighty-fourth year, placing his birth in 372 B.C., and others to his ninety-seventh, placing it in 385. All that we are told of his father is that he died in the third year of the child, who was thus left to the care of his mother. She was a lady of superior character, and well discharged her trust. Her virtues and dealings with her son were celebrated by a great writer in the first century before our era, and for two thousand years she has been the model mother of China.

[1] Mahaffy, *Ibid.*, p. 490.

We have no accounts of Mencius for many years after his boyhood, and he is more than forty years old when he comes before us as a public character. He must have spent much time in study, investigating the questions which were rife as to the fundamental principles of morals and society, and brooding over the condition of the country. The history, the poetry, the institutions, and the great men of the past had received his careful attention. He intimates that he had been in communication with men who had been disciples of Confucius. That sage had become to him the chief of mortal men, the object of his untiring admiration; and in the doctrines which he had taught Mencius recognized the truth for want of an appreciation of which the bonds of order all round him were being relaxed, and the kingdom hastening to a general anarchy.

When he first comes forth from Tsâu, he is accompanied by several eminent disciples. He had probably imitated Confucius in becoming the master of a school, and encouraging the resort to it of inquiring minds that he might resolve their doubts and unfold to them the right methods of government. One of his sayings is that it would be a greater delight to the superior man to get the youth of brightest promise around him and to teach and train them than to enjoy the revenues of the kingdom. His intercourse with his followers was not so intimate as that of Confucius had been with the members of his selected circle; and, while he maintained his dignity among them, he was not able to secure from them the same homage and reverent admiration.

More than a century had elapsed since the death of Confucius, and during that period the feudal kingdom of Châu had been showing more and more of the signs of dissolution, and portentous errors that threatened to upset all social order were widely disseminated. The sentiment of loyalty to the dynasty had disappeared. Several of the marquises and other feudal princes of earlier times had usurped the title of king. The smaller fiefs had been absorbed by the larger ones, or reduced to a state of helpless dependence on them. Tsin, after greatly extending its territory, had broken up into three powerful kingdoms, each about as large as England. Mencius found the nation nominally one, and with the traditions of two thousand years affirming its essential unity, but actually divided into seven monarchies, each seeking to subdue the others under itself. The consequences were constant warfare and chronic misery.

In Confucius's time we meet with recluses who had withdrawn in disgust from the world and its turmoil; but these had now given place to a class of men who came forth from their retirements provided with arts of war or schemes of policy which they recommended to the contending chiefs, ever ready to change their allegiance as they were moved by whim or interest. Mencius was once asked about two of them, "Are they not really great men? Let them be angry, and all the princes are afraid. Let them live quietly, and the flames of trouble are everywhere extinguished." He looked on them as little men, and delighted to proclaim his idea of the great man in such language as the following:—

"To dwell in love, the wide house of the world, to stand in propriety, the correct seat of the world, and to walk in righteousness, the great path of the world; when he obtains his desire for office, to practise his principles for the good of the people, and when that desire is disappointed, to practise them alone; to be above the power of riches and honours to make dissipated, of poverty and mean condition to make swerve from the right, and of power and force to make bend,—these characteristics constitute the great man."

Most vivid are the pictures which Mencius gives of the condition of the people in consequence of the wars of the states. "The royal ordinances were violated; the multi-

After his death a volume of *Menagiana* was published; it was afterwards expanded into two, and, with great additions, into four in the Paris edition of 1715.

MENANDER, the most famous Greek poet of the New Comedy, which prevailed from about the death of Alexander the Great (323 B.C.) to 250. He was born at Athens in 342, and died, it was said, by drowning in the harbour of that city (Piræus) in 291. His social tastes induced him to write plays rather for the upper classes, and to raise comedy to a gentility which it had hardly possessed in the hands of the preceding comic poets. He was the associate, if not the pupil, of Theophrastus, who himself had been a disciple of Plato and Aristotle, and he was the intimate friend and admirer of Epicurus; but he also enjoyed the more distinguished patronage of Demetrius Phalereus (who was likewise a pupil of Theophrastus), and of Ptolemy the son of Lagus.[1] His principal rival in the art was Philemon, who appears to have been more popular with the multitude, and for that reason probably more successful. It is said that out of a hundred comedies Menander gained the prize with but eight. All the extant plays of Terence, with the exception of the *Phormio*, are avowedly taken from Menander; but some of them appear to have been adaptations and combinations of more than one plot, although Terence himself says in the prologue to the *Adelphi* (11) that he copied the Greek model closely, "verbum de verbo expressum extulit." Julius Cæsar called Terence *dimidiatus Menander*, as if two halves of different plays had been fitted into one.[2]

The Attic New Comedy, says Dr Wagner,[3] "may be designated as essentially domestic," *i.e.*, as opposed to that free discussion of the politics of the day which gave to the Old Comedy the place which is held by the "leading articles" of a modern newspaper. "The stock characters were such as the stern or weak father, the son whose follies are seconded by a slave or a hungry parasite, the pettifogger, active in stirring up law suits, and the gasconading soldier of fortune."[4] These and cognate subjects, which formed the stock-in-trade of Menander's plays, are summed up in two well-known lines of Ovid—

"Dum fallax servus, durus pater, improba lena
Vivet, dum meretrix blanda, Menandros erit."

It is a good remark of Dr Wagner's[5] that the last-mentioned of these, the *meretrix blanda* (which probably refers especially to the *Thais*), "holds the most important and conspicuous part in the New Attic Comedy, while married ladies are continually represented as the plague and bore of their husbands' lives." Intrigues with these, generally through the medium of a clever confidential slave, are for the most part the very point or pivot on which the plot turns.

The more literary Romans greatly admired Menander as a poet. Pliny (*N. H.*, xxx. 1, § 7) speaks of him as "Menander litterarum subtilitati sine æmulo genitus." Propertius, contemplating a visit to Athens,[6] anticipates the pleasure of reading Menander in his native city—

"Persequar aut studium linguæ, Demosthenis arma,
Libaboque tuos, scite Menandre, sales."

[1] In allusion to this Pliny writes (*N. H.*, vii. 30, § 111), "Magnum et Menandro in comico socco testimonium regum Ægypti et Macedoniæ contigit classe et per legatos petito; majus ex ipso, regiæ fortunæ prælata litterarum conscientia." This seems to say that Menander had been invited to the courts of Alexander and Ptolemy, as Euripides had been to that of Archelaus, king of Macedonia, but had preferred to write comedies for the Attic stage.

[2] Thus the *Andria*, *Heautontimorumenos*, and *Hecyra* are described severally in the *tituli* prefixed as *Græca* or *tota Græca Menandru*. The *Eunuch* and *Timorumenos* are each based on two plays of Menander, and the *Adelphi* was compiled partly from Menander and partly from Diphilus.

Many of the fragments are obscure, some corrupt; and they have been a fertile field for critical acumen from the time of Bentley. Not unfrequently we come upon the shrewd or original remark of an observer. Thus (frag. 7) "A poor man has no relations, for no one acknowledges him, lest he should beg." Frag. 145, "Everything that takes place is brought about by law, necessity, or fashion." 237, "The gods do not save men through any human means (prayer or sacrifices); if they did, the human would have more power than the divine." 275, "Poverty is the most easily cured of all evils; any friend can do it by merely putting his hand in his pocket." 397, "A poor man who lives in a large town makes himself more wretched than he need; for he cannot help comparing with his own the luxurious lives of the rich." 435, "No man realizes the extent of a sin when he commits it; it is afterwards that he sees it." 460, "A man is convinced not so much by what is said as by the manner of saying it." 474, "There is one thing only that hides vulgarity, villainy, and every other fault,—wealth. Everything but that is carped at and criticized." 517, "People who have no merit of their own generally boast of their birth and their ancestors. But every living man has ancestors, or he would not be a living man." 578, "Wealth acts on a man as wind does on a ship,—it often forces him out of his proper course." 663, "Many a young lady says a great deal in her own favour by saying nothing at all." 688, "A man who abuses his own father is practising blasphemy against the gods." In fact, Menander is characteristically a sententious writer, like Euripides, with whom in the general style of his writings, though not, of course, in his somewhat loose and irregular versification, he is sometimes compared. (F. A. P.)

MENCIUS, the Latinized form of Măng-tsze, "Mr Măng," or "Măng the philosopher," a name in China only second as a moral teacher to that of Confucius. His statue or spirit-tablet (as the case may be) has occupied, in the temples of the sage, since our 11th century, a place among "the four assessors"; and since 1530 A.D. his title has been "the philosopher Măng, sage of the second degree."

The Măngs or Măng-suns had been in the time of Confucius one of the three great clans of Lû (all descended from the marquis Hwan, 711–694 B.C.), which he had endeavoured to curb. Their power had subsequently been broken, and the branch to which Mencius belonged had settled in Tsâu, a small adjacent principality, the name of which still remains in Tsâu hsien, a district of Yenchâu Shan-tung. A magnificent temple to Mencius is the chief attraction of the district city. The present writer visited it in 1873, and was struck by a large marble statue of him in the courtyard in front. It shows much artistic skill, and gives the impression of a man strong in body and mind, thoughtful and fearless. His lineal representative lives in the city, and thousands of Măngs are to be found in the neighbourhood.

The dates of some of the principal events in Mencius's life are fixed by a combination of evidence, and his death is referred by common consent to the year 289 B.C. He had lived to a great age,—some say to his eighty-fourth year, placing his birth in 372 B.C., and others to his ninety-seventh, placing it in 385. All that we are told of his father is that he died in the third year of the child, who was thus left to the care of his mother. She was a lady of superior character, and well discharged her trust. Her virtues and dealings with her son were celebrated by a great writer in the first century before our era, and for two thousand years she has been the model mother of China.

[1] Mahaffy, *Ibid.*, p. 490.

We have no accounts of Mencius for many years afte his boyhood, and he is more than forty years old when h comes before us as a public character. He must have spen much time in study, investigating the questions which wer rife as to the fundamental principles of morals and society and brooding over the condition of the country. The his tory, the poetry, the institutions, and the great men of th past had received his careful attention. He intimates tha he had been in communication with men who had bee disciples of Confucius. That sage had become to him th chief of mortal men, the object of his untiring admiration and in the doctrines which he had taught Mencius recog nized the truth for want of an appreciation of which th bonds of order all round him were being relaxed, and th kingdom hastening to a general anarchy.

When he first comes forth from Tsâu, he is accompanie by several eminent disciples. He had probably imitate Confucius in becoming the master of a school, and en couraging the resort to it of inquiring minds that h might resolve their doubts and unfold to them the righ methods of government. One of his sayings is that i would be a greater delight to the superior man to get th youth of brightest promise around him and to teach an train them than to enjoy the revenues of the kingdom His intercourse with his followers was not so intimate a that of Confucius had been with the members of hi selected circle; and, while he maintained his dignity amon them, he was not able to secure from them the sam homage and reverent admiration.

More than a century had elapsed since the death o Confucius, and during that period the feudal kingdom o Châu had been showing more and more of the sign of dissolution, and portentous errors that threatened t upset all social order were widely disseminated. Th sentiment of loyalty to the dynasty had disappeared Several of the marquises and other feudal princes of earlie times had usurped the title of king. The smaller fiefs ha been absorbed by the larger ones, or reduced to a state o helpless dependence on them. Tsin, after greatly extend ing its territory, had broken up into three powerful king doms, each about as large as England. Mencius foun the nation nominally one, and with the traditions of tw thousand years affirming its essential unity, but actuall divided into seven monarchies, each seeking to subdue th others under itself. The consequences were constant war fare and chronic misery.

In Confucius's time we meet with recluses who ha withdrawn in disgust from the world and its turmoil; bu these had now given place to a class of men who cam forth from their retirements provided with arts of war o schemes of policy which they recommended to the contend ing chiefs, ever ready to change their allegiance as they were moved by whim or interest. Mencius was once aske about two of them, "Are they not really great men? Le them be angry, and all the princes are afraid. Let them live quietly, and the flames of trouble are everywhere ex tinguished." He looked on them as little men, an delighted to proclaim his idea of the great man in such language as the following:—

"To dwell in love, the wide house of the world, to stand i propriety, the correct seat of the world, and to walk in righteousness the great path of the world; when he obtains his desire for office, to practise his principles for the good of the people, and when tha desire is disappointed, to practise them alone; to be above th power of riches and honours to make dissipated, of poverty an mean condition to make swerve from the right, and of power an force to make bend,—these [illegible] constit[illegible] the grea man."

Most vivid are

tudes were oppressed; the supplies of food and drink flowed away like water." It is not wonderful that, when the foundations of government were thus overthrown, speculations should have arisen that threatened to overthrow what he considered to be the foundations of truth and all social order. "A shrill-tongued barbarian from the south," as Mencius called him, proclaimed the dissolution of ranks, and advocated a return to the primitive simplicity,

"When Adam delved and Eve span."

He and his followers maintained that learning was quackery, and statesmanship craft and oppression, that prince and peasant should be on the same level, and every man do everything for himself. Another, called Yang-chû, denied the difference between virtue and vice, glory and shame. The tyrants of the past, he said, were now but so many rotten bones, and the heroes and sages were no more. It was the same with all at death; after that there was but so much putridity and rottenness. The conclusion of the whole matter therefore was—"Let us eat and drink; let us gratify the ears and eyes, get servants and maidens, beauty, music, wine; when the day is insufficient, carry it on through the night. Each one for himself." Against a third heresiarch, of a very different stamp, Mencius felt no less indignation. This was Mo Tî, who found the source of all the evils of the time and of all time in the want of mutual love. He taught, therefore, that men should love others as themselves; princes, the states of other princes as much as their own; children, the parents of others as much as their own. Mo, in his gropings, had got hold of a noble principle, but he did not apprehend it distinctly nor set it forth with discrimination. To our philosopher the doctrine appeared contrary to the Confucian orthodoxy about the five relations of society; and he attacked it without mercy and with an equal confusion of thought. "Yang's principle," he said, "is 'each one for himself,' which does not acknowledge the claims of the sovereign. Mo's is 'to love all equally,' which does not acknowledge the peculiar affection due to a father. But to acknowledge neither king nor father is to be in the state of a beast. The way of benevolence and righteousness is stopped up."

On this seething ocean of lawlessness, wickedness, heresies, and misery Mencius looked out from the quiet of his school, and his spirit was stirred within him to attempt the rescue of the people from the misrule and error. It might be that he would prove the instrument for this purpose. "If Heaven," he said, "wishes that the kingdom should enjoy tranquillity and good order, who is there besides me to bring it about?" He formed his plan, and proceeded to put it in execution. He would go about among the different kings till he should find one among them who would follow his counsels and commit to him the entire administration of his government. That obtained, he did not doubt that in a few years there would be a kingdom so strong and so good that all rulers would acknowledge its superiority, and the people hasten from all quarters to crown its sovereign as monarch of the whole of China. This plan was much the same as that of Confucius had been; but, with the bolder character that belonged to him, Mencius took in one respect a position from which "the master" would have shrunk. The former was always loyal to Châu, and thought he could save the country by a reformation; the latter saw the day of Châu was past, and the time was come for a revolution. Mencius's view was the more correct, but he was not wiser than the sage in forecasting for the future. They could think only of a reformed dynasty or of a changed dynasty, ruling according to the model principles of a feudal constitution, which they described in glowing language. They desired a repetition of the golden age in the remote past; but soon after Mencius disappeared from the stage of life there came the sovereign of Ch'in, and solved the question with fire and sword, introducing the despotic empire which has since prevailed.

An inquiry here occurs—"How, in the execution of his plan, was Mencius, a scholar, without wealth or station, to find admission to the courts of lawless and unprincipled kings, and acquire the influence over them which he expected?" It can only be met by our bearing in mind the position accorded from the earliest times in China to men of virtue and ability. The same written character denotes both scholars and officers. They are at the top of the social scale,—the first of the four classes into which the population has always been divided. This appreciation of learning or culture has exercised a most powerful influence over the government under both conditions of its existence; and out of it grew the system, which was organized and consolidated more than a thousand years ago, of making literary merit the passport to official employment. The ancient doctrine was that the scholar's privilege was from Heaven as much as the sovereign's right; the modern system is a device of the despotic rule to put itself in Heaven's place, and have the making of the scholar in its own hands. The feeling and conviction out of which the system grew prevailed in the time of Mencius. The dynasties that had successively ruled over the kingdom had owed their establishment not more to the military genius of their founders than to the wisdom and organizing ability of the learned men, the statesmen, who were their bosom friends and trusted counsellors. Why should not he become to one of the princes of his day what Î Yin had been to Thang, and Thâi-kung Wang to King Wân, and the duke of Châu to Wû and Ch'ăng? But, though Mencius might be the equal of any of those worthies, he knew of no prince like Thang and the others, of noble aim and soul, who would welcome and adopt his lessons. In his eagerness he overlooked this condition of success for his enterprise. He might meet with such a ruler as he looked for, or he might reform a bad one, and make him the coadjutor that he required. On the strength of these peradventures, and attended by several of his disciples, Mencius went for more than twenty years from one court to another, always baffled, and always ready to try again. He was received with great respect by kings and princes. He would not enter into the service of any of them, but he occasionally accepted honorary offices of distinction; and he did not scruple to receive large gifts which enabled him to live and move about as a man of wealth. In delivering his message he was as fearless and outspoken as John Knox. He lectured great men, and ridiculed them. He unfolded the ways of the old sage kings, and pointed out the path to universal sway; but it was all in vain. He could not stir any one to honourable action. He confronted heresy with strong arguments and exposed it with withering sarcasm; but he could work no deliverance in the earth. The last court at which we find him was that of Lû, probably in 310 B.C. The marquis of that state had given office to Yo-chăng, one of Mencius's disciples, and he hoped that this might be the means of a favourable hearing for himself. So it had nearly happened. On the suggestion of Yo-chăng the marquis had ordered his carriage to be yoked, and was about to step into it, and proceed to bring Mencius to his palace, when an unworthy favourite stepped in and diverted him from his purpose. The disciple told his master what had occurred, reproaching the favourite for his ill-timed intervention; Mencius, however, said to him, "A man's advancement or the arresting of it may seem to be effected by others, but is really beyond their power. My not finding in the marquis of Lû a ruler who would confide

in me and put my lessons in practice is from Heaven." He accepted this incident as a final intimation to him of the will of Heaven. He had striven long against adverse circumstances, but now he bowed in submission. We lose sight of him. He withdrew from courts and the public arena. We have to think of him, according to tradition, passing the last twenty years of his life in the congenial society of his disciples, discoursing to them, and giving the finishing touches to the record of his conversations and opinions, which were afterwards edited by them, and constitute his works. Living, he may have been a failure; dead, yet speaking in them, he has been a great power among the ever-multiplying millions of his countrymen. Nor will any thinker of the West refer to them without interest and benefit. Mencius was not so oracular, nor so self-contained, as Confucius; but his teachings have a vivacity and sparkle of which we never weary, and which is all their own.

We will now attempt to indicate briefly the more important principles which our philosopher thought would have been effectual to regenerate his country, and make an end of misery and heresy within its borders.

And first as to his views on government, and the work to be done by rulers for their subjects. Mencius held with Confucius—and it was a doctrine which had descended to them both from the remotest antiquity—that royal government is an institution of God. An ancient sovereign had said that "Heaven, having produced the people, appointed for them rulers, and appointed for them teachers, who should be assisting to God." Our philosopher, adopting this doctrine, was led by the manifest incompetency of all the rulers of his time to ask how it could be known on what individual the appointment of Heaven had fallen or ought to fall, and he concluded that this could be ascertained only from his personal character and his conduct of affairs. The people must find out the will of Heaven as to who should be their ruler for themselves. There was another old saying which delighted Mencius,—"Heaven sees as the people see; Heaven hears as the people hear." He taught accordingly that, while government is from God, the governors are from the people;—*vox populi vox Dei*.

No claim then of a "divine right" should be allowed to a sovereign if he were not exercising a rule for the good of the people. "The people are the most important element in a nation; the altars to the spirits of the land and grain are the second; the sovereign is the lightest." Mencius was not afraid to follow this utterance to its consequences. The monarch whose rule is injurious to the people, and who is deaf to remonstrance and counsel, should be dethroned. In such a case "killing is no murder."

But who is to remove the sovereign that thus ought to be removed? Mencius had three answers to this difficult question. First, he would have the members of the royal house perform the task. Let them disown their unworthy head, and appoint some better individual of their number in his room. If they could not or would not do this, he thought, secondly, that any high minister, though not allied to the royal house, might take summary measures with the sovereign, assuming that he acted purely with a view to the public weal. His third and grand device was what he called "the minister of Heaven." When the sovereign had become a pest instead of a blessing, he believed that Heaven would raise up some one for the help of the people, some one who should so conduct himself in his original subordinate position as to draw all eyes and hearts to himself. Let him then raise the standard not of rebellion but of righteousness, and he could not help attaining to the highest dignity. Mencius hoped to find one among the rulers of his day who might be made into such a minister, and he counselled one and another to adopt measures with that object. It was in fact counselling rebellion, but he held that the house of Châu had forfeited its title to the throne.

What now were the attributes which Mencius considered necessary to constitute a good government according to his ideal of it? It must be animated by a spirit of benevolence, and ever pursue a policy of righteousness. Its aims must be, first, to make the people well off, and next, to educate them. No one was fit to occupy the throne who could be happy while any of the people were miserable, who delighted in war, who could indulge in palaces and parks which the poorest did not in a measure share with him. Game laws received his emphatic condemnation. Taxes should be light, and all the regulations for agriculture and commerce of a character to promote and encourage them. The rules which he suggested to secure those objects had reference to the existing condition of his country, but they are susceptible of wide application. They carry in them schemes of drainage and irrigation for land, and of free trade for commerce. But it must be, he contended, that a sufficient and certain livelihood be secured for all the people. Without this their minds would be unsettled, and they would proceed to every form of wild licence. They would break the laws, and the ruler would punish them,—punish those whom his neglect of his own duties had plunged into poverty, of which crime was the consequence. He would be, not their ruler, but their "trapper."

Supposing the people to be made well off, Mencius taught that education should be provided for them all. He gave the marquis of Thang a programme of four kinds of educational institutions, which he wished him to establish in his state—in the villages and the towns, for the poor as well as the rich, so that none might be ignorant of their duties in the various relations of society. But after all, unless the people could get food and clothing by their labour, he had not much faith in the power of education to make them virtuous. Give him, however, a government fulfilling the conditions that he laid down, and he was confident there would soon be a people, all contented, all virtuous. And he saw nothing to prevent the realization of such a government. Any ruler might become, *if he would*, "the minister of Heaven," who was his ideal, and the influence of his example and administration would be all-powerful. The people would flock to him as their parent, and help him to do justice on the foes of truth and happiness. Pulse and grain would be abundant as water and fire, and the multitudes, well clothed, and well principled, would sit under the shade of their mulberry trees, and hail the ruler "king by the grace of Heaven."

Secondly, as to Mencius's views about human nature. His conviction of the goodness of that encouraged him to hope for such grand results from good government, and his discussion of this subject gives his principal title to a place among philosophical thinkers.

Opinions were much divided about it among his contemporaries. Some held that the nature of man is neither good nor bad; he may be made to do good and also to do evil. Others held that the nature of some men is good, and that of others bad; thus it is that the best of men sometimes have bad sons, and the worst of men good sons. It was also maintained that the nature of man is evil, and whatever good appears in it is the result of cultivation. In opposition to all these views Mencius contended that the nature of man is good. "Water," he said, "will flow indifferently to the east or west; but will it flow indifferently up or down? The tendency of man's nature to goodness is like the tendency of water to flow downwards. By striking water you may make it leap over your forehead; and by damming and leading it you may make it go up a hill. But such movements are not according to the nature of water; it is the force applied which causes them. When men do what is not good, their nature has been dealt with in this way."

Mencius had no stronger language than this,—as indeed it would be difficult to find any stronger,—to declare his belief of the goodness of human nature. With various, but equally felicitous, illustration he replied to his different opponents. Sometimes he may seem to express himself too strongly, but an attentive study of his writings shows that he is speaking of our nature in its ideal, and not as it actually is,—as we may ascertain, by an analysis of it, that it was intended to be, and not as it has been made to become. In fact, his doctrine of human nature is hardly to be distinguished from that of Bishop Butler, while the Christian prelate is left far behind so far as charm of style is concerned.

Our author insists on the constituents of human nature, dwelling especially on the principles of benevolence, righteousness, propriety, and wisdom or knowledge, the last including the judgment of conscience. "These," said he, "are not infused into us from without. Men have these four principles just as they have their four limbs." But man has also instincts and appetites which seek their own gratification without reference to righteousness or any other control. He met this difficulty by contending that human nature is a constitution, in which the higher principles are designed to rule the lower. "Some constituents of it are noble and some ignoble, some great and some small. The great must not be injured for the small, nor the noble for the ignoble."

One of his most vigorous vindications of his doctrine is the following:—"For the mouth to desire flavours, the eye colours, the ear sounds, and the four limbs ease and rest belong to man's nature. An individual's lot may restrict him from the gratification of them; and in such a case the superior man will not say, 'My nature demands that pleasure, and I *will* get it.' On the other hand, there are love between father and son, righteousness between ruler and minister, the rules of ceremony between host and guest, and knowledge seen in recognizing the able and virtuous, and in the sage's fulfilling the heavenly course;—these are appointed (by Heaven). But they also belong to our nature, and the superior man will not say, 'The circumstances of my lot relieve me from them.'" In his preliminary dissertation to the 7th edition of this encyclopædia, Sir James Mackintosh has said that in his sermons on human nature Butler "taught truths more worthy of the name of discovery than any in the same department of inquiry with

which we are acquainted; if we ought not to except the first steps of the Grecian philosophers towards a theory of morals." Mencius was senior to Zeno, the one of those philosophers to whom Butler has most affinity, and it does not appear that he had left anything for either of them to discover.

When he proceeded from his ideal of human nature to account for the phenomena of conduct so different from what they ought to be according to that ideal, he was necessarily less successful. They puzzled him and they made him indignant and angry. "There is nothing good," he said, "that a man cannot do; he only does not do it." But why does he not do it? Against the stubborn fact Mencius beats his wings and shatters his weapons,—all in vain. He mentions a few ancient worthies who, he conceived, had always been, or who had become, perfectly virtuous. Above them all he extols Confucius, taking no notice of that sage's confession that he had not attained to conformity to his own rule of doing to others as he would have them do to him. No such acknowledgment about himself ever came from Mencius. Therein he was inferior to his predecessor: he had a subtler faculty of thought, and a much more vivid imagination; but he did not know himself nor his special subject of human nature so well.

Our limits will not allow us to go into a detail of his views on other special subjects. A few passages illustrative of his style and general teachings will complete all that can be said of him here. His thoughts, indeed, were seldom condensed like those of "the master" into aphorisms, and should be read in their connexion; but we have from him many words of wisdom that have been as goads to millions for more than two thousand years. For instance:—

"Though a man may be wicked, yet, if he adjust his thoughts, fast, and bathe, he may sacrifice to God."

"When Heaven is about to confer a great office on any man, it first exercises his mind with suffering, and his sinews and bones with toil. It exposes his body to hunger, subjects him to extreme poverty, and confounds his undertakings. In all these ways it stimulates his mind, strengthens his nature, and supplies his incompetencies"

"The great man is he who does not lose his child-heart."

"The sense of shame is to a man of great importance. When one is ashamed of having been without shame, he will afterwards not have occasion for shame."

"To nourish the heart there is nothing better than to keep the desires few. Here is a man whose desires are few: in some things he may not be able to keep his heart, but they will be few. Here is a man whose desires are many; in some things he may be able to keep his heart, but they will be few."

"Benevolence is the distinguishing characteristic of man. As embodied in his conduct, it may be called the path of duty."

"There is an ordination for everything; and a man should receive submissively what may be correctly ascribed thereto. He who has the correct idea of what Heaven's ordination is will not stand beneath a tottering wall. Death sustained in the discharge of one's duties may be correctly ascribed to Heaven. Death under handcuffs and fetters cannot be correctly so ascribed."

"When one by force subdues men, they do not submit to him in heart. When he subdues them by virtue, in their hearts' core they are pleased, and sincerely submit."

Two translations of the works of Mencius are within the reach of European readers:—that by the late Stanislaus Julien, in Latin, Paris, 1824–29; and that forming the second volume of Legge's *Chinese Classics*, Hong Kong, 1862. The latter has been published at London (1875) without the Chinese text. See also E. Faber. *The Mind of Mencius, or Political Economy founded on Moral Philosophy*, translated from the German by A. B. Hutchinson (London, 1882). (J. LE.)

MENDELSSOHN, FELIX (1809–1847). Jakob Ludwig Felix Mendelssohn-Bartholdy, one of the greatest composers of this century, was the grandson of Moses Mendelssohn noticed below, and was born in Hamburg on February 3, 1809.

In consequence of the troubles caused by the French occupation of Hamburg, Abraham Mendelssohn, his father, migrated in 1811 to Berlin, where his grandmother, Fromet, then in the twenty-fifth year of her widowhood, received the whole family into her house, No. 7 Neue Promenade. Here the little Felix and his sister Fanny received their first instruction in music from their mother, under whose care they progressed so rapidly that the altogether exceptional character of their talent soon became unmistakably apparent. Their next teacher was Madame Bigot, who, during the temporary residence of the family in Paris in 1816, gave them some valuable instruction. On their return to Berlin they took lessons in thoroughbass and composition from Zelter, in pianoforte-playing from Ludwig Berger, and in violin-playing from Henning,—the care of their general education being entrusted to the father of the novelist Paul Heyse.

Felix first played in public on the 24th of October 1818, taking the pianoforte part in a trio by Woelfl. On April 11, 1819, he entered the Berlin Singakademie as an alto, and in the following year began to compose with extraordinary rapidity. His earliest dated work is a cantata, *In rührend feierlichen Tönen*, completed on January 13, 1820. During that year alone he produced nearly sixty movements, including songs, pianoforte sonatas, a trio for pianoforte, violin, and violoncello, a sonata for violin and pianoforte, pieces for the organ, and even a little dramatic piece in three scenes. In 1821 he wrote five symphonies for stringed instruments, each in three movements; motetts for four voices; an opera, in one act, called *Soldatenliebschaft*; another, called *Die beiden Pädagogen*; part of a third, called *Die wandernde Comödianten*; and an immense quantity of other music of different kinds, some of which, thought worthy of publication by the editors of his posthumous works, now stands before the world in evidence of the precocity of his genius. The original autograph copies of these early productions are now preserved in the Berlin Library, where they form part of a collection which fills forty-four large volumes, all written with infinite neatness, and for the most part carefully dated—a sufficient proof that the methodical habits which distinguished his later life were formed in early childhood.

In 1821 Mendelssohn paid his first visit to Goethe, with whom he spent sixteen days at Weimar, in company with Zelter. From this year also dates his first acquaintance with Weber, who was then in Berlin superintending the production of *Der Freischütz*; and from the summer of 1822 his introduction, at Cassel, to another of the greatest of his contemporaries, Ludwig Spohr. During this year his pen was even more prolific than before, producing, among other works, an opera, in three acts, entitled *Die beiden Neffen, oder Der Onkel aus Boston*, and a pianoforte concerto, which he played in public at a concert given by Frau Anna Milder.

It had long been a custom with the Mendelssohn family to give musical performances on alternate Sunday mornings in their dining-room, with a small orchestra, which Felix always conducted, even when he was not tall enough to be seen without standing upon a stool. For each of these occasions he produced some new work,—playing the pianoforte pieces himself, or entrusting them to Fanny, while his sister Rebecka sang, and his brother Paul played the violoncello. In this way *Die beiden Neffen* was first privately performed, on the fifteenth anniversary of his birthday, February 3, 1824. Between the 3d and the 31st of March, in this year, he composed his fine symphony in C minor, now known as Op. 10, and soon afterwards the quartett in B minor, Op. 3, and the (posthumous) pianoforte sestett, Op. 110. In this year also began his lifelong friendship with Moscheles, who, when asked to receive him as a pupil, said, "If he wishes to take a hint from me, as to anything new to him, he can easily do so; but he stands in no need of lessons."

In 1825 Abraham Mendelssohn took Felix to Paris, where among other musicians then resident in the French capital he met the two most popular dramatic composers of the age, Rossini and Meyerbeer, and lived on terms of intimacy with Hummel, Kalkbrenner, Rode, Baillot, Herz, and many other artists of European celebrity. On this occasion, also, he made his first acquaintance with Cherubini, who, though he rarely praised any one, expressed a very high opinion of his talent, and recommended him to write a *Kyrie*, for five voices, with full orchestral accompaniments, which he himself described as "exceeding

in thickness" anything he had attempted. From letters written at this period we learn that Felix's estimate of the French school of music was very far from a flattering one; but he formed some friendships in Paris, which were pleasantly renewed on later occasions. He returned to Berlin with his father in May 1825, taking leave of his Parisian friends on the 19th of the month, and interrupting his journey at Weimar for the purpose of paying a second visit to Goethe, to whom he dedicated his quartett in B minor. On reaching home he must have fallen to work with greater zeal than ever; for on the 23d of July in this same year he completed his pianoforte capriccio in F sharp minor (Op. 5), and on the 10th of August an opera, in two acts, called *Die Hochzeit des Camacho,* a work of considerable importance, concerning which we shall presently have to speak more particularly.

No ordinary boy could have escaped uninjured from the snares attendant upon such a life as that which Mendelssohn now lived. Notwithstanding his overwhelming passion for music, his general education had been so well cared for that he was able to hold his own, in the society of his seniors, with the easy grace of an accomplished man of the world. He was already recognized as a leading spirit by the artists with whom he associated, and these artists were men of acknowledged talent and position. The temptations to egoism by which he was surrounded would have rendered most clever students intolerable. But the natural amiability of his disposition, and the healthy influence of his happy home-life, counteracted all tendencies towards inordinate self-assertion; and he is described by all who knew him at this period as the most charming boy imaginable. Even Zelter, though by nature no less repressive than Cherubini, was not ashamed to show that he was proud of him; and Moscheles, whose name was already famous, met him from the first on equal terms.

Soon after his return from Paris, Abraham Mendelssohn removed from his mother's residence to No. 3 Leipziger Strasse, a roomy, old-fashioned house, containing an excellent music-room, and in the grounds adjoining a "Gartenhaus" capable of accommodating several hundred persons at the Sunday performances.[1] In the autumn of the following year this "garden-house" witnessed a memorable private performance of the work by means of which the greatness of Mendelssohn's genius was first revealed to the outer world—the overture to Shakespeare's *Midsummer Night's Dream.* The finished score of this famous composition is dated "Berlin, August 6, 1826,"—that is to say, three days after its author had attained the age of seventeen years and a half. Yet we may safely assert that in no later work does he exhibit more originality of thought, more freshness of conception, or more perfect mastery over the details of technical construction, than in this delightful inspiration, which, though now nearly sixty years old, still holds its place at the head of the most brilliant achievements of our modern schools. The overture was first publicly performed at Stettin, in February 1827, under the direction of the young composer, who with this bright patent of artistic nobility to support his claim, was at once accepted as the leader of a new and highly characteristic manifestation of the spirit of modern progress. Henceforth therefore we must speak of him, not as a student, but as a mature and experienced artist.

Meanwhile *Camacho's Wedding* had been submitted to Herr General-Musik-Director Spontini, with a view to its production at the opera. The libretto, founded upon an episode in the history of Don Quixote, was written by Klingemann, and Mendelssohn threw himself into the spirit of the romance with a keen perception of its peculiar humour. The work was put into rehearsal soon after the composer's return from Stettin, produced on April 29, 1827, and received with great apparent enthusiasm; but, for some reason which it is now impossible to ascertain, a cabal was formed against it, and it never reached a second performance. The critics abused it mercilessly; yet it exhibits merits of a very high order. The solemn passage for the trombones, which heralds the first appearance of the knight of La Mancha, is conceived in a spirit of reverent appreciation of the idea of Cervantes, which would have done honour to a composer of lifelong experience. Even the critics suborned to condemn the work could not refrain from expressing their admiration of this; but it had been decreed that the opera should not live—and it did not.

Mendelssohn was excessively annoyed at this injustice, and some time elapsed before his mind recovered its usual bright tone; but he continued to work diligently for the cause of art. Among other serious undertakings, he formed a choir for the study of the great choral works of Sebastian Bach, then entirely unknown to the public; and, in spite of Zelter's determined opposition, he succeeded, in 1829, in inducing the Berlin Singakademie to give a public performance of the *Passion according to St Matthew*, under his direction, with a chorus of between three and four hundred voices. The scheme succeeded beyond his warmest hopes, and proved the means of restoring to the world great compositions with which we are all now familiar, but which, at that time, had never been heard since the death of Bach. But the obstructive party were grievously offended; and at this period Mendelssohn was far from popular among the musicians of Berlin.

In April 1829 Mendelssohn paid his first visit to London. His reception was most enthusiastic. He made his first appearance before an English audience at one of the Philharmonic Society's concerts—then held in the Argyll Rooms—on the 25th of May, conducting his symphony in C minor from the pianoforte, to which he was led by John Cramer. On the 30th he played Weber's *Concertstück*, from memory, a proceeding at that time extremely unusual. At a concert given by Drouet, on the 24th of June, he played Beethoven's pianoforte concerto in E flat, which had never before been heard in the country; and the overture to *A Midsummer Night's Dream* was also, for the first time, presented to a London audience. On returning home from the concert, Mr Attwood, then organist of St Paul's Cathedral, left the score of the overture in a hackney coach, whereupon Mendelssohn wrote out another, from memory, without an error. At another concert he played, with Moscheles, his still unpublished concerto in E, for two pianofortes and orchestra. After the close of the London season he started with Klingemann on a tour through Scotland, where he was inspired with the first idea of his overture to *The Isles of Fingal*, returning to Berlin at the end of November. Except for an accident to his knee, which lamed him for some considerable time, his visit was a highly successful one, and laid the foundation of many firm friendships and many prosperous negotiations in the time to come.

The visit to England formed in reality the first division only of a great scheme of travel which his father wished him to extend to all the most important art centres in Europe. After refusing the offer of a professorship at Berlin, he started again, in May 1830, for Italy, pausing on his way at Weimar, where he spent a memorable fortnight with Goethe, and reaching Rome, after many pleasant interruptions, on November 1. No possible form of excitement ever prevented him from devoting a certain time every day to composition; but he lost no opportunity

[1] After Mendelssohn's death this house was sold to the Prussian Government; and the "Herrenhaus" now stands on the site of the garden-house.

raised to the highest position attainable in the German musical world. To this new sphere of labour he removed in August 1835, opening the first concert at the Gewandhaus, on the 4th of October, with his overture *Die Meeresstille*, a work possessing great attractions, though by no means on a level with the *Midsummer Night's Dream*, *The Isles of Fingal*, or *Melusine*.

Mendelssohn's reception in Leipsic was most enthusiastic; and under their new director the Gewandhaus concerts prospered exceedingly. Meanwhile *St Paul* steadily progressed, and was first produced, with triumphant success, at the Lower Rhine festival at Düsseldorf, on May 22, 1836. On October 3 it was first sung in English, at Liverpool, under the direction of Sir George Smart; and on March 16, 1837, Mendelssohn again directed it at Leipsic.

The next great event in Mendelssohn's life was his happy marriage, on March 28, 1837, to Cecile Charlotte Sophie Jeanrenaud, whose amiable disposition, surpassing beauty, and indescribable charm of manner endeared her to all who knew her. The honeymoon was scarcely over before he was again summoned to England to conduct *St Paul*, at the Birmingham festival, on September 20th. During this visit he played on the organ at St Paul's and at Christ Church, Newgate Street, with an effect which exercised a lasting influence upon English organists. It was here also that he first contemplated the production of his second oratorio, *Elijah*.

Passing over the composition of the *Lobgesang* in 1840, a sixth visit to England in the same year, the scheme for the erection of a monument to Sebastian Bach, and other events on which space does not permit us to enlarge, we find Mendelssohn in 1841 recalled to Berlin by the king of Prussia, with the title of Kapellmeister. Though this appointment resulted in the production of *Antigone*, *Œdipus Coloneus*, *Athalie*, the incidental music to the *Midsummer Night's Dream*, and other great works, it proved an endless source of vexation, and certainly helped to shorten the composer's life. In 1842 he came to England for the seventh time, accompanied by his wife, conducted his Scotch symphony at the Philharmonic, again played the organ at St Peter's, Cornhill, and Christ Church, Newgate Street, and was received with all possible honour by the queen and the prince consort. He did not, however, permit his new engagements to interfere with the direction of the Gewandhaus concerts; and in 1843 he founded in Leipsic the great conservatoire which soon became the best musical college in Europe, opening it on April 3, in the buildings of the Gewandhaus. In 1844 he conducted six of the Philharmonic concerts in London, producing his new *Midsummer Night's Dream* music, and playing Beethoven's pianoforte concerto in G with extraordinary effect. He returned to his duties at Berlin in September, but happily succeeded in persuading the king to free him from his most onerous engagements, and his delight at this relief was unbounded.

After a brief residence in Frankfort, Mendelssohn returned to Leipsic in September 1845, resuming his old duties at the Gewandhaus, and teaching regularly in the conservatoire. Here he remained, with little interruption, during the winter,—introducing his friend Jenny Lind, then at the height of her popularity, to the critical frequenters of the Gewandhaus, and steadily working at *Elijah*, the first performance of which he conducted at the Birmingham festival, on August 26, 1846. The enthusiastic reception of this great work is well known. Unhappily, the excitement attendant upon its production, added to the irritating effect of the worries at Berlin, made a serious inroad upon the composer's health. On his return to Leipsic he worked on as usual, but it was

clear that his health was seriously impaired. In 1847 he visited England for the tenth and last time, to conduct four performances of *Elijah* at Exeter Hall, on the 16th, 23d, 28th, and 30th of April, one at Manchester on the 20th, and one at Birmingham on the 27th. Again the queen and prince consort received him with marked respect,—one might almost venture to say, affection,—and all seemed prosperous and happy. But the necessary exertion was far beyond his strength. He witnessed Jenny Lind's first appearance at Her Majesty's Theatre, on the 4th of May, and left England on the 9th, little anticipating the trial that awaited him in the tidings of the sudden death of his sister Fanny, which reached him only a few days after his arrival in Frankfort. The loss of his mother in 1842 had shaken him much, but the suddenness with which this last sad intelligence was communicated broke him down completely. He fell to the ground insensible, and never fully recovered. In June he was so far himself again that he was able to travel, with his family, by short stages, to Interlaken, where he stayed for some time, illustrating the journey by a series of water-colour drawings, but making no attempt at composition for many weeks. He returned to Leipsic in September, bringing with him fragments of *Christus*, *Loreley*, and some other unfinished works, taking no part in the concerts, and living in the strictest privacy. On the 9th of October he called on Madame Frege, and asked her to sing his latest set of songs. She left the room for lights, and on her return found him in violent pain, and almost insensible. It was the beginning of the end. He lingered on, now better now worse, through four weary weeks, and on the 4th of November he passed away, in the presence of his wife, his brother, and his three dear friends, Moscheles, Schleinitz, and Ferdinand David. A cross now marks the site of his grave, in the Alte Dreifaltigkeits Kirchhof, at Berlin.

Mendelssohn's title to a place among the greatest composers of the century is incontestable. His style, though differing but little in technical arrangement from that of his classical predecessors, is characterized by a vein of melody peculiarly his own, and easily distinguishable by those who have studied his works, not only from the genuine effusions of contemporary writers, but from the most successful of the servile imitations with which, even during his lifetime, the music-shops were deluged. In less judicious hands the rigid symmetry of his phrasing might, perhaps, have palled upon the ear; but under his skilful management it serves only to impart an additional charm to thoughts which derive their chief beauty from the evident spontaneity of their conception. In this, as in all other matters of a purely technical character, he regarded the accepted laws of art as the medium by which he might most certainly attain the ends dictated by the inspiration of his genius. Though caring nothing for rules, except as means for producing a good effect, he scarcely ever violated them, and was never weary of impressing their value upon the minds of his pupils. His method of counterpoint was modelled in close accordance with that practised by Sebastian Bach. This he used in combination with an elastic development of the sonata-form, similar to that engrafted by Beethoven upon the lines laid down by Haydn. The principles involved in this arrangement were strictly conservative; yet they enabled him, at the very outset of his career, to invent a new style no less original than that of Schubert or Weber, and no less remarkable as the embodiment of canons already consecrated by classical authority than as a special manifestation of individual genius. It is thus that Mendelssohn stands before us as at the same time a champion of conservatism and an apostle of progress; and it is chiefly by virtue of these two apparently incongruous though really perfectly compatible phases of his artistic character that his influence and example have, for so many years, held in check the violence of reactionary opinion which a little injudicious encouragement might easily have fanned into revolutionary fury. Happily, this wholesome influence is still at work among us; and in his oratorios, his symphonies, his overtures, his concertos, and his smaller pianoforte pieces Mendelssohn sets before us an example the value of which is universally recognized, and not likely to be soon forgotten.

Concerning Mendelssohn's private character there have never been two opinions. As a man of the world, he was more than ordinarily accomplished,—brilliant in conversation, and in his lighter moments overflowing with sparkling humour and ready pleasantry, loyal and unselfish in the more serious business of life, and never weary of working for the general good. As a friend he was unvaryingly kind, sympathetic, and as true as steel. His earnestness as a Christian needs no stronger testimony than that afforded by his own delineation of the character of St Paul; but it is not too much to say that his heart and life were pure as those of a little child.

A complete list of Mendelssohn's published compositions—one hundred and nineteen in number, besides some five and twenty unnumbered works of considerable importance—will be found in the thematic catalogue published by Messrs Breitkopf and Härtel at Leipsic, and also in Grove's *Dictionary of Music and Musicians*, vol. ii. pp. 308, 309. Among his miscellaneous writings, we may mention a translation of the *Andria* of Terence, in German verse, and an immense collection of letters, posthumously printed, and calculated to give the reader a far closer acquaintance with his life and character than any biographer can hope to convey. (W. S. R.)

MENDELSSOHN, Moses (1729-1786), philosopher and scholar, well known as Lessing's friend and the prototype of his "Nathan," was born on September 6, 1729, at Dessau on the Elbe, where his Jewish father made a scanty livelihood by teaching a small school and transcribing copies of the "law." The leading events of Mendelssohn's career have been indicated elsewhere (see Jews, vol. xiii. p. 680). His numerous writings include *Ueber Evidenz in metaphysischen Wissenschaften* (1763), which gained the prize in a competition in which Immanuel Kant took part; *Briefe über die Empfindungen* (1764); *Phædon, oder über die Unsterblichkeit der Seele* (1767), an argument for immortality, founded on the nature of the soul as exempting it from the ordinary laws of change, which has been severely criticized by Kant; *Jerusalem, oder die religiöse Macht und Judenthum* (1783), a specially important contribution to the question of Jewish emancipation; a number of contributions to his friend Nicolai's *Literaturbriefen* and *Bibliothek der schönen Wissenschaften*; one or two tracts in Hebrew; and some new German translations from the Old Testament. The controversy which led to the publication of his *Morgenstunden* (1785-86), a reply to Jacobi's *Briefe über die Lehre Spinoza's*, is said to have been more or less directly the cause of his death, which took place on January 4, 1786 (see Jacobi, vol. xiii. p. 537). Of Mendelssohn's three sons, the second, Abraham, settled as a banker in Hamburg and married a Jewess, Lea Salomon Bartholdy, who bore him four children; these, by advice of their mother's brother, himself a conscientious convert from Judaism, were educated as Christians, and thenceforth joined their mother's second surname to their own. The second of them, Felix, is the subject of the preceding notice. In later life Abraham Mendelssohn was accustomed to say,—"When I was young I was the son of my father; now I am the father of my son." See *The Mendelssohn Family*, 1882.

MENDOZA, a city of the Argentine Republic, the only town of the province of Mendoza, lies 700 miles west-north-west of Buenos Ayres, at the foot of the Cordilleras, 2510 feet above the sea-level, in 32° 53′ S. lat. and 68° 45′ W. long. It was formerly a frequent stopping-place on the route across the Andes by the Uspallata Pass, and used to rank as one of the best-built towns in the country, but in 1861 it was almost completely destroyed by an appalling earthquake, in which the people, for the most part collected in the churches, perished to the number of about 12,000. Bravard, a French geologist who had often predicted the catastrophe, was one of those who perished. Extensive ruins still mark the site of the old town; the new town, which has been built at a little distance, has grown rapidly. Situated in a richly cultivated district, Mendoza depends mainly on agriculture and fruit-growing.

The city was founded in 1559 by Garcia de Mendoza; and in 1776 it was made the administrative centre of the vice-royalty of La Plata. See Mulhall, *Handbook of the La Plata States*, 1875; and Mrs Mulhall, *Between the Amazon and the Andes*, 1882.

MENDOZA, Diego Hurtado de (c. 1503-1575), novelist, poet, diplomatist, and historian, was a younger son of the member of the illustrious Mendoza family to whom

the government of Granada was entrusted not long after its surrender, and was born in that city about the year 1503. The marquis of Santillana, so prominent a figure at the court of John II. of Castile, was his great-grandfather. At an early age Mendoza, who had been destined for the church, was sent to Salamanca, where he studied with success, and also, some time between the years 1520 and 1525, produced his *Lazarillo de Tormes*, the work upon which his literary celebrity largely rests. Having persuaded his father to allow him to enter the army, he served with the Spanish troops of Charles V. in Italy, and also availed himself of opportunities as they arose to hear the lectures of famous professors at Bologna, Padua, and Rome. In 1538 he was taken into the diplomatic service of the emperor and sent as ambassador to Venice; there he cultivated friendly relations with the Aldi, and energetically set about collecting a library, not only procuring copies of many old MSS. in the public library of the city, but also sending to Thessaly and Mount Athos for new ones; it was from his collection that the complete text of Josephus was first printed. For some time he held the post of military governor of Siena; and, after having been present in an official capacity in Trent at the beginning of the œcumenical council, he was in 1547 sent as special plenipotentiary to Rome, where he continued to act for some years. In 1554, shortly before the abdication of Charles, he was recalled to Spain, and his official career came to an end. He was never a favourite with Philip II.; and in consequence of a quarrel with a courtier, in which he had lost his temper badly, he was finally banished from court in 1568. The remaining years of his life, which were spent at Granada, he devoted partly to the study of Arabic, partly to poetical composition, and partly to the preparation of his history of the Moorish insurrection of 1568–70 (*Guerra de Granada*). He died at Madrid (which he had obtained leave to visit on some business errand) in April 1575.

Mendoza's *Lazarillo de Tormes*, though written during his college days, was not published until 1553, when it was printed anonymously at Antwerp. Next year it was reprinted at Burgos, but ultimately it was taken exception to by the Inquisition, and the Spanish editions of 1573 and subsequent years are accordingly considerably abridged. It is a comparatively short fragment, written in vigorous and bright Castilian, and was the first example in modern literature of the "novela picaresca" of which Le Sage's *Gil Blas* now ranks as the most perfect specimen. The continuations, first by an anonymous author (1555) and afterwards by H. de Luna (1620), are of very inferior interest. Of Mendoza as a poet all that need be said here is that he followed the modern Italian models quite as far as was compatible with a due regard to his Castilian individuality. His history, though of no great bulk, is, like his novel, a work of remarkable literary execution. It relates indeed only to a comparatively brief episode in a chapter of events for which it is almost impossible to claim much general attention, and it is often needlessly erudite and sometimes provokingly obscure. But as a whole it is singularly well-informed, dignified, and picturesque; "the style is bold and abrupt, but true to the idiom of the language, and the current of thought is deep and strong, easily carrying the reader onward with its flood. Nothing in the old chronicling style of the earlier period is to be compared to it, and little in any subsequent period is equal to it for manliness, vigour, and truth" (Ticknor). The first edition of the *Guerra de Granada* did not appear until 1610, but was even then incomplete; the first perfect edition was that of 1730. The work has frequently been reprinted since.

MENDOZA, Iñigo Lopez de. See Santillana.

MENELAUS, king of Sparta, was the brother of Agamemnon (*q.v.*) and the husband of Helena (*q.v.*). He was one of the heroes of the Trojan horse, and recovered his wife at the sack of the city. On the voyage homewards his fleet was scattered off Malea by a storm which drove him to Crete; after seven years' further wandering to Cyprus, Phœnicia, Egypt, Ethiopia, Libya, and the country of the Erembi, he at last had an interview with Proteus and obtained a favourable wind which brought him home on the very day on which Orestes was holding the funeral feast over Ægisthus and Clytæmnestra. After a long and happy life in Lacedæmon, Menelaus, as the son-in-law of Zeus, did not die but was translated to Elysium.

MENGS, Antony Raphael (1728–1779), was the most celebrated representative of the eclectic school of painting in the 18th century, and played a great part in the early days of the classic revival. He was born in 1728 at Aussig in Bohemia, but his father, a Danish painter, established himself finally at Dresden, whence in 1741 he conducted his son to Rome. Mengs early showed that active intelligence and large capacity for laborious study which secured him the extraordinary distinction which he enjoyed through life. His appointment in 1749 as first painter to the elector of Saxony did not prevent his spending much time in Rome, where he had married in 1748, and abjured the Protestant faith, and where he became in 1754 director of the Vatican school of painting, nor did this hinder him on two occasions from obeying the call of Charles III. of Spain to Madrid. There Mengs produced some of his best work, and specially the ceiling of the banqueting hall, the subject of which was the Triumph of Trajan and the Temple of Glory. After the completion of this work in 1777, Mengs again returned to Rome, and there he died, two years later, in poor circumstances, leaving twenty children, seven of whom were pensioned by the king of Spain. Besides numerous paintings in the Madrid gallery, the Ascension at Dresden, Perseus and Andromeda at St Petersburg, and the ceiling of the Villa Albani must be mentioned among his chief works. In England, the duke of Northumberland possesses a Holy Family, and the colleges of All Souls and Magdalen, at Oxford, have altar-pieces by his hand. In his writings, in Spanish, Italian, and German, Mengs has put forth his eclectic theory of art, which treats of perfection as attainable by a well-schemed combination of diverse excellences,—Greek design, with the expression of Raphael, the chiaroscuro of Correggio, and the colour of Titian. His close intimacy with Winkelmann—who constantly wrote at his dictation—has greatly enhanced his historical importance, for he formed no scholars, and the critic must now concur in Goethe's judgment of Mengs in *Winkelmann und seine Jahrhundert*; he must deplore that so much learning should have been allied to a total want of initiative and utter poverty of invention, and embodied with a strained and artificial mannerism.

See *Opere di Antonio Raffaello Mengs*, Parma, 1780; *Mengs' Werke, übersetzt v. G. F. Prange*, 1786; *Zeitschrift für bildende Kunst*, 1880; Bianconi, *Elogio Storico di Mengs*, Milan, 1780; Nagler's *Künstlerlexikon*.

MENHADEN, economically one of the most important fishes of the United States, known by a great number of local names, "menhaden" and "mossbunker" being those most generally in use. In systematic works it appears under the names of *Clupea menhaden* and *Brevoortia tyrannus*. It is allied to the European species of shad and pilchard, and, like the latter, approaches the coast in its wanderings in immense shoals, which are found throughout the year in some part of the littoral waters between Maine and Florida, the northern shoals retiring into deeper water or to more southern latitudes with the approach of cold weather. The average size of the menhaden is about 12 inches. Although it was long known as a palatable table-fish, and largely used, when salted, for export to the West Indies, and as bait for cod and mackerel, the menhaden fishery has been developed to its present importance only within the last twenty years. A large fleet of steamers and sailing vessels is engaged in it; and a great number of large factories have sprung into existence to extract the oil, which is used for tanning and currying, and for adulterating other more expensive oils, and to manufacture the refuse into a very valuable guano. In the year 1877 2,426,589 gallons of oil and 55,444 tons of guano were produced.

An extensive business is also carried on in converting menhaden of a suitable size into "American sardines."

A very complete account of this fishery is given by G. Brown Goode in "The Natural and Economic History of the American Menhaden," *United States Commission of Fish and Fisheries*, part v., Washington, 1879.

MENIN, a small Belgian town, in the province of West Flanders; it is traversed by the river Lys, which there forms the boundary between France and Belgium. The population in 1880 was 10,200. Commercially and industrially Menin ranks high for its size, possessing, as it does, important manufactures of linen, oil, soap, &c., as well as sugar refineries, breweries, and tanneries, and a good corn and cattle market. Tobacco is extensively grown in the neighbourhood, and forms one of the main items of lawful trade, a good deal of illicit traffic also being carried on across the French frontier.

Menin does not appear to have been in any way worthy of note until the 14th century. Philip II. caused it to be fortified in 1578. It was taken by Turenne in 1658. Vauban subsequently surrounded it with elaborate works, and made it one of the strongest citadels in France; but all its fortifications were razed in 1744. It belonged to the Netherlands in 1815, and became part of Belgium in 1830.

MENINGITIS (from μῆνιγξ, a membrane), a term in medicine applied to inflammation affecting the membranes of the brain (cerebral meningitis) or spinal cord (spinal meningitis) or both.

Of *cerebral meningitis* there are two varieties:—(1) that due to the presence of tubercle in the membranes of the brain, which gives rise to the disease known as tubercular meningitis, or acute hydrocephalus; and (2) simple or acute meningitis, which may arise from various causes. Among the more common are injuries of the head, extension of disease from contiguous parts, such as erysipelas of the scalp or caries of the bones of the ear, exposure to cold or to extreme heat, the presence of tumours in the substance of the brain. It may likewise occur in the course of fevers, rheumatism, and inflammatory affections, and also as a result of mental overwork, sleeplessness, and alcoholic excess. This latter variety of meningitis is less common than the former, but it is on the whole more amenable to treatment. The symptoms present such a general resemblance to those already described in tubercular meningitis that it is unnecessary to refer to them in detail (see HYDROCEPHALUS), and the treatment is essentially the same for both.

Spinal meningitis, or inflammation of the membranes investing the spinal cord, generally results from causes of a similar kind to those producing cerebral meningitis,—injuries, exposure to cold or sudden changes of temperature, diseases affecting adjacent parts such as the vertebral column or the spinal cord itself, or extension downwards of inflammation of the membranes of the brain. It is said to be most common in males. As in the case of the brain, the membranes become extremely congested; exudation of lymph and effusion of serum follow; and the spinal cord and roots of the nerves become more or less involved in the morbid process.

The chief symptoms are fever, with severe pain in the back or loins shooting downwards into the limbs (which are the seat of frequent painful involuntary startings), accompanied with a feeling of tightness round the body. The local symptoms bear reference to the portion of the cord the membranes of which are involved. Thus when the inflammation is located in the cervical portion the muscles of the arms and chest are spasmodically contracted, and there may be difficulty of swallowing or breathing, or embarrassed heart's action, while when the disease is seated in the lower portion, the lower limbs and the bladder and rectum are the parts affected in this way. At first there is excited sensibility (hyperæsthesia) in the parts of the surface of the body in relation with the portion of cord affected. As the disease advances these symptoms give place to those of partial loss of power in the affected muscles, and also partial anæsthesia. These various phenomena may entirely pass away, and the patient after some weeks or months recover; or, on the other hand, they may increase, and end in permanent paralysis.

The treatment is directed to allaying the pain and inflammatory action by opiates. Ergot of rye is strongly recommended by many physicians. The patient should have perfect rest in the recumbent, or better still in the prone, position. Cold applications to the spine may be of use, while scrupulous attention to the functions of the bladder and bowels, and to the condition of the skin with the view of preventing bed-sores, is all-important.

Epidemic Cerebro-spinal Meningitis.—This name, as well as *cerebro-spinal fever*, is applied to a disease defined in the *Nomenclature of Diseases* as "a malignant epidemic fever, attended by painful contractions of the muscles of the neck and retraction of the head. In certain epidemics it is frequently accompanied by a profuse purpuric eruption, and occasionally by secondary effusions into certain joints. Lesions of the brain and spinal cord are found on dissection." This disease appears to have been first distinctly recognized in the year 1837, when it prevailed as an epidemic in the south-west of France, chiefly among troops in garrison. For several years subsequently it existed in various other localities in France, and mostly among soldiers. At the same time in other countries in western and central Europe the disease was observed in epidemic outbreaks, both among civil and military populations. In 1846 it first showed itself in Ireland, chiefly among the inmates of workhouses in Belfast and Dublin. Numerous outbreaks occurred also about the same period in many parts of the United States. In more recent times the disease has repeatedly appeared both in Europe and America, but it has seldom prevailed extensively in any one tract of country, the outbreaks affecting for the most part limited communities, such as garrisons or camps, schools, workhouses, and prisons.

Little is known regarding the causation of this disease. All ages seem liable to suffer, and, as regards sex, males are affected more commonly than females. Occupation and condition of life appear to exercise no influence. It has been observed to occur most frequently in cold seasons. The question of the contagiousness of cerebro-spinal fever remains still unsettled, but the weight of authority appears to be in favour of the theory of the communicability of the disease. It cannot, however, be regarded as contagious in the same degree as some other specific fevers, such as typhus fever, small-pox, or scarlatina.

The following are the more prominent symptoms. After a few days of general discomfort the attack comes on sharply with rigors, intense headache, giddiness, and vomiting. Neuralgic pains in the abdomen, and pain with spasmodic contractions in the muscles of the extremities, occur at an early stage. The headache continues with great severity, and restlessness and delirium supervene, accompanied with periods of somnolence. The pains and spasms rapidly increase, the muscles of the neck, spine, and limbs being specially affected. The patient's head is drawn backwards and rigidly fixed, the spine arched, and the arms and legs powerfully flexed, the whole condition bearing a considerable resemblance to tetanus. For a time there is greatly increased sensibility of the skin, pain being excited by the slightest contact. There is more or less fever present. About the fourth day of the disease an eruption on the skin both of the face and body frequently appears, in the form either of purpuric spots or small clear vesicles. Death may take place in from a few hours to eight or ten days. Should the patient survive the immediate shock of the attack, serious complications are apt to appear in the form of destructive inflammation of the eyes or ears, inflammation with effusion into certain joints, and paralysis of limbs; or, again, recovery may take place after a prolonged convalescence. The mortality appears to vary in different epidemics, in some being as high as 80 per cent., in others only about 20 per cent. Certain forms of the disease are of malignant character from the first, and very rapidly fatal.

The changes found after death in cerebro-spinal fever are intense inflammation of the membrane of the brain and spinal cord, with effusion of serum or pus into the ventricular and arachnoid spaces.

The treatment is similar to that of other febrile conditions, but for the special symptoms of pain, spasm, &c., opium seems to have been found of eminent service, while quinine and ergot of rye are also recommended.

MENNONITES is a name borne by certain Christian communities in Europe and America, denoting their adherence to a type of doctrine of which Menno Simons

was, not indeed the originator, but the chief exponent at the time when the anti-pædo-baptism of the congregations in which he laboured took permanent form in opposition to ordinary Protestantism on the one hand and to the theocratic ideas of the Münster type of anabaptism on the other. The original home of the views afterwards called Mennonite was in Zürich, where, as early as 1525, Grebel and Manz founded a community having for its most distinctive mark baptism upon confession of faith. The chief doctrines of these Zürich Baptists have been already stated in the article BAPTISTS, vol. iii. p. 353. The main interest of the sect lay not in dogma but in discipline. Within the communities evangelical life was reduced to a law of separation from the world, and this separation—enforced by a stringent use of excommunication and the prohibition of marriage beyond the brotherhood—involved not only abstinence from worldly vanities but refusal of civic duties (the state being held to be un-Christian)—refusal to take an oath or use the sword. In their revolt against the corruptions of the mediæval church the Reformers neither denied the continuity of the church as an organization nor impugned the Christian character of the state. The new sect did both; and their position thus appeared so radically subversive of the foundations of society that it is not surprising, under the imperfect views of toleration then current, that they became the objects of bitter persecution from Protestants as well as from Catholics. But the Grebelians had no desire, like the fanatics of Münster, to found a new theocracy in opposition to the anti-Christian state. They sought only to withdraw from what their conscience condemned, content to live as strangers upon earth, and devoting all their energy to preserve the purity of their own communities. The mediæval conception of separation from the world as the true path of Christian perfection had leavened all middle-class society in Europe, and prepared many to accept separatist views of the church as soon as they were reached by the impulse of revolt against Roman Catholicism; the pursuit of holiness in a society protected by a strict discipline is an idea which experience has shown to have a great attraction for one class of earnest minds; hence, in spite of persecutions incomparably fiercer than any of the larger Protestant bodies ever underwent, the new doctrine and praxis rapidly spread from Switzerland to Germany, Holland, and even to France. Each community was quite independent, united to the rest only by a bond of love. There was no sort of hierarchy, but only "exhorters" chosen by the congregation, of whom the most prominent were also "elders" entrusted with the administration of the sacraments—an organization so easily kept alive or reproduced that the movement could hardly be checked by any persecution short of the total annihilation which at length was actually the fate of many of the Swiss communities. The remnants of the Swiss Mennonites broke in 1620 into two parties, the stricter of which, the Ammanites or Upland Mennonites, were distinguished from the Lowland Mennonites by holding that excommunication of one party dissolved marriage, and by their rejection of buttons and the use of the razor. Their persecution lasted till 1710; a few congregations still remain and keep themselves quite distinct from Baptist bodies of more modern origin. In Germany the Mennonites are somewhat more numerous; more important are the German Mennonite colonies in southern Russia, brought thither in 1783 by the empress Catherine, which in turn have recently sent many emigrants to America. America indeed, and especially Pennsylvania, early became a refuge for the Mennonites of Switzerland, the Palatinate, and Holland, and is now the chief home of the body (175,000 in the United States and 25,000 in Canada). The oldest congregation is that of Germantown (since 1683); the most numerous of several divisions are the Old Mennonites, corresponding to the less strict of the Swiss sections.

All these communities in Europe and America are distinguished by an antique simplicity combined with antique prejudices, by indifference to the interests of the greater world, while at the same time their industry and self-concentration have made them generally well-to-do. Their religious type has varied very little in the course of centuries, as indeed is not surprising, their theology being ascetic rather than dogmatic or speculative. The Mennonites of Holland, on the other hand, have passed through an interesting and progressive history.

It was in Holland and the adjoining parts of Low Germany that the personal influence of Menno Simons (1492–1559) was mainly felt. He was originally a priest, and was pastor at his native place Witmarsum in Friesland from 1531 to 1536, when convictions long ripening in his mind compelled him to resign his cure. At this time the anti-pædo-baptist societies in the Low Countries were much agitated. The views which had just before received their political deathblow at Münster (see ANABAPTISTS) were not extinct, and even those who did not share them were by no means at one. Menno attached himself to the Obbenites, who held that on earth true Christians had no prospect but to suffer persecution, refused to use the sword, and looked for no millennium on earth. Menno became one of their elders, and by his wanderings among the scattered and oppressed communities, and especially by the natural eloquence and religious power of his numerous writings, did much to sustain the faith of his associates, to confirm the type of their religious life, and to prevent startling aberrations in doctrine or discipline. He was not an original thinker; but the love which all felt for the man, and which was kept alive for generations by his writings, gave him the place which the name of Mennonites expresses.

It may be ascribed to the influence of Menno's writings that the Dutch Mennonites, though for a time (since 1554) they broke into fractions on questions of discipline, and especially on the effect of excommunication upon marriage, never fell so far apart as regards the type of their religious life as to preclude the possibility of reunion. The Waterlanders in North Holland, who held the least strict doctrine of excommunication, soon moved farther in the direction of liberality, and exchanged the name Mennonites for that of Doopsgezinden (Baptist persuasion). In 1579 they refused to condemn any one for opinions, even on the incarnation, which the word of Scripture did not pronounce necessary to salvation. They aided William the Silent with money, and from 1581 to 1618 even accepted civil office. Meantime the stricter party had undergone various divisions, which, however, in 1627–32 were reunited on the basis of confessions essentially embodying Menno's teachings. They too had learned moderation, at least in their views of excommunication, and their antithesis to the state was softened since the cessation of persecution in 1581, but especially since in 1672 they were recognized as citizens. On the other hand, the adoption of a confession had deepened the separation between them and the liberal Doopsgezinden; but doctrine was never the fundamental principle of the Mennonite communities, confessionalism took no firm root, and the two sections gradually approached, and through a series of partial fusions became at length finally united when the Amsterdam congregations came together in 1801. The persuasion declined much in numbers in the 18th century; since then it has increased, and has now 127 congregations with nearly 50,000 members. The objection to hold civil office disappeared in 1795; that to carry arms in the war of freedom against Napoleon. Baptism on profession of faith and the refusal of the oath, tolerance in matters of doctrine without religious indifference, are the chief marks of the body, which in point of theological culture and general enlightenment, philanthropic zeal and social importance, has long stood very high.

Authorities.—The best life of Menno Simons is Cramer's, 1837. De Hoop Scheffer's article in Herzog-Plitt, *R. E.*, is excellent; only one point of consequence in his account seems to call for modification,—the book against John of Leyden, said to have been published before Menno joined the Obbenites, is almost certainly spurious. See Sepp, *Geschiedkundige Nasporingen*, i. (1872) p. 128 *sq.* The completest edition of Menno's works is that in folio, 1686. Many of them are known only in bad Dutch versions; Menno himself wrote in the "Oostersch" or East Sea Dialect of Low German. For the literature on the Mennonites in general, see De Hoop Scheffer, on whom the foregoing sketch is mainly dependent.

MENSHIKOFF, ALEXANDER DANILOVICH (1672–1729), born at Moscow on the 17th of November (o.s.) 1672, was the son of a poor man, who employed him to sell cakes about the streets of that city. In this humble occupation he attracted the attention of Lefort, one of Peter the Great's most active co-operators, who was pleased with his sprightliness, and took him into his service. Peter, soon afterwards

seeing the youth at Lefort's, was also delighted with him, and took him to be his page. Menshikoff soon became indispensable to the czar, assisting him in his workshop, and displaying signal bravery in the company of his master at the siege of Azoff. He formed one of the suite of Peter during his travels, and worked with him at Saardam and Deptford. Throughout his wars with the Swedes, Menshikoff was the companion of the czar, and greatly distinguished himself. For his gallantry at the battle of the Neva, on the 7th of May (o.s.) 1703, he received the order of St Andrew. In 1704 he was made general, and at the request of the czar created a prince of the Holy Roman Empire. His house on the Vasilii-Ostroff was magnificent; there ambassadors were received, and banquets were given gorgeous with gold and silver plate. Unfortunately there is a dark side to the picture, and the favourite was guilty of extortion to such an extent as to bring him under his master's censure. On the death of Peter the position of Menshikoff became very perilous; his successes had raised about him a host of enemies eager for his downfall. The Golitzins, Dolgoroukis, and all those who formed what may be called the Old Russian party, wished to proclaim the son of Alexis emperor. Those, however, whose aggrandizement was bound up with Peter's reforms—Menshikoff, Apraksin, Bontourlin, Goloffkin, and others—were in favour of giving the crown to Peter's widow, who accordingly ascended the throne as Catherine I. During her reign the influence of Menshikoff was unbounded, and he virtually governed the country; but the empress died in 1727, after a reign of two years. She had made a will, no doubt at the instigation of the favourite, to the effect that Peter, her grandson, was to be czar under the guardianship of Menshikoff, whose daughter Mary was to be married to the youthful sovereign. Under pretence of taking care of the young czar, Menshikoff caused him to be removed to his house and surrounded him with his creatures. He was now at the height of his power; foreign ambassadors remarked that even the great Peter himself was never feared so much. The young czar, however, showed no affection for Mary Menshikoff, and the girl was equally apathetic towards her betrothed, being in love with a member of the family of Sapieha at the time her father had forced her into the engagement. The Dolgoroukis used the aversion of the young prince to his *fiancée* as a means of creating dislike to the father. A chain of events was gradually leading to the downfall of the favourite. He was soon refused admittance to the summer palace, whither the young czar had retired. Next he was arrested, and so overpowered was he at his disgrace that he had an apoplectic stroke. In vain did he address letters both to the emperor and his sister. Shortly after, by order of the czar, the fallen magnate departed from St Petersburg, but more like a nobleman retiring to his estate than a culprit going into exile. The people regarded him with dislike, and most of them rejoiced over his fall. On his way a courier arrived with orders to take the czar's ring of betrothal from his daughter Mary and give her back her own, which had been worn by Peter II. Menshikoff was not permitted to pass through Moscow, but was conducted to Oranienburg, in the government of Riazan, and there placed under strict surveillance. Soon afterwards the whole family was banished to Siberia, and arrived at Berezoff towards the end of 1727. Menshikoff's wife died on the journey, and was buried near Kazan. On the arrival of the prisoners they were lodged in a wooden house, consisting of four rooms. But Menshikoff did not long endure the horrors of exile in this inclement region. According to Mannstein, he died (November 12, o.s., 1729) of an apoplectic stroke, because there was no one at Berezoff, as he himself remarked, who understood how to open a vein. The young czar ordered the release from exile of the two remaining children of Menshikoff,—his daughter Mary had died at Berezoff in the same year as her father,—and restored some of their property to them.

MENSHIKOFF, ALEXANDER SERGEIEVICH (1787–1869), great-grandson of Peter's favourite, born in 1787, entered the Russian service as attaché to the embassy at Vienna. He accompanied the emperor Alexander throughout his campaigns against Napoleon, and attained the rank of general, but retired from active service in 1823. He then devoted himself to naval matters, and put the Russian marine, which had fallen into decay during the reign of Alexander, on an efficient footing. On the outbreak of the Crimean War he was appointed commander-in-chief, and suffered a severe defeat at the Alma. On the death of the emperor Nicholas in 1855 he was recalled, ostensibly on account of failing health. He died in 1869.

MENSURATION

MENSURATION, or the art of measuring, involves the construction of measures, the methods of using them, and the investigation of rules by which magnitudes which it may be difficult or impossible to measure directly are calculated from the ascertained value of some associated magnitude. It is usual, however, to employ the term mensuration in the last of these senses; and we may therefore define it to be that department of mathematical science by which the various dimensions of bodies are calculated from the simplest possible measurements.

The determination of the lengths and directions of straight lines, including what are familiarly known as problems in heights and distances, generally depends on the solution of triangles, and will be discussed in the articles TRIGONOMETRY and SURVEYING. The remaining portions of the subject are the determinations of the lengths of curves, the areas of plane or other figures, and the volumes and surfaces of solids; and it is of mensuration as thus restricted that the present article will discuss some of the more important problems.

§ 1. *Units of Length, Area, and Volume.*—In measuring any magnitude we select some standard or "unit" to measure by. Thus in measuring length we take for unit an inch, a foot, or a yard. From the unit of length we derive the units of area and volume. Thus we define the unit of area to be the area of the square described upon the unit of length, and the unit of volume to be the volume of the cube whose edge is the unit of length or whose side is the unit of area. For example, if an inch be taken as the unit of length, the square whose side is 1 inch is the unit of area, and the cube whose edge is 1 inch is the unit of volume. The length of a line, the area of a surface, and the volume of a solid are then expressed by the numbers, whole or fractional, of units of length, area, and volume which they respectively contain. Hence, if l denote the linear unit, the length of a line which contains a units is al, or simply a since l is unity; similarly the area of a surface which contains b units of area is bm, or simply b, where m is the unit of area.

§ 2. *Commensurable and Incommensurable Magnitudes.*—When two magnitudes have a common measure, that is, when another magnitude can be found which is contained in each an exact number of times; they are said to be "commensurable." Thus a line $4\frac{1}{2}$ and another $3\frac{1}{2}$ inches

long are commensurable; for, if $\frac{1}{2}$ inch be taken as unit of length, the former contains the unit nine times and the latter seven times. If no common measure can be found, the two magnitudes are said to be "incommensurable." For instance, 1 and $\sqrt{2}$ have no common measure; for $\sqrt{2}=1\cdot4142\ldots$ an interminable decimal, and hence no unit, however small, can be found which will be contained in each an exact number of times. If, however, we take $\sqrt{2}=1\cdot4$, the error will be less than $\frac{1}{10}$; if $\sqrt{2}=1\cdot414$, the error will be less than $\frac{1}{1000}$, &c. Hence, by taking a sufficient number of figures, we can find a fraction which will differ from $\sqrt{2}$ by less than any assignable quantity, and therefore we can always find two commensurable magnitudes that will represent two incommensurable ones to any degree of accuracy we please. In what follows we need therefore only consider commensurable lines.

§ 3. *Area of a Rectangle.*—Let the side AB (fig. 1) contain a units and the side BC b units of length. If we divide AB into a equal parts, each equal to the unit of length, and similarly BC into b equal parts, and if through the points of division we draw lines parallel to the sides of the rectangle, these lines will divide the rectangle into a series of rectangles, each of which is the unit of area, since each is a square whose sides are of unit length. As we have a rows of these rectangles, and b in each row, the whole number of rectangles will be ab. Therefore

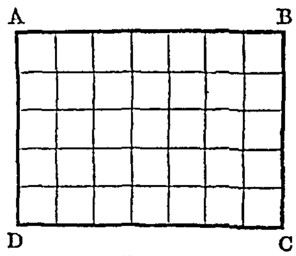

Fig. 1.

$$\text{area of ABCD}=ab \text{ units of area}$$
$$=ab$$

PART I.—PLANE FIGURES.

Section I.—Plane Figures contained by Straight Lines.

A. *The Rectangle.*

§ 4. Let ABCD (fig. 2) be a rectangle, and let AB=CD=a, BC=DA=b, AC=c, and the angle BAC=α; it is required to find its area. Since a rectangle is completely determined when two independent data, one of which at least is a length, are given connecting its parts, we can determine its area in the following cases.

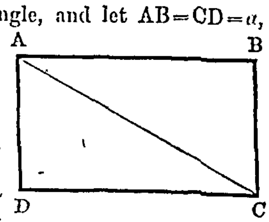

Fig. 2.

(α) *When its length* a *and its breadth* b *are given.*—It has already been proved (§ 3) that

$$\text{area of ABCD}=ab;$$

or the area of a rectangle is equal to its length multiplied by its breadth.

Example.—Let $a=12$ feet 6 inches and $b=9$ inches, then

$$\text{area of ABCD}=12\cdot5\times\cdot75=9\cdot375 \text{ square feet.}$$

If we make use of logarithms in the above calculation we have

$$\log\text{area}=\log a+\log b.$$
$$\log a=\log 12\cdot5\ =1\cdot0969100$$
$$\log b=\log\ \ \cdot75=\bar{1}\cdot8750613$$
therefore $\qquad\log\text{area}=\ \cdot9719713;$
hence $\qquad\text{area}=9\cdot375.$

(β) *When a side* a *and the diagonal* c *are given.*—By Euclid i. 47 we have

$$b^2=c^2-a^2, \text{ or } b=\sqrt{c^2-a^2},$$
therefore $\qquad\text{area of ABCD}=ab=a\sqrt{c^2-a^2};$
or $\qquad\log\text{area}=\log a+\frac{1}{2}\log(c+a)+\frac{1}{2}\log(c-a).$

Example.—Let $a=238$ and $c=456$, then

$$\log a=\ \log 238=2\cdot3765770$$
$$\tfrac{1}{2}\log(c+a)=\tfrac{1}{2}\log 694=1\cdot4206797$$
$$\tfrac{1}{2}\log(c-a)=\tfrac{1}{2}\log 218=1\cdot1692282$$
therefore $\qquad\log\text{area}=4\cdot9664849;$
hence $\qquad\text{area}=92573\cdot1.$

(γ) *When a side* a *and* α *its inclination to the diagonal are given.*—Since

$$\frac{b}{a}=\tan\alpha,\quad b=a\tan\alpha,$$
and therefore $\qquad\text{area of ABCD}=ab=a^2\tan\alpha;$
or $\qquad\log\text{area}=2\log a+\text{L}\tan\alpha-10.$

Example.—Let $a=36$ and $\alpha=32°\ 25'\ 15''$, then

$$2\log a=2\log 36=\ 3\cdot1126050$$
$$\text{L}\tan\alpha=\text{L}\tan 32°\ 25'\ 15''=\ 9\cdot8028622$$
therefore $\qquad\log\text{area}=12\cdot9154672-10=2\cdot9154672;$
hence $\qquad\text{area}=823\cdot127.$

(δ) *When the diagonal* c *and* α *its inclination to either of the sides are given.*—We have

$$a=c\cos\alpha,\text{ and } b=c\sin\alpha,$$
therefore $\text{area of ABCD}=ab=c^2\sin\alpha\cos\alpha=\frac{1}{2}c^2\sin 2\alpha;$
or $\qquad 2\text{area}=c^2\sin 2\alpha,$
and hence $\qquad\log 2\text{area}=2\log c+\text{L}\sin 2\alpha-10.$

§ 5. A square being a rectangle whose sides are equal, we can at once determine its area. When one datum, which must be a length, is given the square is completely determined, and hence we have only two cases to consider.

(α) *When the side is given.*—From § 4, α, we have at once

$$\text{area of square}=ab=a\times a=a^2.$$

(β) *When the diagonal* c *is given.*—From § 4, β, we have

$$a^2+a^2=c^2,\text{ or } a^2=\tfrac{1}{2}c^2;$$
hence $\qquad\text{area of square}=a^2=\frac{1}{2}c^2,\text{ or } 2\text{area}=c^2;$
and therefore $\qquad\log 2\text{area}=2\log c.$

B. *Right-angled Triangles.*

§ 6. The diagonal of every rectangle divides it into two equivalent right-angled triangles (Eucl. i. 34), and hence the area of the right-angled triangle ABC (fig. 2) is equal to half the area of the corresponding rectangle ABCD.

C. *Triangles Generally.*

§ 7. In every triangle there are six elements to be considered, namely, the three sides and the three angles. If any three of these six be given, provided one is a length, the triangle is completely determined, and hence its area can be found.

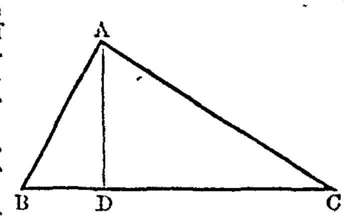

Fig. 3.

§ 8. *Length of Perpendiculars of a Triangle.*—In the triangle ABC (fig. 3) let BC=a, CA=b, AB=c, AD the perpendicular from A on BC=h, BD=x, and CD=y.

Since BDA and CDA are right angles, we have

$$c^2=x^2+h^2,\text{ and } b^2=y^2+h^2,$$
and therefore
$$b^2-c^2=y^2-x^2=(y+x)(y-x)=a(y-x);$$
whence $\qquad y-x=\dfrac{b^2-c^2}{a}.$

But $y+x=a$, and, by solving these equations, we obtain

$$y=\frac{b^2+a^2-c^2}{2a}.$$

Again

$$h^2=b^2-y^2=b^2-\left(\frac{b^2+a^2-c^2}{2a}\right)^2=\frac{(2ab)^2-(b^2+a^2-c^2)^2}{4a^2}$$
$$=\frac{(a+b+c)(b+c-a)(c+a-b)(a+b-c)}{4a^2};$$
hence $\qquad h=\dfrac{1}{2a}\sqrt{(a+b+c)(b+c-a)(c+a-b)(a+b-c)}.$

Now let $a+b+c=2s$, then $b+c-a=2(s-a)$, $c+a-b=2(s-b)$, and $a+b-c=2(s-c)$.

Therefore, on substituting and reducing, we obtain

$$h=\frac{2}{a}\sqrt{s(s-a)(s-b)(s-c)}.$$

Similarly the perpendiculars from B and C on the opposite sides are respectively

$$\frac{2}{b}\sqrt{s(s-a)(s-b)(s-c)},\text{ and } \frac{2}{c}\sqrt{s(s-a)(s-b)(s-c)}.$$

§ 9. We now proceed to investigate formulæ for the area of a triangle in the following important cases.

(α) *When the base* a *and the altitude* h *are given.*—Since a

triangle is equel to half a rectangle of the same base and altitude, we have at once

$$\text{area ABC} = \tfrac{1}{2}ah.$$

Example.—Let $a=40$ chains and $h=14{\cdot}52$ chains, then

$$\text{area} = \tfrac{1}{2}\times 40\times 14{\cdot}52 = 290{\cdot}4 \text{ square chains.}$$

(β) *When two sides* a *and* c *and the included angle* B *are given.*—From fig. 3 $\frac{h}{c} = \sin B$, and therefore $h = c\sin B$;

hence $\quad \text{area} = \tfrac{1}{2}ah = \tfrac{1}{2}ac\sin B$;

or $\quad \log 2\text{area} = \log a + \log c + \text{L}\sin B - 10.$

Example.—Let $a=40$, $c=30$, and $B=30°$, then

$$\text{area} = \tfrac{1}{2}ac\sin B = \tfrac{1}{2}\times 40\times 30\times\tfrac{1}{2} = 300.$$

(γ) *When the three sides* a, b, c *are given.*—From § 8

$$h = \frac{2}{a}\sqrt{s(s-a)(s-b)(s-c)},$$

and therefore

$$\text{area} = \tfrac{1}{2}ah = \tfrac{1}{2}a\times\frac{2}{a}\sqrt{s(s-a)(s-b)(s-c)} = \sqrt{s(s-a)(s-b)(s-c)};$$

or $\quad \log\text{area} = \tfrac{1}{2}\{\log s + \log(s-a) + \log(s-b) + \log(s-c)\}.$

Since $2s = a+b+c$, we have

$$\text{area of triangle} = \tfrac{1}{4}\sqrt{2(a^2b^2+b^2c^2+c^2a^2)-(a^4+b^4+c^4)}.$$

Example 1.—Let $a=13$, $b=14$, and $c=15$, then

$$s = \tfrac{1}{2}(13+14+15) = 21,\quad s-a = 21-13 = 8,$$
$$s-b = 21-14 = 7,\ \text{ and } s-c = 21-15 = 6;$$

therefore $\quad \text{area} = \sqrt{21\times 8\times 7\times 6} = 84.$

Example 2.—Let $a=255$, $b=238$, and $c=221$, then

$$\begin{aligned} \log s &= \log 357 = 2{\cdot}5526682 \\ \log(s-a) &= \log 102 = 2{\cdot}0086002 \\ \log(s-b) &= \log 119 = 2{\cdot}0755470 \\ \log(s-c) &= \log 136 = 2{\cdot}1335389 \end{aligned}$$

therefore $\quad \log\text{area} = \tfrac{1}{2}(8{\cdot}7703543) = 4{\cdot}3851771$;

hence $\quad \text{area} = 24276.$

(δ) *When any two angles* B *and* C *and the adjacent side* a *are given.*—Since

$$\frac{c}{a} = \frac{\sin C}{\sin A},\quad c = \frac{a\sin C}{\sin A},$$

and therefore (by β)

$$\text{area} = \tfrac{1}{2}ac\sin B = \frac{a^2\sin B\sin C}{2\sin A},\quad \text{where } A = 180° - (B+C),$$

or $\quad \log 2\text{area} = 2\log a + \text{L}\sin B + \text{L}\sin C + \text{L}\operatorname{cosec} A - 30.$

Since all the angles of a triangle are given when any two are given, we can find the area of a triangle when any two angles and any one side are given. Thus, when A, B, and c are given, we know C also, and the problem reduces to a case of the preceding.

(ε) *When the three medians* α, β, γ *are given.*—If a, b, c be the three sides of a triangle, and α, β, γ the three medians, *i.e.*, the lines drawn from the angles to the middle points of the opposite sides, then by well-known geometrical propositions we have

$$4(\alpha^2+\beta^2+\gamma^2) = 3(a^2+b^2+c^2),$$
$$16(\alpha^2\beta^2+\beta^2\gamma^2+\gamma^2\alpha^2) = 9(a^2b^2+b^2c^2+c^2a^2),$$

and $\quad 16(\alpha^4+\beta^4+\gamma^4) = 9(a^4+b^4+c^4).$

Now (§ 9, γ)

area of triangle $= \tfrac{1}{4}\sqrt{2(a^2b^2+b^2c^2+c^2a^2)-(a^4+b^4+c^4)}$,

therefore $= \tfrac{1}{3}\sqrt{2(\alpha^2\beta^2+\beta^2\gamma^2+\gamma^2\alpha^2)-(\alpha^4+\beta^4+\gamma^4)}$.

D. *Parallelograms.*

§ 10. The opposite sides and angles of a parallelogram being equal, three independent data, one of which at least is a length, are necessary and sufficient to determine it completely.

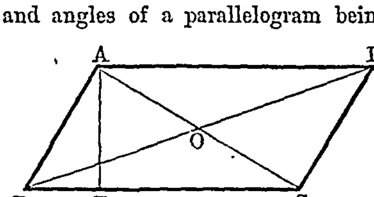

Fig. 4.

In the parallelogram ABCD (fig. 4) let $BC = DA = a$, $AB = CD = b$, $AC = c$, $AE = h$, the angle $ABC = \alpha$ and $AOD = \beta$.

Since the diagonal AC divides the parallelogram into two equivalent triangles, we obtain

(α) $\quad$ area of ABCD = 2 area of triangle ABC $= 2\times\tfrac{1}{2}\,a\times h$ (§ 9, α) $= ah$;

(β) area of ABCD = 2 area ABC $= 2\times\tfrac{1}{2}ab\sin\alpha$ (§ 9, β) $= ab\sin\alpha$;

or $\quad \log\text{area} = \log a + \log b + \text{L}\sin\alpha - 10$;

(γ) $\quad$ area of ABCD = 2 area ABC = 2(ABO + CBO)

$$= 2\{\tfrac{1}{2}\text{BO.AO}\sin\text{AOB} + \tfrac{1}{2}\text{BO.CO}\sin\text{COB}\} = 2\{\tfrac{1}{2}\text{BO.AC}\sin\beta\}$$
$$= \tfrac{1}{2}\text{BD.AC}\sin\beta = \tfrac{1}{2}cd\sin\beta,$$

or $\quad \log 2\text{area} = \log c + \log d + \text{L}\sin\beta - 10.$

§ 11. If the parallelogram be *equiangular* (a rectangle), $c=d$, and area $= \tfrac{1}{2}c^2\sin\beta$. If it be *equilateral* (a rhombus), $\beta = 90°$, and area $= \tfrac{1}{2}cd$. If it be both *equiangular* and *equilateral* (a square), $c=d$ and $\beta=90°$, and area $= \tfrac{1}{2}c^2$ as before (§ 5, β).

E. *Trapeziums.*

§ 12. To determine a trapezium completely four data are necessary and sufficient.

In the trapezium ABCD (fig. 5) let $BC = a$, $CD = b$, $DA = c$, $AB = d$,

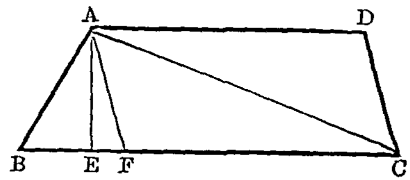

Fig. 5.

and AE perpendicular to $BC = h$, and draw AF parallel to CD, then

(α) $\quad$ area ABCD = area ABC + area ADC

$$= \tfrac{1}{2}ah + \tfrac{1}{2}ch$$
$$= \tfrac{1}{2}(a+c)h;$$

or the area is equal to half the sum of the parallel sides multiplied by the perpendicular between them.

Again, area of ABF $= \tfrac{1}{2}\text{BF}\times\text{AE}$ (§ 9, α) $= \tfrac{1}{2}(a-c)h$,

also $\quad$ area of ABF $= \sqrt{s(s-\text{AB})(s-\text{BF})(s-\text{FA})}$,

where $\quad 2s = \text{AB} + \text{BF} + \text{FA}$;

hence $\quad h = \dfrac{2}{a-c}\sqrt{s(s-\text{AB})(s-\text{BF})(s-\text{FA})}$, therefore

(β) $\quad$ area of ABCD $= \tfrac{1}{2}(a+c)h = \dfrac{a+c}{a-c}\sqrt{s(s-\text{AB})(s-\text{BF})(s-\text{FA})}$

$$= \tfrac{1}{4}\frac{a+c}{a-c}\sqrt{(-a+b+c+d)(a+b-c-d)(a+b-c+d)(a-b-c+d)},$$

since $\quad AB = d$, $BF = a-c$, and $FA = CD = b$.

Thus we can find the area of a trapezium in terms of its sides.

§ 13. If $c=0$, ABCD becomes a triangle, and its area

$$= \tfrac{1}{4}\sqrt{(-a+b+d)(a+b-d)(a+b+d)(a-b+d)}.$$

Again, if $c=a$, then also $b=d$, and ABCD becomes a parallelogram, and its area takes the indeterminate form $\frac{0}{0}$, as it should do, since four sides do not completely determine a parallelogram.

F. *Quadrilaterals Generally.*

§ 14. A quadrilateral is completely determined when five independent data are given. We consider the following cases.

(α) *When any diagonal and the perpendiculars on it from the opposite vertices are given.*

The quadrilateral ABCD (fig. 6) = ABD + BCD

$$= \tfrac{1}{2}\text{BD.AE} + \tfrac{1}{2}\text{BD.CF}$$
$$= \tfrac{1}{2}\text{BD(AE + CF)};$$

or the area is equal to half the product of the diagonal and the sum of the perpendiculars.

If the diagonal BD fall without the figure, as in the concave quadrilateral ABCD (fig. 7), then it is clear that

area ABCD $= \tfrac{1}{2}$BD(AE − CF).

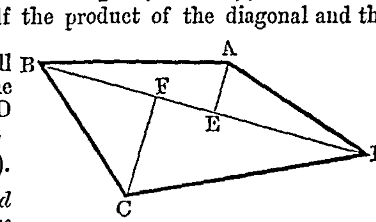

Fig. 6.

(β) *When the diagonals and their included angle are given.*—In the quadrilateral ABCD (fig. 8, p. 16) let $BD = h$, $AC = k$, and angle $DEA = \alpha$, then

$$\begin{aligned} \text{ABCD} &= \text{ABD} + \text{BCD} \\ &= \tfrac{1}{2}\text{BD.AE}\sin\alpha + \tfrac{1}{2}\text{BD.CE}\sin\alpha \ (\S\ 10.\ \gamma) \\ &= \tfrac{1}{2}h(\text{AE} + \text{CE})\sin\alpha \\ &= \tfrac{1}{2}hk\sin\alpha; \end{aligned}$$

or the area is equal to the product of the diagonals and the sine of their contained angle.

The same result holds when one of the diagonals falls without the quadrilateral, as in fig. 7, as the reader can easily verify.

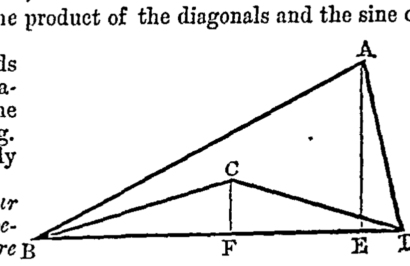

Fig. 7.

(γ) *When the four sides and the angle between the diagonals are given.*—If a, b, c, d be the sides and α the angle between the diagonals it can easily be shown that

$$\text{area of quadrilateral} = \tfrac{1}{4}(a^2-b^2+c^2-d^2)\tan\alpha.$$

(δ) *When the four sides are given and the opposite angles are supplementary.*—In fig. 8 let $AB=a$ $BC=b$, $CD=c$, $DA=d$, $AC=h$, angle $ABC=\alpha$, angle $CDA=\beta$, and let $\alpha+\beta=180°$, then

$$\text{area of } ABCD = ABC + ADC = \tfrac{1}{2}ab\sin\alpha + \tfrac{1}{2}cd\sin\beta.$$

But

$$\sin\beta = \sin(180° - \alpha) = \sin\alpha,$$

therefore

$$\text{area of } ABCD = \tfrac{1}{2}(ab+cd)\sin\alpha.$$

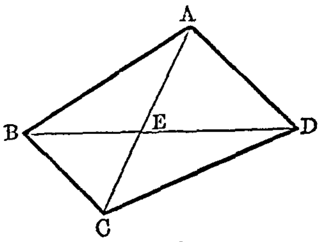

Fig. 8.

This gives us the area of the quadrilateral in terms of the four sides and one angle.

Again we have

$$a^2+b^2-2ab\cos\alpha = h^2 = c^2+d^2-2cd\cos\beta = c^2+d^2+2cd\cos\alpha,$$

therefore $\cos\alpha = \dfrac{a^2+b^2-c^2-d^2}{2(ab+cd)}$, and hence

$$1+\cos\alpha = \frac{(a+b+c-d)(a+b-c+d)}{2(ab+cd)}, \text{ and}$$

$$1-\cos\alpha = \frac{(c+d+a-b)(c+d-a+b)}{2(ab+cd)}.$$

From this we obtain

$$\sin^2\alpha = (1+\cos\alpha)(1-\cos\alpha)$$
$$= \frac{(b+c+d-a)(c+d+a-b)(d+a+b-c)(a+b+c-d)}{4(ab+cd)^2}.$$

Now let $a+b+c+d=2s$,

then $\tfrac{1}{2}(ab+cd)\sin\alpha = \sqrt{(s-a)(s-b)(s-c)(s-d)}$;

therefore area of $ABCD = \sqrt{(s-a)(s-b)(s-c)(s-d)}$,

or $\log \text{area} = \tfrac{1}{2}\{\log(s-a)+\log(s-b)+\log(s-c)+\log(s-d)\}$.

If $d=0$, the quadrilateral becomes a triangle, and its area is $\sqrt{(s-a)(s-b)(s-c)s}$ as before. In extracting the square root of $\sin\alpha$ we take the positive sign, since the angle α is less than two right angles.

G. *Regular Polygons.*

§ 15. Since a regular polygon is both equilateral and equiangular, a circle can be inscribed within it and also described about it, and thus the n straight lines drawn from the common centre of the two circles to the n vertices of the polygon divide it into n triangles equal in every respect. Therefore the area of the polygon is equal to n times the area of any one of these triangles.

§ 16. *Radius of Inscribed and Circumscribed Circles.*—Let AB (fig. 9) $=a$ be a side of a regular polygon of n sides; let C be the centre of the inscribed and circumscribed circles, $CD=r$ the radius of the former, and $CE=R$ the radius of the latter. The angle ACB is evidently equal to the nth part of four right angles, that is

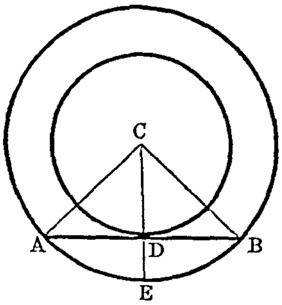

Fig. 9.

$$ACB = \frac{360°}{n}, \text{ and } ACD = \tfrac{1}{2}ACB = \frac{180°}{n}.$$

Now $AD = \dfrac{a}{2} = CD\tan ACD = r\tan\dfrac{180°}{n}$,

and $AD = \dfrac{a}{2} = AC\sin ACD = R\sin\dfrac{180°}{n}$;

therefore $r = a\times\tfrac{1}{2}\cot\dfrac{180°}{n}$,

and $R = a\times\tfrac{1}{2}\operatorname{cosec}\dfrac{180°}{n}$.

§ 17. *Perimeter of Polygon.*—The perimeter of the polygon of n sides is na, *i.e.*, $2nr\tan\dfrac{180°}{n}$, or $2nR\sin\dfrac{180°}{n}$.

From this it follows that the perimeters of the inscribed and circumscribed regular polygons of n sides of a circle of radius r are

$$2nr\sin\frac{180°}{n} \text{ and } 2nr\tan\frac{180°}{n} \text{ respectively.}$$

§ 18. *Area of Polygon.*

(α) *In terms of* r.—The area of polygon

$$= nACB = nAD\,.\,CD = n\times r^2\tan\frac{180°}{n}.$$

(β) *In terms of* R.—The triangle ACB

$$= \tfrac{1}{2}AC\,.\,CB\sin ACB = \tfrac{1}{2}R^2\sin\frac{360°}{n},$$

and therefore area of polygon $= \tfrac{1}{2}nR^2\sin\dfrac{360°}{n}$.

(γ) *In terms of* a.—The triangle ACB

$$= \tfrac{1}{2}AB\,.\,CD = \frac{a}{2}\times r = \frac{a}{2}\times\tfrac{1}{2}a\cot\frac{180°}{n} = \frac{a^2}{4}\cot\frac{180°}{n},$$

and therefore area of polygon $= a^2\times\dfrac{n}{4}\cot\dfrac{180°}{n}$,

or $\log 4\,\text{area} = \log n + L\cot\dfrac{180°}{n} + 2\log a - 10$.

From α and β it follows that the areas of the inscribed and circumscribed regular polygons of n sides of a circle of radius r are

$$\tfrac{1}{2}nr^2\sin\frac{360°}{n} \text{ and } nr^2\tan\frac{180°}{n} \text{ respectively.}$$

§ 19. In the formula (§ 18, γ) for the area of a polygon, the factor $\dfrac{n}{4}\cot\dfrac{180°}{n}$ has a definite value for every value of n, and hence, if we find its value once for all for a large number of values of n, and tabulate the results, we can find the area of a regular polygon of n sides by multiplying the square of its side by the appropriate tabular value.

Again, if $a=1$ we have

$$r = \tfrac{1}{2}\cot\frac{180°}{n} \text{ and } R = \tfrac{1}{2}\operatorname{cosec}\frac{180°}{n};$$

and thus we obtain in a similar manner the radius of the inscribed and circumscribed circles by multiplying the side by the appropriate tabular value of $\tfrac{1}{2}\cot\dfrac{180°}{n}$ and $\tfrac{1}{2}\operatorname{cosec}\dfrac{180°}{n}$ respectively.

§ 20. The following table contains the values of $\dfrac{n}{4}\cot\dfrac{180°}{n}$ and their logarithms, and the values of $\tfrac{1}{2}\cot\dfrac{180°}{n}$ and $\tfrac{1}{2}\operatorname{cosec}\dfrac{180°}{n}$ for all values of n from 3 to 12.

n	$\frac{n}{4}\cot\frac{180°}{n}$	Logarithms.	$\frac{1}{2}\cot\frac{180°}{n}$	$\frac{1}{2}\operatorname{cosec}\frac{180°}{n}$
3	0·4330127	$\bar{1}$·6365006	0·28867	·57735
4	1·0000000	0·0000000	0·50000	·70710
5	1·7204774	0·2356490	0·68819	·85065
6	2·5980762	0·4146519	0·86602	1·0000
7	3·6339124	0·5603745	1·0383	1·1523
8	4·8284271	0·6380568	1·2071	1·3065
9	6·1818242	0·7911166	1·3737	1·4619
10	7·6942088	0·8861610	1·5388	1·6180
11	9·3656407	0·9715375	1·7028	1·7747
12	11·1961524	1·0490688	1·8660	1·9318

Let A denote the area of a polygon of n sides and A′ the corresponding tabular value of $\dfrac{n}{4}\cot\dfrac{180°}{n}$, then

$$A = a^2A',$$

or

$$\log A = 2\log a + \log A'.$$

H.—*Length of the Radius of the Inscribed, Escribed, and Circumscribed Circles of a Triangle.*

§ 21. (α) *Radius of Inscribed Circle.*—Let O (fig. 10) be the centre of the circle inscribed in the triangle ABC and touching the sides in D, E, and F. Join OA, OB, and OC. The angles at D, E, F are right angles (Eucl. iii. 18). Let $BC=a$, $CA=b$, $AB=c$, and $OD=OE=OF=r$.

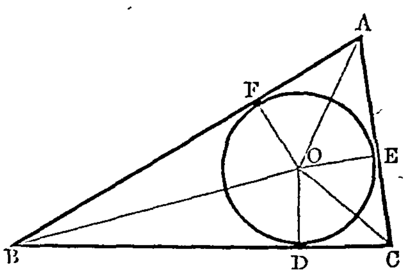

Fig. 10.

Now $ABC = BOC + COA + AOB$

$$= \tfrac{1}{2}ar + \tfrac{1}{2}br + \tfrac{1}{2}cr = \tfrac{1}{2}(a+b+c)r = rs;$$

whence $r = \dfrac{\text{area of } ABC}{s} = \dfrac{\sqrt{s(s-a)(s-b)(s-c)}}{s}$.

(β) *Radius of Escribed Circles.*—Let $OD=OE=OF=r_a$, then

$$ABC = ACO + ABO - BOC$$
$$= \tfrac{1}{2}br_a + \tfrac{1}{2}cr_a - \tfrac{1}{2}ar_a = \tfrac{1}{2}(b+c-a)r_a = r_a(s-a);$$

and $r_a = \dfrac{\text{area of } ABC}{s-a} = \dfrac{\sqrt{s(s-a)(s-b)(s-c)}}{s-a} = \sqrt{\dfrac{s(s-b)(s-c)}{s-a}}$.

Similarly

$$r_b = \sqrt{\frac{s(s-a)(s-c)}{s-b}} \text{ and } r_c = \sqrt{\frac{s(s-a)(s-b)}{s-c}}.$$

(γ) *Radius of Circumscribed Circle.*—Let AD (fig. 12) $=p$ the perpendicular from A on the side BC, and AE $=2$R the diameter

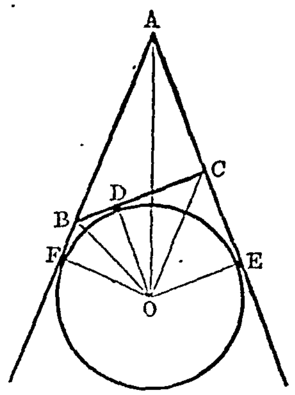

Fig. 11.

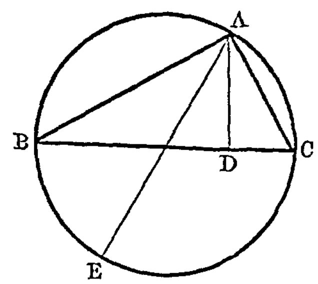

Fig. 12.

of the circle, then (Eucl. vi. C) we have

$$2R\times p=b\times c,$$

therefore

$$2R\times ap=abc.$$

Now $ap=2\Delta$, where Δ denotes the area of ABC;

hence

$$R=\frac{abc}{4\Delta}=\frac{abc}{4\sqrt{s(s-a)(s-b)(s-c)}}.$$

Example.—Let $a=13$, $b=14$, and $c=15$; then r will be found to be 4, r_a $10\frac{1}{2}$, r_b 12, r_c 14, and R $8\frac{1}{8}$.

Section II.—Plane Figures contained by Curved Lines.

A. *The Circle.*

§ 22. *Circumference of a Circle.*—If we inscribe in any circle a regular polygon of n sides, and also circumscribe a regular polygon of the same number of sides, it is clear that the perimeter of the circle is intermediate between the perimeters of the inscribed and circumscribed polygons, and that the difference between the perimeters of the inscribed and circumscribed polygons can be made as small as we please by sufficiently increasing n. A similar statement holds with reference to the areas of the circle and the inscribed and circumscribed polygons. With the above assumptions it is easily proved that the circumference of a circle bears a constant ratio to its diameter. Hence we have

$$\text{Circumference}=C=\text{constant}\times\text{radius}=\text{constant}\times r.$$

It is usual to denote this constant by 2π, and therefore

$$C=2\pi r=\pi d,\ \text{where } d \text{ is the diameter of the circle.}$$

§ 23. *Numerical Value of* π.—The constant π being, as can be easily proved, an interminable decimal, we can only approximate to its value, but this we can do to any degree of accuracy we please. If s and σ denote respectively a side of the inscribed and circumscribed polygons of n sides, and s' and σ' a side of the inscribed and circumscribed polygons of $2n$ sides, it can easily be shown that

$$(\alpha)\ \sigma=\frac{rs}{\sqrt{r^2-(\frac{1}{2}s)^2}},\qquad(\beta)\ s'^2=2r\left\{r-\sqrt{r^2-(\tfrac{1}{2}s)^2}\right\},$$

$$(\gamma)\ \sigma'=\frac{rs'}{\sqrt{r^2-(\frac{1}{2}s')^2}},$$

where r is the radius of the circle.

If we take $r=\frac{1}{2}$ we find, by means of these formulæ, and by assuming the value of s when $n=6$, that the perimeter of inscribed polygon of 96 sides $=3·140$ . . . . , and the perimeter of circumscribed polygon of 96 sides $=3·142$. . . .

From this we learn that the circumference of the circle, in this case π, is greater than 3·140 . . . . and less than 3·142 . . . . , and therefore as far as the second place of decimals

$$\pi=3·14.$$

By taking greater and greater values of n we obtain closer and closer approximations to π.

The preceding method for approximating to the value of π is the simplest afforded by elementary geometry, and is also the oldest; but better and more rapid methods are furnished by the higher mathematics. The calculation of π has been carried to 707 places of decimals, the following being the first 20 figures in the result:—

$$3·14159265358979323846.$$

For all practical purposes it is sufficient to take

$$\pi=3·14159\ \text{or}\ \frac{355}{133}.$$

§ 24. The following table contains the functions of π that are of most frequent occurrence in mensuration:—

	Number.	Logarithm.		Number.	Logarithm.
π	3·1415927	0·4971499	π^2	9·8696044	0·9942997
2π	6·2831853	0·7981799			
4π	12·5663706	1·0992099	$\frac{1}{6\pi^2}$	0·0168869	$\bar{2}$·2275490
$\frac{1}{2}\pi$	1·5707963	0·1961199			
$\frac{1}{3}\pi$	1·0471976	0·0200286	$\sqrt{\pi}$	1·7724539	0·2485750
$\frac{1}{4}\pi$	0·7853982	$\bar{1}$·8950899

$\frac{180}{\pi}$	57·2957795	1·7581226	$\log_e\pi$	1·1447299	0·0587030

§ 25. *Units of Angular Measurement.*—In measuring lines we select some line of constant length as the standard or unit; similarly in measuring angles we require to take some angle of constant magnitude as unit angle. The right angle is by its nature the simplest unit angle, but, for convenience, we take the $\frac{1}{90}$th part of a right angle for unit, and call it a degree, which is subdivided into sixty equal parts called minutes, and these again into sixty equal parts called seconds. For theoretical purposes we define the unit angle to be *the angle subtended at the centre of a circle by an arc equal to the radius.* This angle we call a "radian." In many treatises the radian measure of an angle is called the circular measure.

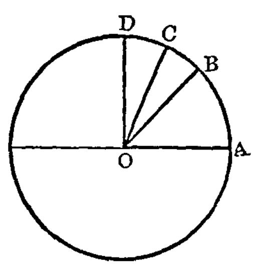

Fig. 13.

§ 26. *The radian is a constant angle.*—Let OA (fig. 13) $=$ arc AB $=r$, then AOB $=$ radian, and let AOD $=90°$; then

$$\text{arc AD}=\tfrac{1}{4}\times2\pi r=\tfrac{1}{2}\pi r;$$

and, since angles at the centre of a circle are proportional to the arcs on which they stand (Eucl. vi. 33),

$$\frac{\text{number of degrees in radian AOB}}{\text{number of degrees in AOD}}=\frac{AB}{AD}=\frac{r}{\frac{1}{2}\pi r}=\frac{2}{\pi};$$

therefore number of degrees in radian

$$=90°\times\frac{2}{\pi}=57°·2957795=\text{constant.}$$

§ 27. *Number of Radians in any Angle.*—Let AOC (fig. 13) be any angle, AOB the radian, and AC $=s$; then

$$\frac{\text{number of radians in AOC}}{\text{one radian}}=\frac{AC}{AB}=\frac{s}{r};$$

therefore number of radians in AOC $=\dfrac{s}{r}$.

If AOC $=90°$, then $s=\frac{1}{2}\pi r$, and number of radians $=\frac{1}{2}\pi$; there are thus π radians in two and 2π in four right angles.

When $r=1$ we have number of radians $=s$, and hence in some treatises for the number of radians in an angle we find the length of the arc given.

§ 28. *To transfer from degrees to radians and conversely.*—Let x denote the number of degrees in an angle, and θ the number of radians in the same, then, since $\dfrac{x}{180°}=\dfrac{\theta}{\pi}$,

$$(\alpha)\ \theta=\frac{\pi x°}{180},\quad(\beta)\ x°=\frac{180}{\pi}\theta.$$

§ 29. The following table contains the values of θ for values of x up to 180°, and also for minutes and seconds.

Degrees.	Radian.	Degrees.	Radian.	Degrees.	Radian.	Minutes.	Radian. ·0	Seconds.	Radian. ·000
1	·0174533	61	1·0646508	121	2·1118484	1	002909	1	0048
2	·0349066	62	1·0821041	122	2·1293017	2	005818	2	0097
3	·0523599	63	1·0995574	123	2·1467550	3	008727	3	0145
4	·0698132	64	1·1170107	124	2·1642083	4	011636	4	0194
5	·0872665	65	1·1344640	125	2·1816616	5	014544	5	0242
6	·1047198	66	1·1519173	126	2·1991149	6	017453	6	0291
7	·1221730	67	1·1693706	127	2·2165682	7	020362	7	0339
8	·1396263	68	1·1868239	128	2·2340214	8	023271	8	0388
9	·1570796	69	1·2042772	129	2·2514747	9	026180	9	0436
10	·1745329	70	1·2217305	130	2·2689280	10	029089	10	0485
20	·3490659	80	1·3962634	140	2·4434610	20	058178	20	0970
30	·5235988	90	1·5707963	150	2·6179939	30	087266	30	1454
40	·6981317	100	1·7453293	160	2·7925268	40	116355	40	1939
50	·8726646	110	1·9198622	170	2·9670597	50	145444	50	2424
60	1·0471976	120	2·0943951	180	3·1415927	60	174533	60	2909

As an example of the use of this table we proceed to find the value of θ when $x = 68^\circ\ 45'\ 17''\cdot 8$.

$$\begin{aligned} \text{When } x &= 68^\circ & \theta &= 1\cdot 1868239\,, \\ x &= 40' & \theta &= \cdot 0116355\,, \\ x &= \ 5' & \theta &= \cdot 0014544\,, \\ x &= 10'' & \theta &= \cdot 0000485\,, \\ x &= \ 7'' & \theta &= \cdot 0000339\,, \\ \text{and when } x &= 0''\cdot 8 & \theta &= \underline{\cdot 0000039}\,, \\ \text{therefore when } x &= 68^\circ\ 45'\ 17''\cdot 8 & \theta &= \overline{1\cdot 2000001}\,. \end{aligned}$$

§ 30. Combining the results of §§ 27 and 28 we obtain

$$(\alpha) \quad \theta = \frac{s}{r}, \text{ and } x = \frac{180}{\pi} \cdot \frac{s}{r}\,;$$

$$(\beta) \quad r = \frac{s}{\theta} = \frac{180}{\pi} \cdot \frac{s}{x}\,;$$

$$(\gamma) \quad s = r\theta = \frac{\pi}{180} \cdot rx\,.$$

§ 31. *Length of Arcs of Circles.*—The following are the more important cases:—

(α) *In terms of the chord of the arc and the radius of the circle.*—Let AB (fig. 14) $= 2c$, AC $= r$, and AEB $= s$, then

$$\text{AD} = \tfrac{1}{2}\text{AB} = c = r \sin \tfrac{1}{2}\text{C}, \text{ whence C is known, and therefore}$$
the arc s is found (§ 30, γ).

(β) *In terms of the height of the arc and the radius of the circle.*—Let DE $= h =$ height of arc, then

$$\text{CD} = \text{CE} - \text{DE} = r - h\,,$$

and
$$\cos \tfrac{1}{2}\text{C} = \frac{\text{CD}}{\text{AC}} = \frac{r-h}{r}\,,$$

whence C is found, and therefore s.

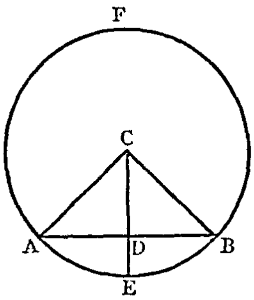

Fig. 14.

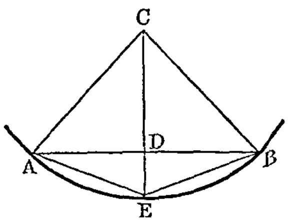

Fig. 15.

§ 32. *Huygens's Approximation to the Length of a Circular Arc.*—Let AB (fig. 15) $= p$ be the chord of the arc AEB, and AE $=$ EB $= q$ that of half the arc, then the arc AEB $= \frac{1}{3}(8q - p)$ approximately.

For, let r denote the radius, s the arc AEB, and 2θ the angle ACB, then $\theta = \dfrac{s}{2r}$. Again, AB $= p = 2\text{AD} = 2r \sin\theta = 2r \sin\dfrac{s}{2r}$; and similarly $q = 2r \sin\dfrac{s}{4r}$.

Now
$$\sin\theta = \theta - \frac{\theta^3}{\underline{|3}} + \frac{\theta^5}{\underline{|5}} - \&c.\,;$$

therefore
$$p = 2r\left\{\frac{s}{2r} - \frac{1}{\underline{|3}}\left(\frac{s}{2r}\right)^3 + \frac{1}{\underline{|5}}\left(\frac{s}{2r}\right)^5 - \&c.\right\}$$

$$= s - \frac{s^3}{2\,.\,3\,.\,4\,.\,r^2} + \frac{s^5}{2\,.\,3\,.\,4\,.\,5\,.\,16\,.\,r^4} - \&c.$$

Similarly
$$8q = 16r\left\{\frac{s}{4r} - \frac{1}{\underline{|3}}\left(\frac{s}{4r}\right)^3 + \frac{1}{\underline{|5}}\left(\frac{s}{4r}\right)^5 - \&c.\right\}$$

$$= 4s - \frac{s^3}{2\,.\,3\,.\,4\,.\,r^2} + \frac{s^5}{2\,.\,3\,.\,4\,.\,5\,.\,64\,.\,r^4} - \&c.$$

Hence, neglecting powers of $\dfrac{s}{r}$ beyond the fourth, we obtain

$$\frac{8q-p}{3} = s\left(1 - \frac{s^4}{7680r^4}\right) = s$$

approximately.

In practice it is sometimes more convenient to use the equivalent form

$$s = 2q + \tfrac{1}{3}(2q - p)\,.$$

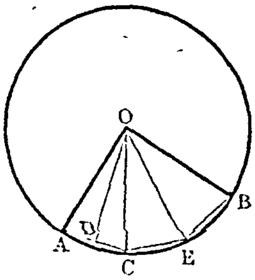

Fig. 16.

§ 33. *Area of Sector of a Circle.*—Let the sector be OAB (fig. 16). Divide the arc AB into n equal parts, and draw the chords of these. Let P denote the perimeter of the broken line AB, A the area of the polygon AOB, and p the altitude of any one of the n equal triangles of which this polygon is made up.

Now in the limit, when n is indefinitely increased, P becomes the arc AB $= s$, a result which we symbolize thus—

$$\mathop{\mathrm{L}}_{n=\infty} \mathrm{P} = \text{arc AB} = s\,.$$

Similarly
$$\mathop{\mathrm{L}}_{n=\infty} p = \text{radius} = r\,.$$

Again, the area of the sector is equal to the area of the polygon when the broken line AB becomes the arc AB, that is,

$$\text{sector} = \mathop{\mathrm{L}}_{n=\infty} \mathrm{A} = \mathop{\mathrm{L}}_{n=\infty} \tfrac{1}{2}p \times \mathrm{P} = \tfrac{1}{2} \mathop{\mathrm{L}}_{n=\infty} p \times \mathop{\mathrm{L}}_{n=\infty} \mathrm{P}\,.$$
$$= \tfrac{1}{2}rs\,.$$

§ 34. Let S denote the area of a sector of a circle, then, by means of the above result and § 27, we have

$$(\alpha) \quad \mathrm{S} = \tfrac{1}{2}sr\,,$$
$$(\beta) \quad \mathrm{S} = \tfrac{1}{2}r\theta\,.\,r = \tfrac{1}{2}r^2\theta\,.$$

§ 35. We proceed to find the area of a sector of a circle in the following additional cases:—

(α) *When the chord of the sector and the radius of the circle are given.*—In fig. 14 let AB $= 2c$, and let AC $= r$, then we have

$$\sin\frac{\text{ACB}}{2} = \frac{\text{AD}}{\text{AC}} = \frac{c}{r}\,;$$

whence ACB and therefore θ is known, and S can be found by § 34.

ACB has two values, the smaller one giving the area of the minor, and the larger that of the major conjugate sector.

(β) *When the chord and height of the chord are given.*—Let DE (fig. 14) $= h$ and AB $= 2c$, then

$$\text{AC}^2 = r^2 = \text{AD}^2 + \text{DC}^2 = c^2 + (r-h)^2, \text{ whence}$$

$r = \dfrac{c^2 + h^2}{2h}$, and therefore by previous case the area can be found.

(γ) *When the chord and angle subtended at the centre are given.*—Let AB (fig. 14) $= 2c$ and ACB $= \theta$, then

$$\frac{c}{r} = \sin\frac{\text{ACB}}{2}, \text{ or } r = \frac{c}{\sin\frac{1}{2}\theta}\,,$$

therefore area of sector $= \frac{1}{2}r^2\theta = \frac{1}{2}\left(\dfrac{c}{\sin\frac{1}{2}\theta}\right)^2 \times \theta\,.$

§ 36. *Area of a Circle.*—The circle being a sector whose arc is the whole circumference we obtain at once

$$\text{area of circle} = \tfrac{1}{2}r \times s = \tfrac{1}{2}r \times 2\pi r = \pi r^2.$$

An independent proof of this proposition might be given by means of the inscribed and circumscribed polygons, and from the area of a circle the area of a sector can be deduced. The infinitesimal calculus affords a simple and elegant proof (see § 44).

§ 37. If A denote the area, r the radius, $d = 2r$ the diameter, and C the circumference of a circle, we have

$$(\alpha) \quad \mathrm{A} = \pi r^2,$$
$$(\beta) \quad \mathrm{A} = \tfrac{1}{2} \times 2\pi r \times r = \tfrac{1}{2}\mathrm{C}r\,,$$
$$(\gamma) \quad \mathrm{A} = \frac{4\pi^2 r^2}{4\pi} = \frac{\mathrm{C}^2}{4\pi}\,,$$
$$(\delta) \quad \mathrm{A} = \frac{\pi 4r^2}{4} = \frac{\pi d^2}{4}\,.$$

Whence we see that the area of a circle is obtained by multiplying
(α) the square of its radius by $\pi = 3\cdot 14159$,
(β) the radius by half the circumference,
(γ) the square of the circumference by $\dfrac{1}{4\pi} = \cdot 07957$,
(δ) the square of the diameter by $\frac{1}{4}\pi = \cdot 78539$.

§ 38. Again, from the above formulæ we deduce

$$(\alpha) \quad r = \frac{1}{\sqrt{\pi}}\mathrm{A} = \cdot 5641896 \times \mathrm{A}\,,$$
$$(\beta) \quad d = \frac{2}{\sqrt{\pi}}\mathrm{A} = 1\cdot 1283792 \times \mathrm{A}\,,$$
$$(\gamma) \quad c = 2\sqrt{\pi}\mathrm{A} = 3\cdot 5449077 \times \mathrm{A}\,,$$

thus obtaining radius, diameter, and circumference from area.

§ 39. *Area of a Circular Ring.*—Let r and r_1 denote the radii of the outer and inner circles respectively (fig. 17), then the area of the space between them

$$= \pi r^2 - \pi r_1^2 = \pi(r + r_1)(r - r_1)\,.$$

The circles need not be concentric, and the reader should note that the area of the ring is equal to the area of an ellipse whose major and minor axes are $r + r_1$ and $r - r_1$ (see § 51).

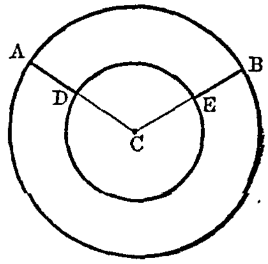

Fig. 17.

§ 40. *Area of the Sector of an Annulus.*—Let angle ACB $= \theta$ in fig. 17, then the area of ABED

$$= \text{sector ACB} - \text{sector DCE}$$
$$= \tfrac{1}{2}r^2\theta - \tfrac{1}{2}r_1^2\theta\,,$$
$$= \tfrac{1}{2}\theta(r + r_1)(r - r_1)\,.$$

Again, let $AB=l$, $DE=l_1$, and $CA-CD=r-r_1=h$, then

$$r=\frac{l}{\theta}\text{ and }r_1=\frac{l_1}{\theta}\text{ ; therefore}$$

$$r+r_1=\frac{1}{\theta}(l+l_1),\text{ and}$$

$$\text{area of sector}=\tfrac{1}{2}\theta(r+r_1)(r-r_1)=\tfrac{1}{2}\theta\left(\frac{l+l_1}{\theta}\right)h=\tfrac{1}{2}h(l+l_1).$$

§ 41. *Area of a Segment of a Circle.*—(a) *When the radius and the angle subtended at the centre are given.*—In fig. 14, let AEB be a segment of a circle, then its area

$$\begin{aligned}&=\text{sector ACB}-\text{triangle ACB.}\\&=\tfrac{1}{2}r^2\theta-\tfrac{1}{2}r^2\sin\theta\ (\S\S\ 9,\ 34)\\&=\tfrac{1}{2}r^2(\theta-\sin\theta).\end{aligned}$$

If the segment be greater than a semicircle $\sin\theta$ is negative and the formula becomes

$$\tfrac{1}{2}r^2(\theta+\sin\theta),$$

as is also geometrically evident.

We might in a similar manner find the area of a segment of a circle

(β) when the chord and radius are given,
(γ) when the chord and its height are given,
(δ) when the radius and height of the chord are given,
(ϵ) when the chord and angle subtended by the chord are given.

In all these cases the method of proceeding is obvious, a segment being the difference between a sector and a triangle.

§ 42. *Area of a Lune.*—Let ADB and ACB (fig. 18) be two segments of circles, then the area of the lune ADBC

$$=\text{segment ADB}-\text{segment ACB.}$$

Hence if we so choose our data that we can determine the areas of the two segments we have only to take their difference to find the area of the lune.

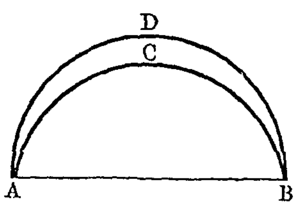

Fig. 18.

§ 43. *Area of a Circular Zone.*—Let AB and CD (fig. 19) be two parallel chords, then the area of the zone ABCD

$$\begin{aligned}&=\text{circle}-\text{segment AHB}-\text{segment DFC;}\\\text{or}\quad&=\text{segment AED}+\text{trapezium ABCD}+\text{segment BGC}\\&=2\text{ segment AED}+\text{trapezium ABCD.}\end{aligned}$$

§ 44. The INFINITESIMAL CALCULUS (*q.v.*) furnishes a simple and elegant proof of the formulæ for the areas of a circle and a sector. If $y=\phi(x)$ be the equation to a plane curve referred to rectangular

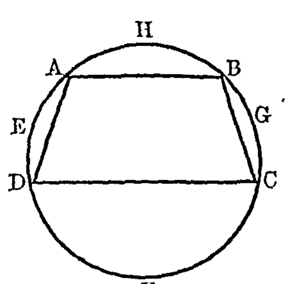

Fig. 19.

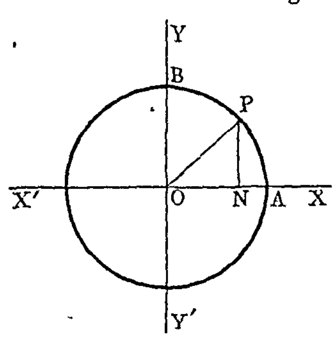

Fig. 20.

axes, then the area between the curve, the axis of x, and two ordinates corresponding to the abscissæ a and b is represented by the integral

$$\int_a^b\phi(x)dx.$$

Let x and y be the coordinates of P (fig. 20), then if $OP=r$ the equation to the circle is $y^2=r^2-x^2$, and therefore

$$\text{area of quadrant AOB}=\int_0^r\sqrt{r^2-x^2}\,dx$$

$$=\left[\frac{r^2}{2}\sin^{-1}\frac{x}{r}+\frac{x}{2}\sqrt{r^2-x^2}\right]_0^r=\frac{r^2}{2}\times\frac{\pi}{2}=\frac{\pi r^2}{4},$$

and therefore area of whole circle $=\pi r^2$.

§ 45. If the equation to a plane curve be given in polar coordinates, the area bounded by two radii and the curve is equal to

$$\tfrac{1}{2}\int_{\theta_1}^{\theta_2}r^2d\theta,$$

where θ_1 and θ_2 are the values of θ corresponding to the limiting radii.

For example, let AOP (fig. 20) be θ, then area of circle

$$=\frac{r^2}{2}\int_0^{2\pi}d\theta=\frac{2\pi r^2}{2}=\pi r^2\text{ as before.}$$

The area of a sector can be found in a similar manner.

B. *The Parabola.*

§ 46. *Length of an Arc of any Plane Curve.*—If a plane curve be referred to rectangular axes, then the length of any arc of the curve

$$=s=\int\left\{1+\left(\frac{dy}{dx}\right)^2\right\}^{\frac{1}{2}}dx=\int\left\{1+\left(\frac{dx}{dy}\right)^2\right\}^{\frac{1}{2}}dy$$

taken between proper limits, *i.e.*, the extremities of the arc. See INFINITESIMAL CALCULUS.

§ 47. *Arc of a Parabola.*—Let the axes of coordinates be the axis

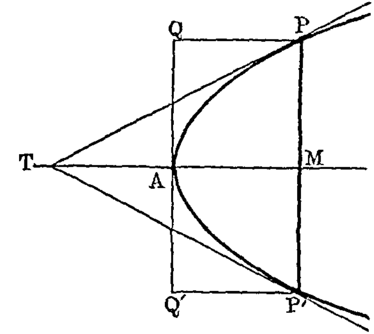

Fig. 21.

of x and the tangent at the vertex A (fig. 21), then, the equation to the parabola being $y^2=2mx$, where $m=2a=\frac{1}{2}$ latus rectum, we have

$$\frac{dx}{dy}=\frac{y}{m},\text{ and hence}$$

$$\begin{aligned}s=\text{arc AP}&=\int_0^{y_1}\left\{1+\frac{y^2}{m^2}\right\}^{\frac{1}{2}}dy\\&=\frac{y_1\sqrt{y_1^2+m^2}}{2m}+\frac{m}{2}\log_e\left(\frac{y_1+\sqrt{y_1^2+m^2}}{m}\right);\end{aligned}$$

therefore whole arc $PAP'=\frac{y_1}{m}\sqrt{y_1^2+m^2}+m\log_e\left(\frac{y_1+\sqrt{y_1^2+m^2}}{m}\right)$.

Since $y_1^2=2mx_1$, the formula may be written

$$\text{arc PAP}'=\sqrt{4x_1^2+y_1^2}+\frac{y_1^2}{2x_1}\log_e\left(\frac{2x_1+\sqrt{4x_1^2+y_1^2}}{y_1}\right).$$

§ 48. *Area of a Parabola.*—Taking the equation to the parabola in the form $y^2=4px$, we get

$$\text{area of segment PAP}'\text{ (fig. 21)}=2\int_0^{x_1}2\sqrt{px}\,dx$$

$$=\tfrac{8}{3}p^{\frac{1}{2}}x_1^{\frac{3}{2}}=\tfrac{4}{3}x_1y_1=\frac{y_1^3}{3p}.$$

From these formulæ we see that the area of a parabolic segment varies directly as the cube of the square root of the abscissa, and directly as the cube of the ordinate, and that it is equal to $\frac{2}{3}$ rectangle PQQ′P′, or $\frac{4}{3}$ triangle PTP′.

A similar relation holds for the segment cut off by any chord, and thus the area of any parabolic segment can be determined in terms of any data that are sufficient to determine the segment.

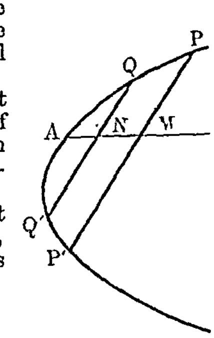

Fig. 22.

§ 49. *Area of a Parabolic Zone.*—Let PM (fig. 22) $=y_1$, $QN=y_2$, $AM=x_1$, $AN=x_2$, and let the ordinates be inclined to the axis at an angle α.

$$\begin{aligned}\text{Area of zone PQQ′P′}&=\text{segment PAP′}\\&\quad-\text{segment QAQ′}\\&=\frac{y_1^3-y_2^3}{3p}\times\sin\alpha.\end{aligned}$$

Now $y_1^2=4px_1$ and $y_2^2=4px_2$, therefore $\frac{y_1^2-y_2^2}{4(x_1-x_2)}=p$, and hence on substituting for p we have area of zone

$$=\tfrac{4}{3}(x_1-x_2)\left(\frac{y_1^3-y_2^3}{y_1^2-y_2^2}\right)\sin\alpha=\tfrac{4}{3}\,\frac{x_1-x_2}{y_1+y_2}(y_1^2+y_1y_2+y_2^2)\sin\alpha.$$

C. *The Ellipse.*

§ 50. *Circumference of an Ellipse.*—The equation to the ellipse being $\frac{x^2}{a^2}+\frac{y^2}{b^2}=1$, where a and b are the semiaxes, we have

$$\frac{dy}{dx} = -\frac{b^2x}{a^2y}, \text{ and therefore (fig. 23)}$$

arc of quadrant AB $= \int_0^a \left\{ \frac{a^2 - e^2x^2}{a^2-x^2} \right\}^{\frac{1}{2}} dx$, where $e^2 = \frac{a^2-b^2}{a^2}$.

This integral may be shown to be equal to the series

$$\frac{\pi a}{2}\left(1 - \frac{e^2}{2^2} - \frac{1\,.\,3e^4}{2^2\,.\,4^2} - \frac{1\,.\,3^2\,.\,5e^6}{2^2\,.\,4^2\,.\,6^2} - \&c. \right),$$

a rapidly converging series when e is a small fraction.

By taking more and more terms of the above series we can approximate as nearly as we please to the circumference of an ellipse. For example, we have quadrant AB

$$= \frac{\pi a}{2}\left(1 - \frac{e^2}{4} \right) = \frac{\pi a}{2}\left(1 - \frac{e^2}{2} \right)^{\frac{1}{2}}$$

to a first approximation; hence whole circumference

$$= \pi \left\{ \frac{(2a)^2 + (2b)^2}{2} \right\}^{\frac{1}{2}} \text{ nearly.}$$

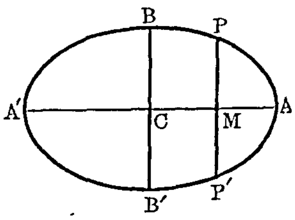

Fig. 23

§ 51. *Area of an Ellipse.*—We have at once

$$\text{area} = 4\int_0^a y dx 4 = \frac{b}{a}\int_0^a \sqrt{a^2 - x^2}dx.$$

But $\int_0^a \sqrt{a^2-x^2}dx$ is the area of the quadrant of a circle of radius a. Thus

$$\text{area of ellipse} = 4\frac{b}{a}\,\frac{\pi a^2}{4} \text{ (§ 44)}$$
$$= \pi ab.$$

The following proof is worth the reader's attention. By a well-known theorem in conic sections the orthogonal projection of a circle on a given plane is an ellipse. Now, if A denote the area of any plane figure, A′ the area of the projected figure, and θ the angle between the planes it can easily be shown, by dividing the two areas by planes indefinitely near to each other and perpendicular to the common section of the planes, that

$$A\cos\theta = A'.$$

In the case of the circle and ellipse $A = \pi a^2$ and $\cos\theta = \frac{b}{a}$;

hence area of ellipse $= \pi a^2 \times \frac{b}{a} = \pi ab$.

§ 52. *Area of an Ellipse in terms of a Pair of Conjugate Diameters.*—Let a' and b' denote the semiconjugate diameters, and α the angle between them, then by an elementary property of the ellipse

$$ab = a'b'\sin\alpha;$$

hence area of ellipse $= \pi a'b'\sin\alpha$.

D. *The Hyperbola.*

§ 53. *Area of a Segment of an Hyperbola.*—The equation of an hyperbola being $\frac{x^2}{a^2} - \frac{y^2}{b^2} = 1$, we have

$$y = \frac{b}{a}\sqrt{x^2-a^2}\text{; hence (fig. 24)}$$

$$\text{area of the segment PAP}' = 2\,\frac{b}{a}\int_a^{x_1}\sqrt{x^2-a^2}dx$$

$$= \frac{b}{a}x_1\sqrt{x_1^2-a^2} - ab\log_e\left(\frac{x_1+\sqrt{x_1^2-a^2}}{a}\right)$$

$$= x_1y_1 - ab\log_e\left(\frac{x_1}{a}+\frac{y_1}{b}\right).$$

§ 54. *Area of a Sector of an Hyperbola.*—The sector PAP′C is equal to triangle PCP′ − segment PAP′

$$= x_1y_1 - \left\{ x_1y_1 - ab\log_e\left(\frac{x_1}{a}+\frac{y_1}{b}\right)\right\}$$

$$= ab\log_e\left(\frac{x_1}{a}+\frac{y_1}{b}\right).$$

§ 55. *Area of a Zone of an Hyperbola.*—In fig. 24 the zone PP′Q′Q

$$= \text{segment QAQ}' - \text{segment PAP}'$$

$$= x_2y_2 - ab\log_e\left(\frac{x_2}{a}+\frac{y_2}{b}\right) - x_1y_1 + ab\log_e\left(\frac{x_1}{a}+\frac{y_1}{b}\right)$$

$$= x_2y_2 - x_1y_1 - ab\log_e\left(\frac{ay_2+bx_2}{ay_1+bx_1}\right), \text{ where}$$

x_1, y_1 and x_2, y_2 are the coordinates of P and Q respectively.

If the axes of coordinates be inclined at an angle α, we multiply the above results by $\sin\alpha$ to obtain the correct areas.

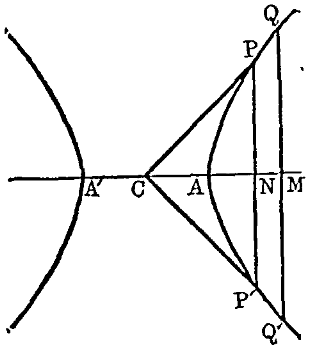

Fig. 24.

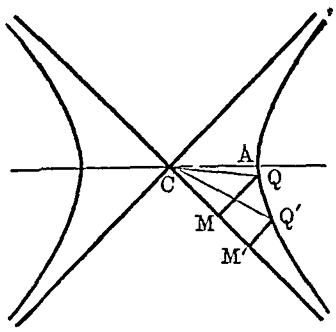

Fig. 25.

§ 56. *Area bounded by an Hyperbola and its Asymptotes.*—The equation of an hyperbola referred to its asymptotes is of the form

$$xy = c^2.$$

Let CM′ (fig. 25) $= x_1$, CM $= x_2$, Q′M′ $= y_1$, Q M $= y_2$, then, if α be the angle between the asymptotes,

$$\text{area of QMM}'\text{Q}' = \int_{x_2}^{x_1} y\sin\alpha\,dx$$

$$= c^2\sin\alpha\int_{x_2}^{x_1}\frac{dx}{x} = c^2\sin\alpha\log_e\left(\frac{x_1}{x_2}\right) = c^2\sin\alpha\log_e\left(\frac{y_2}{y_1}\right),$$

since $\qquad x_1 = \frac{c^2}{y_1}$ and $x_2 = \frac{c^2}{y_2}$.

Now $\qquad c^2 = \frac{a^2+b^2}{4}$ and $\sin\alpha = \frac{2ab}{a^2+b^2}$, and therefore

$$(\alpha) \qquad \text{area} = \tfrac{1}{2}ab\log_e\left(\frac{x_1}{x_2}\right) = \tfrac{1}{2}ab\log_e\left(\frac{y_2}{y_1}\right).$$

Again, let MM′ $= x_1 - x_2 = p$, then

$$c^2 = x_1y_1 = x_2y_2 = \frac{py_1y_2}{y_2-y_1}, \text{ therefore}$$

$$(\beta) \qquad \text{QMM}'\text{Q}' = \frac{py_1y_2}{y_2-y_1}\log_e\left(\frac{x_1}{x_2}\right)\sin\alpha = \frac{py_1y_2}{y_2-y_1}\log_e\left(\frac{y_2}{y_1}\right)\sin\alpha.$$

Again, since

$$\tfrac{1}{2}x_1y_1\sin\alpha = \tfrac{1}{2}c^2\sin\alpha = \tfrac{1}{2}x_2y_2\sin\alpha,$$

we have $\qquad$ triangle QCM = Q′CM′, and hence

the sector QCQ′ = QMM′Q′.

The corresponding results for a rectangular hyperbola are obtained by substituting in the above formulæ $\frac{1}{2}a^2$ for c^2 and 1 for $\sin\alpha$.

Section III.—Plane Irregular, Rectilineal, and Curvilineal Figures.

A. *Irregular Rectilineal Figures.*

§ 57. The area of any irregular polygon can be found by dividing it into triangles, trapeziums, &c., in the most convenient manner, and adding together all the areas. For example,

ABCDEF (fig. 26) = CKB + BKHA + AHF + FGE + EGID + DIC.

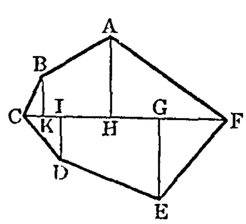

Fig. 26.

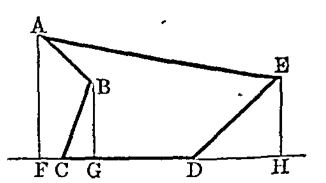

Fig. 27.

It may sometimes happen that some of the component figures have to be subtracted instead of added; for example,

ABCDE (fig. 27) = AFHE + BCG − AFGB − EDH.

§ 58. Again, the irregular rectilineal figure P_1P_2 . . . P_8P_9 (fig. 28) can be broken up into a series of triangles and trapeziums as shown in the figure, and hence its area can be found.

§ 59. A figure made up of straight lines may be measured by cutting it up into triangles by lines drawn from some one vertex to the others. For example (fig. 29),

ABCDEF = ABC + ACD + ADE + AEF.

If the polygon be concave some of the triangles will have to be subtracted.

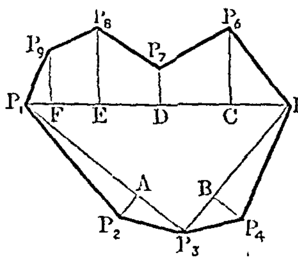

Fig. 28.

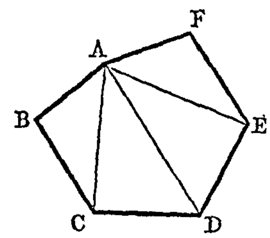

Fig. 29.

§ 60. *Area of a Polygon in terms of the Coordinates of its Angular Points.*—Let the coordinates of P, Q, R (fig. 30) be (x_1, y_1), (x_2, y_2), and (x_3, y_3) respectively, and let the axes be inclined at an angle α. Draw PL, QM, and RN parallel to OY, then

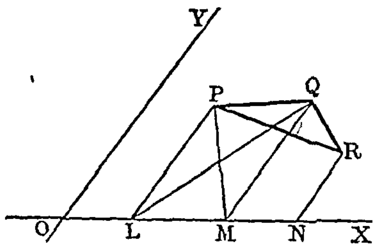

Fig. 30.

$$LM = OM - OL = x_2 - x_1,$$
$$MN = ON - OM = x_3 - x_2,$$
and
$$NL = ON - OL = x_3 - x_1.$$

Now $\quad PQR = PLMQ + QMNR - PLNR.$

But $\quad PLMQ = PLM + QMP = PLM + QLM$
$$= \tfrac{1}{2}PL \cdot LM \sin\alpha + \tfrac{1}{2}QM \cdot LM \sin(180° - \alpha) \ (\S\ 9,\ \beta)$$
$$= \tfrac{1}{2}(x_2 - x_1)(y_1 + y_2)\sin\alpha.$$

Similarly $\quad QMNR = \tfrac{1}{2}(x_3 - x_2)(y_2 + y_3)\sin\alpha,$

and $\quad PLNR = \tfrac{1}{2}(x_3 - x_1)(y_3 + y_1)\sin\alpha$; hence

$$\text{area of } PQR = \tfrac{1}{2}\sin\alpha\{y_1(x_2 - x_3) + y_2(x_3 - x_1) + y_3(x_1 - x_2)\};$$

or in the notation of determinants

$$= \tfrac{1}{2}\sin\alpha \begin{vmatrix} 1 & 1 & 1 \\ x_1 & x_2 & x_3 \\ y_1 & y_2 & y_3 \end{vmatrix}.$$

When the axes are rectangular $\sin\alpha = \sin 90° = 1$, and the formula for the area becomes

$$\tfrac{1}{2}\{y_1(x_2 - x_3) + y_2(x_3 - x_1) + y_3(x_1 - x_2)\}$$
$$= \tfrac{1}{2}\begin{vmatrix} 1 & 1 & 1 \\ x_1 & x_2 & x_3 \\ y_1 & y_2 & y_3 \end{vmatrix}.$$

§ 61. The area of any rectilineal figure of n sides can be found by taking any point within the figure and joining it to the n vertices of the figure, thus dividing it into n triangles the area of each of which can be obtained as in the preceding case.

We may, however, find the area of the figure directly.

For example, in fig. 31

$$PQRST = PP'T'T + TT'S'S + SS'R'R - RR'Q'Q - QQ'P'P,$$

and in fig. 32

$$PQRSTU = PP'U'U + RR'Q'Q + TT'S'S - PP'Q'Q - RR'S'S - TT'U'U.$$

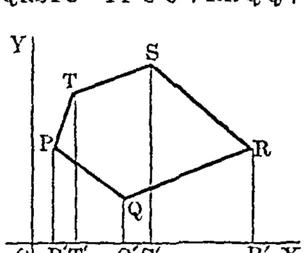

Fig. 31.

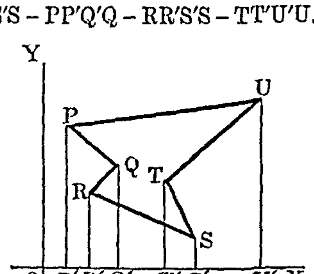

Fig. 32.

B. *Irregular Curvilineal Figures.*

§ 62. *Length of any Curve.*—If we divide the given arc into an even number of intervals and regard these as approximately circular, we can find an approximation to the length of the arc by means of Huygens's formula, § 32. For example, if we divide ABC (fig. 33) into four parts in D, B, and E, and draw the chords AD, AB, DB, BE, BC, and EC, then

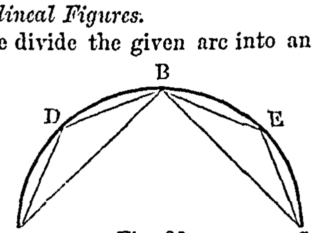

Fig. 33.

$$\text{arc } AC = AD + DB + BE + EC + \tfrac{1}{3}(AD + DB + BE + EC - AB - BC)$$

approximately.

For other methods of approximation, see Rankine's *Rules and Tables.*

§ 63. *Area of an Irregular Curvilineal Figure.*—For rough approximations the following, called the trapezoidal method, may be used:—

Divide A_1A_n (fig. 34) into n equal parts, and through the points

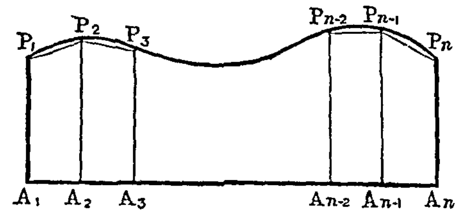

Fig. 34.

of division draw the ordinates, called by surveyors offsets, A_1P_1, A_2P_2, &c.

Let $\quad A_1P_1 = s_1,\ A_2P_2 = s_2$, &c., $A_nP_n = s_n$, and
$\quad A_1A_2 = A_2A_3 = \ .\ .\ .\ = A_{n-1}A_n = a.$

Join P_1P_2, P_2P_3, &c., then the area of the polygon $A_1A_nP_nP_2P_1$
$$= A_1A_2P_2P_1 + A_2A_3P_3P_2 + \ .\ .\ .\ .\ + A_{n-1}A_nP_nP_{n-1}$$
$$= \tfrac{1}{2}a(s_1 + s_2) + \tfrac{1}{2}a(s_2 + s_3) + \ .\ .\ .\ .\ + \tfrac{1}{2}a(s_{n-1} + s_n)\ (\S\ 13,\ a)$$
$$= a\{\tfrac{1}{2}(s_1 + s_n) + s_2 + s_3 + \ .\ .\ .\ . + s_{n-1}\}.$$

If we take n sufficiently great the difference between the area of the polygon and the curvilineal figure can be made as small as we please, in other words, the smaller we make a the more accurately will the above formula represent the area of the curvilineal figure.

The curve may either be wholly convex or wholly concave to the line A_1A_n, or partly convex and partly concave.

§ 64. *Simpson's Rule.*—Let A_1A_n (fig. 34) be divided into an *even* number of equal parts, and as before through the points of division draw the ordinates A_1P_1, A_2P_2, &c.

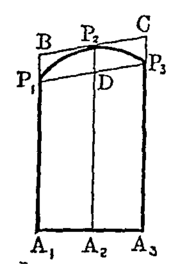

Fig. 35.

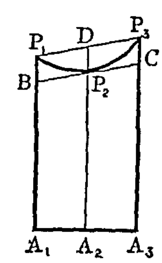

Fig. 36.

Let $A_1A_3P_3P_1$ (figs. 35, 36) be a part of the figure thus divided; join P_1P_3, and through P_2 draw BC parallel to P_1P_3 to meet A_1P_1 in B and A_3P_3 in C. Conceive a parabola to be drawn through $P_1P_2P_3$ having its axis parallel to the ordinates, then

$$A_1P_1P_2P_3A_3 = \text{trapezium } A_1P_1DP_3A_3 \pm \text{parabolic segment } P_1P_2P_3$$
$$= a(s_1 + s_3) \pm \tfrac{4}{3}a\{s_2 \sim \tfrac{1}{2}(s_1 + s_3)\} = \tfrac{1}{3}a(s_1 + 4s_2 + s_3).$$

Now when the points P_1, P_2, P_3 are near each other the parabolic curve will coincide very nearly with the given curve; hence

$$A_1P_1P_2P_3A_3 = \tfrac{1}{3}a(s_1 + 4s_2 + s_3) \text{ very nearly.}$$

Similarly $\quad A_3P_3P_5A_5 = \tfrac{1}{3}a(s_3 + 4s_4 + s_5)$, &c.;

hence whole area of figure

$$= \tfrac{1}{3}a\{s_1 + s_n + 2(s_3 + s_5 + \ .\ .\ .\ . + s_{n-2}) + 4(s_2 + s_4 + \ .\ .\ .\ . + s_{n-1})\};$$

whence the rule:—add together the two extreme ordinates, twice the sum of the intermediate odd ordinates, and four times the sum of the even ones, and multiply this result by one-third of the common distance between the ordinates; the result is the area,—*accurately* if the curved boundary be the arc of a parabola, in other cases approximately.

The curve may either be wholly convex or wholly concave to the line A_1A_n, or partly convex and partly concave, provided in the latter case the points of contrary flexure occur only at the odd ordinates, for otherwise the intermediate arcs could not be even approximately parabolic. When points of contrary flexure occur ordinates may be drawn at these points, and the intermediate arcs being found separately may be added to obtain the whole area.

§ 65. In the two preceding sections we investigated two formulæ for approximating to the areas of curvilinear figures. We now proceed to consider the subject more generally.

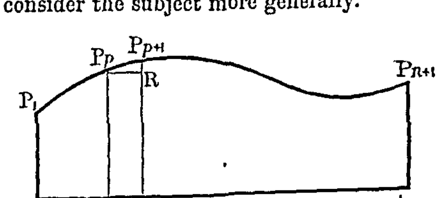

Fig. 37.

Let the equation to the curve $P_1P_pP_{n+1}$ (fig. 37) agree with the

equation $y = \mathrm{A} + \mathrm{B}x + \mathrm{C}x^2 + \ldots + \mathrm{K}x^n$ for $n+1$ points between P_1 and P_{n+1}, then the area of the curvilinear figure bounded by the straight lines $\mathrm{A}_1\mathrm{P}_1$, $\mathrm{A}_1\mathrm{A}_{n+1}$, and $\mathrm{A}_{n+1}\mathrm{P}_{n+1}$ and the curve $\mathrm{P}_1\mathrm{P}_{n+1}$ will agree very nearly with the curvilinear figure bounded by the same straight lines and the curve whose equation is $y = \mathrm{A} + \mathrm{B}x + \mathrm{C}x^2 + \ldots + \mathrm{K}x^n$, and the greater the number of common points the closer will be the agreement.

Let $\mathrm{A}_1\mathrm{A}_{n+1}$ be divided into n equal parts, each equal to h, then $\mathrm{A}_1\mathrm{A}_{n+1} = nh$. Now

when $x=0$, $y = y_1 = \mathrm{A}$;

when $x=h$, $y = y_2 = \mathrm{A} + \mathrm{B}h + \mathrm{C}h^2 + \ldots + \mathrm{K}h^n$;

when $x=2h$, $y = y_3 = \mathrm{A} + \mathrm{B}(2h) + \mathrm{C}(2h)^2 + \ldots + \mathrm{K}(2h)^n$;

. . . .

when $x=ph$, $y = y_{p+1} = \mathrm{A} + \mathrm{B}(ph) + \mathrm{C}(ph)^2 + \ldots + \mathrm{K}(ph)^n$;

. . . .

when $x=nh$, $y = y_{n+1} = \mathrm{A} + \mathrm{B}(nh) + \mathrm{C}(nh)^2 + \ldots + \mathrm{K}(nh)^n$.

From these $n+1$ equations the $n+1$ quantities A, B, ... K can be determined as functions of $y_1, y_2, \ldots\ldots y_{n+1}$, and h.

Next let $\mathrm{A}_1\mathrm{A}_{n+1}$ be divided into m equal parts each equal to h. Thus $mh = nh$ and hence $h = \frac{nh}{m}$

Now the area of the rectangle $\mathrm{A}_p\mathrm{A}_{p+1}\mathrm{P}_p\mathrm{R} = \mathrm{A}_p\mathrm{A}_{p+1} \times \mathrm{A}_p\mathrm{P}_p$.

But $\mathrm{A}_p\mathrm{P}_p = y_p = \mathrm{A} + \mathrm{B}(ph) + \mathrm{C}(ph)^2 + \ldots + \mathrm{K}(ph)^n$

$$= \mathrm{A} + \mathrm{B}\frac{p.nh}{m} + \mathrm{C}\left(\frac{p.nh}{m}\right)^2 + \ldots + \mathrm{K}\left(\frac{p.nh}{m}\right)^n,$$

since $$h = \frac{nh}{m};$$

and $$\mathrm{A}_p\mathrm{A}_{p+1} = h = \frac{nh}{m};$$

therefore area of $\mathrm{A}_p\mathrm{R}$

$$nh\left\{\frac{\mathrm{A}}{m} + \mathrm{B}nh\frac{p}{m^2} + \mathrm{C}n^2h^2\frac{p^2}{m^3} + \ldots + \mathrm{K}n^nh^n\frac{p^n}{m^{n+1}}\right\}.$$

Hence the area of the whole figure

$$= \mathrm{L}_{m=\infty}\sum_{p=1}^{p=m} nh\left\{\frac{\mathrm{A}}{m} + \mathrm{B}nh\frac{p}{m^2} + \mathrm{C}n^2h^2\frac{p^2}{m^3} + \ldots + \mathrm{K}n^nh^n\frac{p^n}{m^{n+1}}\right\}$$

$$= \mathrm{L}_{m=\infty} nh\left\{\mathrm{A}\frac{\mathrm{S}_0}{m} + \mathrm{B}nh\frac{\mathrm{S}_1}{m^2} + \mathrm{C}n^2h^2\frac{\mathrm{S}_2}{m^3} + \ldots + \mathrm{K}n^nh^n\frac{\mathrm{S}_n}{m^{n+1}}\right\},$$

where $$\mathrm{S}_n = 1^n + 2^n + 3^n + \ldots + m^n.$$

Now if we take the limit of each of the terms

$$\frac{\mathrm{S}_0}{m}, \frac{\mathrm{S}_1}{m^2}, \frac{\mathrm{S}_2}{m^3}, \ldots \frac{\mathrm{S}_n}{m^{n+1}},$$

we obtain area of curvilinear figure

$$= nh\left\{\mathrm{A} + \frac{\mathrm{B}}{2}nh + \frac{\mathrm{C}}{3}n^2h^2 + \ldots + \frac{\mathrm{K}}{n+1}n^nh^n\right\}.$$

From this general result we can deduce "Simpson's Rule" and also another rule called "Weddle's Rule."

Thus let $n=2$; that is, assume that the curve under consideration has three points in common with the curve whose equation is $y = \mathrm{A} + \mathrm{B}x + \mathrm{C}x^2$, *i.e.*, with a parabola, then

$$y_1 = \mathrm{A},$$
$$y_2 = \mathrm{A} + \mathrm{B}h + \mathrm{C}h^2,$$
$$y_3 = \mathrm{A} + 2\mathrm{B}h + 4\mathrm{C}h^2.$$

Now the area is approximately

$$= 2h\{\mathrm{A} + \tfrac{1}{2}\mathrm{B}2h + \tfrac{1}{3}\mathrm{C}\,2^2h^2\}$$
$$= \tfrac{1}{3}h\{6\mathrm{A} + 6\mathrm{B}h + 8\mathrm{C}h^2\}$$
$$= \tfrac{1}{3}h\{y_1 + 4y_2 + y_3\}, \text{ Simpson's Rule.}$$

If we now put $n=6$, we have area of curvilinear figure

$$= 6h\{\mathrm{A} + \tfrac{1}{2}\mathrm{B}6h + \tfrac{1}{3}\mathrm{C}6^2h^2 + \tfrac{1}{4}\mathrm{D}6^3h^3 + \tfrac{1}{5}\mathrm{E}6^4h^4 + \tfrac{1}{6}\mathrm{F}6^5h^5 + \tfrac{1}{7}\mathrm{G}6^6h^6\}.$$

Now $$y_1 = \mathrm{A},$$
$$y_2 = \mathrm{A} + \mathrm{B}h + \mathrm{C}h^2 + \ldots + \mathrm{G}h^6,$$
. . . .
$$y_7 = \mathrm{A} + \mathrm{B}(6h) + \mathrm{C}(6h)^2 + \ldots\ \mathrm{G}(6h)^6.$$

From this system of equations we can determine A, B, C, . . . G, and substituting the values so obtained in the above expression we obtain the following remarkable formula for the approximate area:

$$\text{area} = \tfrac{3}{10}h\{(y_1 + y_3 + y_5 + y_7) + y_4 + 5(y_2 + y_4 + y_6)\}.$$

This formula, called Weddle's Rule, gives the closest approximation to the curvilinear area that can be obtained by any simple rule.

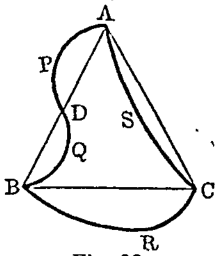

Fig. 38.

We are now in a position to find the approximate area of any irregular plane figure. For the given figure can be divided into plane rectilinear and curvilinear figures, the areas of which can be separately determined by the rules already given. For example, APQRS (fig. 38)

$$= \mathrm{ABC} + \mathrm{APD} + \mathrm{BRC} - \mathrm{DQB} - \mathrm{ASC}.$$

PART II. SOLIDS.

Section I. Solids contained by Planes.

A. *Prisms, Pyramids, and Prismatoids.*

§ 66. *Volume of a Right Prism.*—First let the prism be a rectangular parallelepiped (fig. 39), and let the side AB contain a units of length, BC b units of length, and CD c units of length. If we divide AB into a equal parts, BC into b equal parts, and CD into c equal parts, and if, through the points of division we draw planes parallel to the sides of the parallelepiped, these planes will divide it into a series of parallelepipeds, whose edges are each equal to the unit of length. Each horizontal layer contains ab of these cubes, and since there are c layers the whole number of cubes will be abc. But each of these is the unit of volume, and therefore

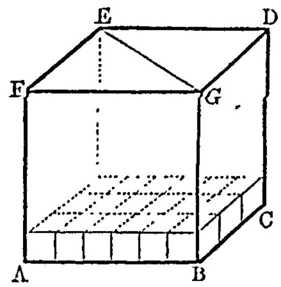

Fig. 39.

volume of ABCD $= abc = ab \times c =$ area of base ABC $\times$ altitude c.

In the above demonstration we have assumed the edges to be commensurable, but from § 2 it follows that the proof will hold also when the edges are incommensurable. If the parallelepiped be cut by a plane BGE it will be divided into two equal triangular right prisms, and hence

volume of right triangular prism $= \tfrac{1}{2}ab \times c =$ area of its base $\times$ altitude.

Since every prism can be divided into triangular prisms as in fig. 40, we have at once

volume of right prism A′ABCDE $=$ A′ABC $+$ A′ACD $+$ A′ADE
$= \mathrm{ABC} \times \mathrm{BB'} + \mathrm{ACD} \times \mathrm{CC'} + \mathrm{ADE} \times \mathrm{DD'}$
$= (\mathrm{ABC} + \mathrm{ACD} + \mathrm{ADE}) \times$ altitude
(since $\mathrm{BB'} = \mathrm{CC'} = \mathrm{DD'} =$ altitude)
$=$ area of base ABCDE $\times$ altitude.

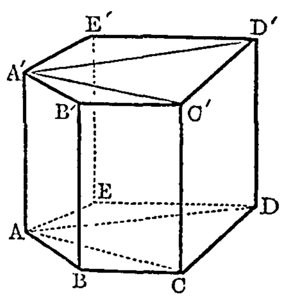

Fig. 40.

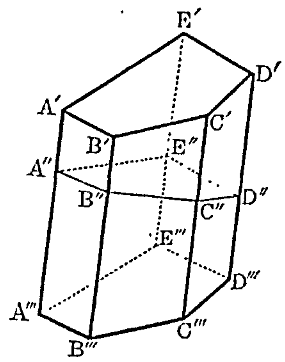

Fig. 41.

§ 67. *Volume of an Oblique Prism.*—Draw the right section A″B″C″D″E″ (fig. 41), and let A′ denote its area and A the area of the base A′B′C′D′E′. Let l denote the length of the prism, h its altitude, and α the angle between the planes A′B′C′D′E′ and A″B″C″D″E″.

Conceive the part above the right section placed at the other extremity of the prism. Then we have a right prism, whose volume $= \mathrm{A'} \times l$ (§ 66); but $\mathrm{A'} = \mathrm{A}\cos\alpha$, since A′ is the projection of A (§ 51),

and $$l = \frac{h}{\cos\alpha}; \text{ hence}$$

$$\text{volume} = \mathrm{A'} \times l = \mathrm{A}\cos\alpha \times \frac{h}{\cos\alpha} = \mathrm{A} \times h;$$

or the volume of any prism is equal to the area of its base multiplied by its altitude.

§ 68. *Surface of a Prism.*—Since the lines $A''B''$, $B''C''$, &c. (fig. 41), which make up the perimeter of the right section are all in one plane perpendicular to the parallel edges $A'A'''$, $B'B'''$, &c., they are perpendicular to these edges and are therefore the altitudes of the parallelograms $A'B'B'''A'''$, $B'C'C'''B'''$, &c., respectively. The lateral surface of the prism is equal to the sum of these parallelograms, and therefore

$$=A'A'''\times A''B''+B'B'''\times B''C''+\ \ldots\ldots$$
$$=A'A'''(A''B''+B''C''+\ \ldots\ldots),$$

since $\quad A'A'''=B'B'''=\text{\&c.};$

or the lateral surface of any prism is equal to the perimeter of its right section multiplied by the length of the prism.

If the prism be *right*, that is, if the faces be perpendicular to the base, then its lateral surface is equal to the perimeter of its base multiplied by its length.

The whole surface of any prism is obtained by adding to the lateral surface the areas of its bases.

§ 69. If the prism be *regular*, that is, if the bases be regular polygons, then

area of base $=a^2\times\frac{n}{4}\cot\frac{180°}{n}$ (§ 18, γ), where n is the number of sides each of length a, and therefore

$$\text{volume}=a^2\times\frac{n}{4}\cot\frac{180°}{n}\times h,$$

where h is the altitude of the prism.

Again, if the prism be right and regular, then

$$\text{its lateral surface}=nah+2a^2\times\frac{n}{4}\cot\frac{180°}{n}.$$

§ 70. *Volume of a Pyramid.*—Let VABC (fig. 42) be for simplicity a triangular pyramid. Divide VA into n equal portions, and through the points of section draw planes parallel to the base ABC, and through BC and through the intersections of these planes with VBC draw planes parallel to VA. Let h denote the altitude of the pyramid, then the distance of the base of the r^{th} prism from the vertex V

$$=r\times\frac{h}{n},$$

and, if A denote the area of ABC, we have

$$\frac{\text{base of } r^{\text{th}} \text{ prism}}{\text{A}}=\frac{r^2h^2}{n^2}\times\frac{1}{h^2}=\frac{r^2}{n^2},$$

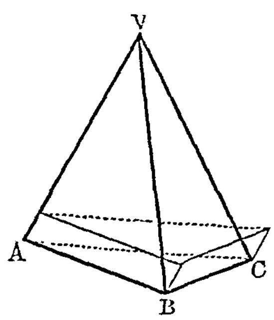

Fig. 42.

since, by a well-known theorem in solid geometry, the areas of sections of a pyramid made by planes parallel to the base are proportional to the squares of their altitudes.

Thus we have

$$\text{base of } r^{\text{th}} \text{ prism}=\frac{r^2}{n^2}\text{A, and therefore}$$

$$\text{its volume}=\frac{r^2}{n^2}\text{A}\times\frac{h}{n}\ (\S\ 67)$$
$$=\frac{h\text{A}}{n^3}\times r^2.$$

Therefore volume of whole pyramid

$$=h\text{A}\mathop{\mathrm{L}}_{n=\infty}\frac{1^2+2^2+\ \ldots\ +r^2+\ \ldots\ +n^2}{n^3}$$
$$=h\text{A}\mathop{\mathrm{L}}_{n=\infty}\frac{n(n+1)(2n+1)}{6n^3}=h\text{A}\times\tfrac{1}{3};$$

or the volume of any pyramid is equal to one-third of the area of its base multiplied by its height.

From this we see that pyramids on equal bases are to one another as their altitudes.

If the pyramid be *regular*, that is, if its base be a regular polygon the perpendicular through whose centre passes through the vertex,

$$\text{its volume}=\tfrac{1}{3}\times a^2\times\frac{n}{4}\cot\frac{180°}{n}\times h.$$

§ 71. *Surface of a Regular Pyramid.*—The lateral surface of the regular pyramid VABCDEF (fig. 43) is equal to the sum of the areas of the n congruent triangles which make up the lateral surface of the pyramid.

Now area of triangle $\text{VAB}=\frac{1}{2}\text{AB}\times\text{VG}$; hence whole lateral surface $=\frac{1}{2}n\text{AB}\cdot\text{VG}=\frac{1}{2}nal$, where l is the slant height and a the length of the side of the base.

Again, if $\text{VO}=h=$ altitude of pyramid, we have

$$l=\text{VG}=\sqrt{\text{VO}^2+\text{OG}^2}=\sqrt{h^2+\frac{a^2}{4}\cot^2\frac{180°}{n}},$$

therefore whole surface = base + lateral surface

$$=a^2\times\frac{n}{4}\cot\frac{180°}{n}+\tfrac{1}{2}na\sqrt{h^2+\frac{a^2}{4}\cot^2\frac{180°}{n}}$$
$$=\frac{na}{2}\left(\frac{a}{2}\cot\frac{180°}{n}+\sqrt{h^2+\frac{a^2}{4}\cot^2\frac{180°}{n}}\right).$$

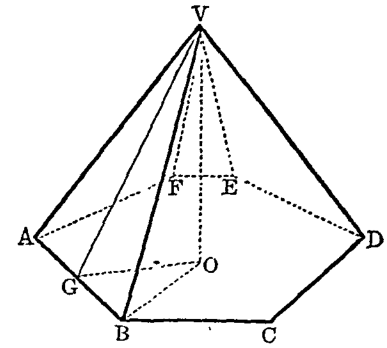

Fig. 43.

§ 72. *The Prismatoid.*—If we have a polyhedron whose bases are two polygons in parallel planes, the number of sides in each being the same or different, and if we so join the vertices of these bases that each line in order forms a triangle with the preceding line and one side of either base, the figure so formed is called a "prismatoid," and holds in stereometry a position similar to that of the trapezium in planimetry. To make the investigation of the volume of the prismatoid as simple as possible, we take the case where the lower base is a polygon of four and the upper one of three sides.

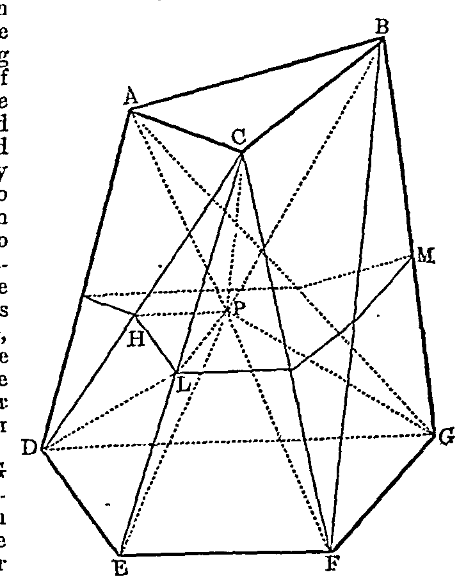

Fig. 44.

Let ABCDEFG (fig. 44) be the prismatoid, of which ABC or A_1 is the upper and DEFG or A_3 the lower base, and let HLM be the section equidistant from the bases. Take any point P in this section and join it to the corners of the prismatoid. We thus divide the polyhedron into two pyramids PABC and PDEFG, and a series of polyhedra of which CPDE may be taken as a specimen.

Let h be the altitude of the prismatoid, then $\frac{1}{2}h$ is the altitude of each of the pyramids PABC, PDEFG, and hence

$$\text{volume of PABC }=\tfrac{1}{6}h\text{A}_1,\text{ and}$$
$$\text{volume of PDEFG}=\tfrac{1}{6}h\text{A}_3.$$

Again join PH, PL, and LD, then

volume of CPDE = 2 volume of CPDL,
since DE = 2HL,
and volume of CPDL = 2 volume of CPHL,
hence volume of CPDE = 4 volume of CPHL.

Now volume of $\text{CPHL}=\frac{1}{6}h\times$ area of HLP, and therefore volume of $\text{CPDE}=\frac{4}{6}h\times$ area of HLP.

Similarly the volume of every such polyhedron is $\frac{4}{6}h\times$ the area of its own portion of the middle section. Hence if A_2 denote the area of the middle section we have

$$\text{volume of prismatoid}=\tfrac{1}{6}h\text{A}_1+\tfrac{1}{6}h\text{A}_3+\tfrac{4}{6}h\text{A}_2$$
$$=\tfrac{1}{6}h(\text{A}_1+4\text{A}_2+\text{A}_3).$$

§ 73. *Volume of the Frustum of a Pyramid.*—Let $A'A'''B'B'''C'C'''$ (fig. 45) be a frustum of the pyramid $VA'B'C'$, and let A_1 and A_3 denote the areas of the ends $A'B'C'$, $A'''B'''C'''$ respectively. Let $\text{VP}=x=$ altitude of pyramid $VA'''B'''C'''$, and let $\text{PQ}=h=$ altitude of frustum.

Now $\quad\left(\dfrac{x}{x+h}\right)^2=\dfrac{\text{A}_3}{\text{A}_1},\ \text{ whence } x=\dfrac{h\sqrt{\text{A}_3}}{\sqrt{\text{A}_1}-\sqrt{\text{A}_3}}.$

Again frustum $=\text{VA}'\text{B}'\text{C}'-\text{VA}'''\text{B}'''\text{C}'''$

$$=\tfrac{1}{3}\left\{\text{A}_1(x+h)-\text{A}_3x\right\}$$

$$=\tfrac{1}{3}\left\{\text{A}_1\left(\frac{h\sqrt{\text{A}_1}}{\sqrt{\text{A}_1}-\sqrt{\text{A}_3}}\right)-\text{A}_3\left(\frac{h\sqrt{\text{A}_3}}{\sqrt{\text{A}_1}-\sqrt{\text{A}_3}}\right)\right\}$$

$$=\tfrac{1}{3}h(\text{A}_1+\sqrt{\text{A}_1\text{A}_3}+\text{A}_3)\,;$$

a formula which applies to the frusta of all pyramids regular and irregular.

The above result may be otherwise expressed. For, let $\text{A}'\text{B}'=a_1$ and $\text{A}'''\text{B}'''=a_3$, then, if $\text{A}''\text{B}''\text{C}''$ be a section equidistant from the ends of the frustum, $\text{A}''\text{B}''=a_2=\tfrac{1}{2}(a_1+a_3)$.

Now $\text{A}_1=pa_1^2$ and $\text{A}_3=pa_3^2$ (see § 70);
hence $\text{A}_2=$area of $\text{A}''\text{B}''\text{C}''=pa_2^2=p\left(\frac{a_1+a_3}{2}\right)^2$, which gives

$$4\text{A}_2=pa_1^2+2pa_1a_3+pa_3^2=\text{A}_1+2\sqrt{\text{A}_1\text{A}_3}+\text{A}_3\,;$$

therefore volume of frustum

$$=\tfrac{1}{6}h(2\text{A}_1+2\sqrt{\text{A}_1\text{A}_3}+2\text{A}_3)=\tfrac{1}{6}h(\text{A}_1+4\text{A}_2+\text{A}_3)\,;$$

or the volume of the frustum of a pyramid is obtained by adding the areas of the ends to four times the area of the middle section, and multiplying the sum by one-sixth of the altitude.

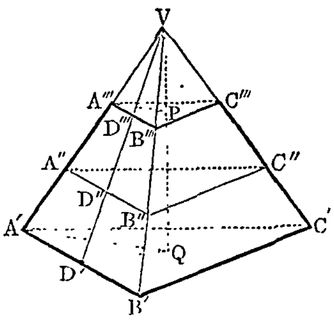

Fig. 45.

The above result can be obtained at once from § 72, since $\text{A}'\text{B}'\text{C}'\text{A}'''\text{B}'''\text{C}'''$ is a prismatoid with similar bases.

§ 74. *Surface of the Frustum of a Regular Pyramid.*—In fig. 45 let the perimeter of $\text{A}_1=p_1$, that of $\text{A}_2=p_2$, and that of $\text{A}_3=p_3$, and let $\text{VD}'=l_1$, $\text{VD}'''=l_3$, and therefore $\text{D}'\text{D}'''=\text{VD}'-\text{VD}'''=l_1-l_3=l$. The lateral surface of the frustum is equal to the difference between the lateral surfaces of the pyramids $\text{VA}'\text{B}'\text{C}'$ and $\text{VA}'''\text{B}'''\text{C}'''$,

$$=\tfrac{1}{2}p_1l_1-\tfrac{1}{2}p_3l_3\,.$$

But, since $\frac{l_1}{l_3}=\frac{a_1}{a_3}=\frac{na_1}{na_3}=\frac{p_1}{p_3}$, we have $l_1=\frac{p_1l}{p_1-p_3}$ and $l_3=\frac{p_3l}{p_1-p_3}$, therefore lateral surface of frustum

$$=\tfrac{1}{2}l\left(\frac{p_1^2-p_3^2}{p_1-p_3}\right)=l\left(\frac{p_1+p_3}{2}\right)=lp_2\,;$$

or the lateral surface of the frustum of a regular pyramid is equal to the product of the slant height and the perimeter of the section equidistant from the ends.

Otherwise.—The top and base being regular polygons, the inclined faces are congruent trapeziums. Let l be the height of each trapezium, and let there be n of them, then

$$\text{area of each face}=\frac{l}{2}\left(\frac{p_1}{n}+\frac{p_3}{n}\right),$$

and therefore the area of lateral surface $=\frac{l}{2}(p_1+p_3)=lp_2$.

§ 75. If h the altitude of the frustum be given, we deduce the slant height and then proceed as before. Thus let $\text{VP}=h_3$, $\text{VQ}=h_1$, and using the same notation as in §§ 72, 73, and 74 we have

$$\frac{h_1}{h_1-h_3}=\frac{a_1}{a_1-a_3}\,,\text{ which gives }h_1=\frac{a_1(h_1-h_3)}{a_1-a_3}=\frac{a_1h}{a_1-a_3}\,.$$

Again $\quad l_1^2=h_1^2+\tfrac{1}{4}a_1^2\cot^2\frac{180^\circ}{n}$, and $l=\left(\frac{a_1-a_3}{a_1}\right)l_1$;

whence l is known since l_1 is known in terms of h.

When the pyramid is irregular the lateral planes are non-congruent trapeziums, the areas of which can be found separately by § 12, and hence the whole surface.

§ 76. *Volume of the Frustum of a Triangular Prism.*—Let A denote the area of ABC (fig. 46), and let h_1, h_2, h_3 be the altitudes of A′, B′, C′ respectively with reference to the plane ABC. Divide the frustum into three pyramids B′A′AC, B′ABC, and B′A′CC′ by the planes B′AC and B′A′C. These three pyramids are respectively equal to BA′AC, B′ABC, and ABCC′;
hence volume of frustum $=\tfrac{1}{3}h_1\text{A}+\tfrac{1}{3}h_2\text{A}+\tfrac{1}{3}h_3\text{A}$
$=\tfrac{1}{3}\text{A}(h_1+h_2+h_3)$.

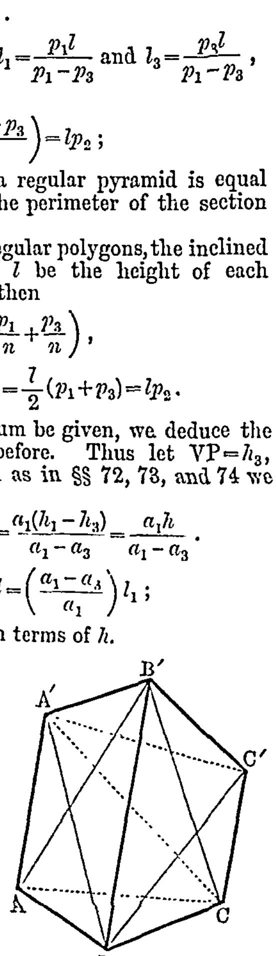

Fig. 46.

§ 77. If the prism be right or oblique, the volume of a frustum is equal to one-third of the area of its right section multiplied by the sum of the parallel edges. For divide the frustum AA′B′C′ (fig. 47) into two frusta by a plane A″B″C″ of area A at right angles to the edges, then

$$\text{AA}'\text{B}'\text{C}'=\text{AA}''\text{B}''\text{C}''+\text{A}''\text{A}'\text{B}'\text{C}'$$

$$=\tfrac{1}{3}\text{A}(\text{AA}''+\text{BB}''+\text{CC}'')+\tfrac{1}{3}\text{A}(\text{A}'\text{A}''+\text{B}'\text{B}''+\text{C}'\text{C}'')$$

$$=\tfrac{1}{3}\text{A}(\text{AA}''+\text{BB}''+\text{CC}''+\text{A}'\text{A}''+\text{B}'\text{B}''+\text{C}'\text{C}'')$$

$$=\tfrac{1}{3}\text{A}(\text{AA}'+\text{BB}'+\text{CC}')\,.$$

Again, since every prism can be divided into triangular prisms, we can find by repeated applications of the above proposition the volume of the frustum of any prism whatever. For example, if

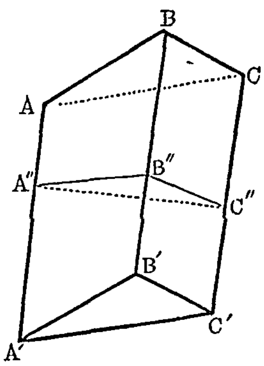

Fig. 47.

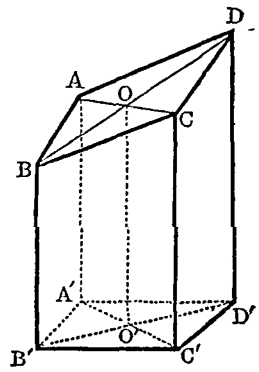

Fig. 48.

the base of the frustum of a right prism AA′B′C′D′ (fig. 48) be a rectangle 12 feet by 6 feet, and the parallel edges in order 6, 4, 10, and 12 feet, then

$$\text{A}=\text{area of base}=12\times 6=72\text{ square feet.}$$

$$\text{Frustum}=\text{ABCA}'\text{B}'\text{C}'+\text{ADCA}'\text{D}'\text{C}'$$

$$=\tfrac{1}{3}\times\tfrac{1}{2}\text{A}(\text{AA}'+\text{BB}'+\text{CC}')+\tfrac{1}{3}\times\tfrac{1}{2}\text{A}(\text{AA}'+\text{CC}'+\text{DD}')$$

$$=\tfrac{1}{6}\text{A}(2\text{AA}'+2\text{CC}'+\text{BB}'+\text{DD}')=576.$$

§ 78. *Volume of a Wedge.*—The wedge (fig. 49) being merely the frustum of a triangular prism, we have at once

$$\text{volume}=\tfrac{1}{3}\text{A}(\text{FE}+\text{AD}+\text{BC})\,,$$

where A is the area of its right section; otherwise, the wedge may be considered a prismatoid whose upper base is a straight line, and hence its volume $=\tfrac{1}{6}h(4\text{A}_2+\text{A}_3)$, since $\text{A}_1=0$.

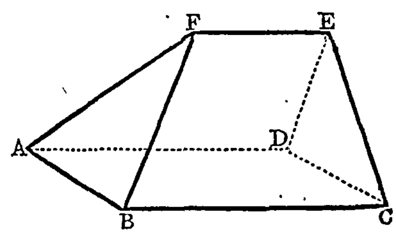

Fig. 49.

B. *Regular Polyhedra.*

§ 79. The regular polyhedra are five in number, namely, the *tetrahedron, cube, octahedron, dodecahedron,* and *icosahedron,* whose solid angles are formed respectively by three equilateral triangles, three squares, four equilateral triangles, three pentagons, and five equilateral triangles.

Since a regular polyhedron admits of having a sphere inscribed within it and described about it, it can easily be shown that the volume of the polyhedron

$$=a^3\times\frac{nl}{24}\times\frac{\cos\frac{\pi}{m}\cot^2\frac{\pi}{n}}{\left\{-\cos\left(\frac{\pi}{m}+\frac{\pi}{n}\right)\cos\left(\frac{\pi}{m}-\frac{\pi}{n}\right)\right\}^{\frac{1}{2}}}\,;$$

and from § 18, γ, it follows that the surface of the polyhedron

$$=a^2\times\frac{ln}{4}\cot\frac{\pi}{n}\,,$$

where $\quad l=$the number of faces,
$m=$the number of faces in each solid angle,
$n=$the number of edges in each face,
and $\quad a=$the length of each side.

The following table contains the surfaces and volumes for the five regular polyhedra whose edge is 1.

Polyhedron.	Surface.	Volume.
Tetrahedron	1·7320508	0·1178511
Cube	6·0000000	1·0000000
Octahedron	3·4641016	0·4714045
Dodecahedron	20·6457788	7·6631189
Icosahedron	8·6602540	2·1816950

The surface and volume of a regular polyhedron whose edge is a is obtained by multiplying the surface and volume of a similar polyhedron whose edge is 1 by a^2 and a^3 respectively.

Section II. Solids contained by Surfaces which are not all Planes.

A. *The Cylinder.*

§ 80. *Volume of a Cylinder* (fig. 50).—Inscribe in the cylinder a polygonal prism of which the number of sides may be increased indefinitely. Then in the limit the base of the prism becomes the base of the cylinder, and the volume of the prism the volume of the cylinder. Now by § 67 we have

$$\text{volume of prism} = \text{area of base} \times \text{altitude};$$

hence $$\text{volume of cylinder} = \text{area of base} \times \text{altitude}.$$

§ 81. *Surface of a Right Cylinder.*—As above, in the limit the base of the prism becomes the base of the cylinder, and the surface of the prism the surface of the cylinder. Now the lateral surface of prism

$= \text{perimeter of right section} \times \text{length}$

$= \text{perimeter of base} \times \text{length}$, in the case of a right prism (§ 68);

hence lateral surface of right cylinder = circumference of base × length.

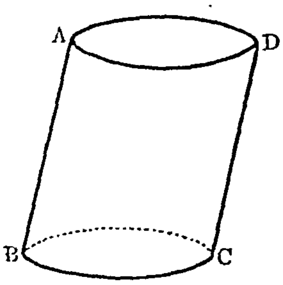

Fig. 50.

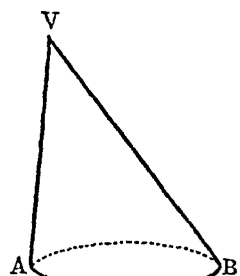

Fig. 51.

B. *The Cone.*

§ 82. *Volume of a Cone* (fig. 51).—Inscribe within the cone a pyramid of which the number of sides may be indefinitely increased, then in the limit the base of the pyramid becomes the base of the cone and the volume of the pyramid the volume of the cone.

By § 70 $\quad \text{volume of pyramid} = \frac{1}{3}\,\text{base} \times \text{altitude},$

and hence $\quad \text{volume of cone} = \frac{1}{3}\,\text{base} \times \text{altitude}.$

§ 83. *Volume of the Frustum of a Cone.*—From § 73 we find that the volume of the frustum of a pyramid

$$= \tfrac{1}{3}h(A_1 + \sqrt{A_1A_3} + A_3);$$

hence, since in the limit the frustum of the pyramid becomes the frustum of the cone, we have

$$\text{volume of conical frustum} = \tfrac{1}{3}h(A_1 + \sqrt{A_1A_3} + A_3),$$

where A_1 and A_3 are the areas of the terminating planes of the frustum.

Let the terminating planes be circles of radii r_1 and r_3, then volume of frustum

$$= \tfrac{1}{3}h(\pi r_1^2 + \pi r_1 r_3 + \pi r_3^2) = \tfrac{1}{3}\pi h(r_1^2 + r_1 r_3 + r_3^2).$$

Again, by the same section we have

$$\text{volume of frustum of pyramid} = \tfrac{1}{6}h(A_1 + 4A_2 + A_3),$$

therefore $\quad \text{volume of conical frustum} = \tfrac{1}{6}\pi h(r_1^2 + 4r_2^2 + r_3^2),$

where r_2 is the radius of the circular section parallel to the terminating planes and equidistant from them.

§ 84. *Surface of a Right Cone.*—The lateral surface of a regular pyramid is by § 71

$$= \tfrac{1}{2}\,\text{perimeter of base} \times \text{slant height};$$

hence, since in the limit the surface of the pyramid becomes the surface of the cone, the lateral surface of a right cone is equal to half the circumference of its base multiplied by the slant height.

Thus the lateral surface of a right cone of slant height l and the radius of whose base is r is equal to

$$\tfrac{1}{2} \times 2\pi r \times l = \pi r l,$$

and $\quad \text{whole surface} = \text{lateral surface} + \text{area of base}$

$$= \pi r l + \pi r^2$$
$$= \pi r(l + r).$$

Again, if h, the altitude of the cone, be given, we have

$$l = \sqrt{h^2 + r^2},$$

and therefore $\quad \text{whole surface} = \pi r(\sqrt{h^2 + r^2} + r).$

§ 85. *Surface of the Frustum of a Right Cone.*—The lateral surface of the frustum of a regular pyramid is equal to the product of the slant height and the perimeter of its middle section (§ 74); hence in the limit we find that the lateral surface of the frustum of a right cone is equal to the product of its slant height and the circumference of the section equidistant from its parallel faces.

Let r_1 and r_3 denote the radii of the ends of the frustum, and l the length of the slant height, then

$$r_2 = \tfrac{1}{2}(r_1 + r_3) = \text{radius of middle section},$$

and therefore

$$\text{lateral surface} = 2\pi r_2 \times l = 2\pi \times \tfrac{1}{2}(r_1 + r_3) \times l = \pi l(r_1 + r_3),$$

and $\quad \text{whole surface} = \pi r_1^2 + \pi l(r_1 + r_3) + \pi r_3^2.$

If h, the altitude of the frustum, be given, we have

$$l = \sqrt{h^2 + (r_1 - r_3)^2}.$$

C. *The Sphere.*

§ 86. *Surface of a Spherical Zone.*—Let AB (fig. 52) be a small arc of the sphere, and let AA′, BB′ be perpendicular to the axis XX′, to find the surface of the zone generated by the arc AB. Join AB, and draw OP perpendicular to AB, BD parallel to XX′, and PP′ parallel to AA′ or BB′. The chord AB generates the frustum of a cone, whose lateral surface $= 2\pi PP' \times AB$.

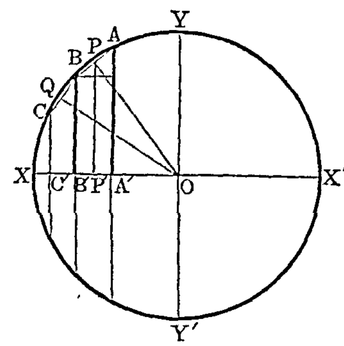

Fig. 52.

But, since the triangles ABD and OPP′ are similar,

$$\frac{AB}{BD} = \frac{OP}{PP'},$$

therefore $\quad \text{area of conical frustum} = 2\pi.OP.BD = 2\pi.OP.A'B'.$

Similarly $\quad$ the area of the frustum generated by $BC = 2\pi.OQ.B'C'$.

But in the limit when the chords AB, BC, &c., are indefinitely diminished, the perpendiculars OP, OQ, &c., become each $= r$, and hence by summing all the areas we get in the limit

$$\text{area of zone} = 2\pi r \times (\text{projection of arc on axis of revolution}).$$

Hence the convex surface of a segment of a sphere is equal to the circumference of a great circle multiplied by the height of the segment or zone.

§ 87. *Surface of a Sphere.*—The whole sphere being a zone whose height is $2r$, we obtain at once

$$\text{surface of sphere} = 2\pi r \times 2r = 4\pi r^2;$$

or the surface of a sphere is equal to four great circles.

The total surface of the cylinder circumscribing the sphere of radius r is $6\pi r^2$, hence the surface of the sphere $= \frac{2}{3}$ surface of circumscribing cylinder.

§ 88. *Surface of a Lune, a Spherical Triangle, and a Spherical Polygon.*—It is shown in spherical trigonometry that

(α) the area of a lune included between two great circles of a sphere of radius r, and whose inclination is θ radians, is

$$2\theta r^2;$$

(β) the area of a spherical triangle whose angles are A, B, C is

$$(A + B + C - \pi)r^2;$$

(γ) the area of a spherical polygon of r sides is

$$\{P - (r-2)\pi\}r^2, \text{ where P is the sum of its angles.}$$

§ 89. *Measurement of Solid Angles.*—A convenient unit for the measurement of plane angles is the "radian." If we assume that each unit of surface of a sphere subtends the same solid angle at the centre, we can deduce a very convenient unit for the measurement of solid angles. This unit, which has received the name "steradian," we define to be the solid angle subtended at the centre of a sphere by a portion of the surface whose area is r^2.

§ 90. *Number of Steradians in an Angle.*—Let A be the angle at the centre of a sphere, and let S be the portion of the surface of the sphere which it intercepts, then

$$\frac{\text{number of steradians in A}}{1} = \frac{S}{r^2}.$$

For example, if A be a plane solid angle, S = a hemisphere $= 2\pi r^2$; hence the number of steradians in a plane solid angle $= \dfrac{S}{r^2} = \dfrac{2\pi r^2}{r^2} = 2\pi$, and therefore the number of steradians in the solid angle at a point $= 4\pi$. This solid angle is sometimes called a steregon.

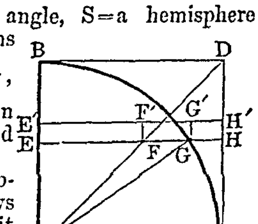

Fig. 53.

Hence, if we can find the surface subtended by any solid angle, we can always find its magnitude in terms of the unit solid angle.

§ 91. *Volume of a Sphere.*—Let ABC (fig. 53) be the quadrant of a circle, draw DB and DC tangents to it, then, if AD be joined and the whole figure be conceived as

rotating round AB, ABD, ABC, and ABDC will generate a cone, a hemisphere, and a cylinder respectively.

Now draw two parallel planes EFGH and E'F'G'H' very near each other and perpendicular to AB, and draw FF' and GG' parallel to AB, then, by § 80,

$$\begin{aligned} &\text{volume generated by EHH'E'} = \pi EH^2 \times EE', \\ &\quad ,, \qquad ,, \qquad EGG'E' = \pi EG^2 \times EE', \\ &\quad ,, \qquad ,, \qquad EFF'E' = \pi EF^2 \times EE'. \end{aligned}$$

Thus volume generated by EFF'E' + volume generated by EGG'E'

$$\begin{aligned} &= \pi(EF^2 + EG^2) \times EE' = \pi(EA^2 + EG^2) \times EE' \\ &= \pi(AG^2) \times EE' = \pi EH^2 \times EE' \\ &= \text{volume generated by EHH'E'}. \end{aligned}$$

Therefore in the limit, when the number of slices is indefinitely increased, and their thickness indefinitely diminished, we have volume of cone generated by AF + volume of spherical zone generated by CG = volume of cylinder generated by CH.

Let r = radius of sphere, h = AE = height of zone ACGE, then

$$\text{volume of cone} = \tfrac{1}{3}\pi h^2 \times h = \tfrac{1}{3}\pi h^3, \text{ and}$$

$$\text{volume of cylinder} = \pi r^2 \times h,$$

therefore $\quad$ volume of spherical zone $= \pi r^2 h - \tfrac{1}{3}\pi h^3$

$$= \tfrac{1}{3}\pi h(3r^2 - h^2).$$

The height of a hemisphere is r,

therefore $\quad$ volume of hemisphere $= \tfrac{1}{3}\pi r(3r^2 - r^2) = \tfrac{2}{3}\pi r^3$,

and $\quad$ volume of whole sphere $= \tfrac{4}{3}\pi r^3$,

a result readily obtainable by the infinitesimal calculus, or by inscribing within the sphere a series of triangular pyramids whose vertices all meet at the centre of the sphere, and the angles of whose bases all rest on the surface. In the limit the altitude of each pyramid becomes the radius of the sphere, and the sum of the bases of the pyramids the surface of the sphere; hence

$$\text{volume} = \tfrac{1}{3}S \times r = \tfrac{1}{3} \times 4\pi r^2 \times r = \tfrac{4}{3}\pi r^3.$$

The volume of the circumscribing cylinder $= \pi r^2 \times 2r = 2\pi r^3$,

therefore volume of sphere $= \tfrac{2}{3}$ volume of circumscribing cylinder.

§ 92. Let S denote the surface of a sphere and V its volume, then from §§ 87 and 91 we have

$$(\alpha)\ r = \frac{\sqrt{S}}{2\sqrt{\pi}} = \sqrt[3]{\frac{3}{4\pi}} \times \sqrt[3]{V};$$

$$(\beta)\ S = \sqrt[3]{\pi(6V)^2};$$

$$(\gamma)\ V = \frac{1}{6\sqrt{\pi}}\sqrt{(S)^3};$$

formulæ which give the radius in terms of the surface or volume, the surface in terms of the volume, and the volume in terms of the surface.

§ 93. *Volume of a Spherical Shell.*—Let r and r_1 denote the radii of the two spheres, then

$$\begin{aligned} \text{volume of shell} = V &= \tfrac{4}{3}\pi r_1^3 - \tfrac{4}{3}\pi r^3 \\ &= \tfrac{4}{3}\pi(r_1^3 - r^3) \\ &= \tfrac{4}{3}\pi(r_1 - r)(r_1^2 + r_1 r + r^2). \end{aligned}$$

Now let $r_1 - r = h$, then

$$V = \tfrac{4}{3}\pi r_1^2 h\left(1 + \frac{r}{r_1} + \frac{r^2}{r_1^2}\right).$$

If h be small compared with r_1, then r/r_1 is very nearly equal to 1, and we have approximately

$$V = \tfrac{4}{3}\pi r_1^2 h(1 + 1 + 1) = 4\pi r_1^2 h.$$

Again, if h be nearly equal to r_1, r is very small, and r/r_1 is also very small, so that we have approximately

$$V = \tfrac{4}{3}\pi r_1^2 h.$$

§ 94. *Volume of a Spherical Segment.*—Let CRC' (fig. 54) be a section of a spherical segment whose altitude RQ is p, then, if OQ $= h$, volume of segment CRC' = volume of hemisphere − volume of zone AA'C'C

$$\begin{aligned} &= \tfrac{2}{3}\pi r^3 - \tfrac{1}{3}\pi h\{3r^2 - h^2\}, \text{ § 91.} \\ &= \tfrac{2}{3}\pi r^3 - \tfrac{1}{3}\pi(r - p)\{3r^2 - (r - p)^2\} \\ &= \tfrac{1}{3}\pi p^2(3r - p). \end{aligned}$$

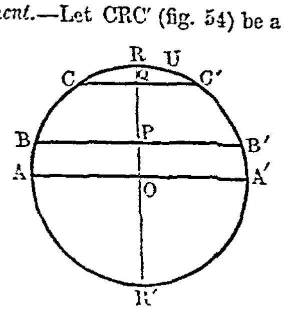

Fig. 54.

If we put $p = 2r$, we obtain as before volume of sphere $= \tfrac{4}{3}\pi r^3$.

Again if CQ $= a_1$ we have

$$CQ^2 = a_1^2 = RQ.R'Q = p(2r - p),$$

$$\text{whence } r = \frac{a_1^2 + p^2}{2p},$$

therefore $\quad$ volume of segment $= \tfrac{1}{6}\pi p(3a_1^2 + p^2)$.

§ 95. *Volume of a Spherical Frustum.*—When one of the terminating planes passes through the centre we have already found that the volume

$$= \tfrac{1}{3}\pi h(r^2 - h^2),$$

where h is its altitude.

Now suppose that neither of the terminating planes passes through the centre; for example, to find the volume of the frustum BB'C'C. Let RQ $= p$ and RP $= q$, then

$$\begin{aligned} BB'C'C &= \text{segment RBB'} - \text{segment RCC'} \\ &= \tfrac{1}{6}\pi q(3a_2^2 + q^2) - \tfrac{1}{6}\pi p(3a_1^2 + p^2), \end{aligned}$$

where a_1 and a_2 are the radii of the ends CC' and BB'.

Let $q - p = h$ = height of frustum, and, since, from the geometry of the figure,

$$\frac{a_1^2 + p^2}{p} = \frac{a_2^2 + q^2}{q} = 2r,$$

we have $\quad$ volume $= \tfrac{1}{6}\pi h\{3(a_1^2 + a_2^2) + h^2\}$,

a result which may also be obtained by considering BB'C'C as the difference of the two zones AA'C'C and AA'B'B.

D. *Spheroid.*

§ 96. *Surface of a Prolate Spheroid.*—The prolate spheroid is the solid generated by the revolution of an ellipse about its major axis. If S be the surface generated by an arc of the curve, then

$$S = 2\pi\int y\sqrt{1 + \left(\frac{dy}{dx}\right)^2}\,dx, \text{ taken between proper limits.}$$

In the case before us

$$S = 2\pi b^2 + 2\pi\frac{ab}{e}\sin^{-1}e,$$

where e is the eccentricity (INFINITESIMAL CALCULUS, art. 179).

§ 97. *Surface of an Oblate Spheroid.*—The oblate spheroid is the solid generated by the revolution of an ellipse about its minor axis (fig. 55).

Here surface $= 2\pi a^2 + \pi\dfrac{b^2}{e}\log_e\dfrac{1 + e}{1 - e}$ (INFINITESIMAL CALCULUS, art. 179).

§ 98. *Volume of a Spheroid.*—We have volume of prolate spheroid

$$= \pi\int_{-a}^{+a} b^2\left(1 - \frac{x^2}{a^2}\right)dx = 2\pi b^2\int_0^a\left(1 - \frac{x^2}{a^2}\right)dx = \tfrac{4}{3}\pi ab^2.$$

Similarly volume of oblate spheroid $= \tfrac{4}{3}\pi a^2 b$.

Thus,

$$(\alpha)\quad \frac{\text{volume of prolate spheroid}}{\text{volume of oblate spheroid}} = \frac{\tfrac{4}{3}\pi ab^2}{\tfrac{4}{3}\pi a^2 b} = \frac{b}{a};$$

$$(\beta)\quad \frac{\text{sphere described on major axis}}{\text{prolate spheroid}} = \frac{\tfrac{4}{3}\pi a^3}{\tfrac{4}{3}\pi ab^2} = \frac{a^2}{b^2};$$

$$(\gamma)\quad \frac{\text{sphere described on minor axis}}{\text{oblate spheroid}} = \frac{\tfrac{4}{3}\pi b^3}{\tfrac{4}{3}\pi a^2 b} = \frac{b^2}{a^2}.$$

§ 99. *Volume of a Segment of a Spheroid.*

(α) *The prolate spheroid.*—This segment is generated by the revolution of AMP (fig. 23, p. 20) about AM, and hence

$$\text{its volume} = \pi\int_0^h y^2dx = \pi\frac{b^2}{a^2}\int_0^h(2ax - x^2)dx = \frac{\pi}{3} \times \frac{b^2h^2}{a^2}(3a - h),$$

where A is the origin and AM $= h$.

(β) *The oblate spheroid.*—The segment in this case is generated by the revolution of BMP (fig. 55) about BC, and hence

$$\text{its volume} = \pi\int_0^h y^2dx = \pi\frac{a^2}{b^2}\int_0^h(2bx - x^2)dx = \frac{\pi}{3} \times \frac{a^2h^2}{b^2}(3b - h),$$

where B is the origin and BM $= h$.

§ 100. *Volume of the Frustum of a Spheroid when one of the Terminating Planes passes through the Centre.*

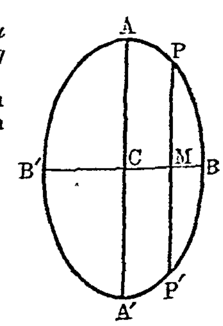

Fig. 55.

(α) *The prolate spheroid.*—The frustum in this case is generated by the revolution of BCMP about CM (fig. 23).

Now volume generated by BCMP

$$\begin{aligned} &= \text{volume generated by BCA} \\ &\quad - \text{volume generated by PMA} \\ &= \tfrac{2}{3}\pi ab^2 - \frac{\pi}{3} \times \frac{b^2h^2}{a^2}(3a - h) \\ &= \frac{\pi}{3} \times \frac{b^2k}{a^2}(3a^2 - k^2), \text{ where} \end{aligned}$$

k = CM = height of frustum $= a - h$.

(β) *The oblate spheroid.*—We can show in a similar manner that the volume generated in this case

$$= \frac{\pi}{3} \times \frac{a^2k}{b^2}(3b^2 - k^2).$$

The above formulæ may be put into another form. Thus, in the case of the prolate spheroid, since the point P lies on the ellipse $b^2x^2 + a^2y^2 = a^2b^2$, we have

$$b^2k^2 + a^2b_1^2 = a^2b^2, \text{ where } b_1 = PM, \text{ which gives}$$

$$k^2 = a^2\frac{(b^2 - b_1^2)}{b^2};$$

whence, by substitution, the volume of prolate frustum

$$=\tfrac{1}{3}\pi k(2b^2+b_1^2).$$

Similarly we can show that the volume of the oblate frustum

$$=\tfrac{1}{3}\pi k(2a^2+a_1^2),$$

where $a_1=\mathrm{PM}$.

These formulæ play an important part in the gauging of casks.

E. *Paraboloid.*

§ 101. *Surface of a Paraboloid.*—Let the equation to the parabola be $y^2=4ax$, and let the coordinates of P (fig. 21, p. 19) be x_1, y_1, then the surface of the paraboloid generated by the revolution of AM about AP

$$=2\pi\int_0^{x_1} y\sqrt{1+\left(\frac{dy}{dx}\right)^2}\,dx=4\pi\sqrt{a}\int_0^{x_1}\sqrt{x}\,\sqrt{\frac{x+a}{x}}\,dx$$
$$=\tfrac{8}{3}\pi\sqrt{a}\left\{(x_1+a)^{\frac{3}{2}}-a^{\frac{3}{2}}\right\}.$$

§ 102. *Volume of a Paraboloid.*—With the same notation we have

$$\text{volume}=\pi\int_0^{x_1}y^2dx=4\pi a\int_0^{x_1}x\,dx=\tfrac{1}{2}\pi\times 4ax_1\times x_1=\tfrac{1}{2}\pi y_1^2\times x_1\,;$$

or the volume of a paraboloid generated by the revolution of a part of a parabola between the vertex and any point is equal to half the volume of the circumscribing cylinder.

§ 103. If the coordinates of Q be x_2, y_2, then the volume of the frustum PP′Q′Q

$$=\tfrac{1}{2}\pi\left\{y_2^2x_2-y_1^2x_1\right\}=2\pi a(x_2^2-x_1^2)=\tfrac{1}{2}\pi(y_2^2+y_1^2)h\,,$$

where $h=\mathrm{MN}$; hence the volume of the frustum of a paraboloid is equal to half the sum of the areas of its ends multiplied by its height.

F. *Ellipsoid.*

§ 104. *Volume of an Ellipsoid.*—The equation to the ellipsoid being

$$\frac{x^2}{a^2}+\frac{y^2}{b^2}+\frac{z^2}{c^2}=1\,,$$

the equation to the elliptic section at the distance z from the origin is

$$\frac{x^2}{a^2}+\frac{y^2}{b^2}=1-\frac{z^2}{c^2}\,.$$

Now if we draw an indefinite number of parallel planes perpendicular to the axis of z, each slice will be an infinitely thin cylindrical plate, and accordingly the whole volume of the ellipsoid

$=\int A\,dz$, where A is the area of the elliptic section.

But $A=\pi ab\left(1-\dfrac{z^2}{c^2}\right)$, § 51,

therefore $\quad\text{volume}=\pi ab\displaystyle\int_{-c}^{c}\left(1-\frac{z^2}{c^2}\right)dz=\tfrac{4}{3}\pi abc$:

The sphere being an ellipsoid whose axes are all equal, we obtain as before

$$\text{volume of sphere}=\tfrac{4}{3}\pi a^3=\tfrac{4}{3}\pi r^3.$$

G. *Hyperboloid.*

§ 105. *Volume of an Hyperboloid.*—The hyperboloid is generated by the revolution of the hyperbolic segment ANP about AN (fig. 24, p. 20). If the coordinates of P be x_1, y_1, then

$$\text{volume of hyperboloid}=\pi\int_a^{x_1}y^2dx=\pi\frac{b^2}{a^2}\int_a^{x_1}(x^2-a^2)dx$$
$$=\pi\frac{b^2}{a^2}\left\{\frac{x_1^3}{3}-a^2x_1+\frac{2a^3}{3}\right\}=\frac{\pi b^2h^2}{3a^2}(3a+h)\,,$$

where $h=\mathrm{AN}=x_1-a$.

Again, since x_1, y_1 is on the curve, we have

$a^2y_1^2-b^2(a+h)^2=-a^2b^2$, which gives $\dfrac{b^2}{a^2}=\dfrac{y_1^2}{2ah+h^2}$; whence

$$\text{volume of hyperboloid}=\frac{\pi hy_1^2}{3}\times\frac{3a+h}{2a+h}\,.$$

H. *Solids to which the "Prismoidal Formula" applies.*

§ 106. It was shown in § 72 that the volume of any polyhedron bounded by two parallel planes and by plane rectilinear figures

$$=\tfrac{1}{6}h(A_1+4A_2+A_3),$$

where A_1, A_3, and A_2 denote respectively the areas of the two ends and of the middle section.

We now proceed to show that the same formula determines the volumes of all solids bounded by two parallel planes, provided the area of any section parallel to these planes can be expressed as a rational integral algebraic function of the third degree in x, where x is the distance of the section from either plane.

Let $\phi(x)=A+Bx+Cx^2+Dx^3+\;.\;.\;.\;.\;+Kx^n$ denote the area of the section in question.

Now the solid between the sections $\phi(0)$ and $\phi(4)$ is equal to the solid between the sections $\phi(0)$ and $\phi(2)$ plus the solid between the sections $\phi(2)$ and $\phi(4)$. Hence if the prismoidal formula is to hold in this case, we have

$$\tfrac{1}{6}h\{\phi(0)+4\phi(2)+\phi(4)\}$$
$$=\tfrac{1}{12}h\{\phi(0)+4\phi(1)+\phi(2)\}+\tfrac{1}{12}h\{\phi(2)+4\phi(3)+\phi(4)\}\,,$$

where h is the distance between the sections $\phi(0)$ and $\phi(4)$. Hence we have

$$\phi(0)-4\phi(1)+6\phi(2)-4\phi(3)+\phi(4)=0\,.$$

Now
$$\begin{aligned}
&\phi(0)=A\\
-&4\phi(1)=-4A-4B-4C-4D-4E-\;.\;.\;.\;.\;-4K\\
+&6\phi(2)=6A+12B+24C+48D+96E+\;.\;.\;.\;.\;+6\cdot 2^nK\\
-&4\phi(3)=-4A-12B-36C-108D-324E-\;.\;.\;.\;.\;-4\cdot 3^nK\\
+&\;\;\phi(4)=A+4B+16C+64D+256E+\;.\;.\;.\;.\;+4^nK.
\end{aligned}$$

Therefore $\quad 0=0+0+0+0+24E+PF+\;.\;.\;.\;.\;+TK.$

Hence $E=F=\;.\;.\;.\;.\;K=0$, and therefore $\phi(x)$ must be a function of the third degree in order that the prismoidal formula may apply.

§ 107. If we take $\phi(x)=A+Bx+Cx^2+Dx^3$, there will be as many possible varieties as there are combinations of four things, one, two, three, and four together, *i.e.*, $2^4-1=15$ varieties. Corresponding to each of these there will be *at least one solid* the area of a section of which at a distance x from one of the parallel planes is $\phi(x)=A+Bx+Cx^2+Dx^3$, and *at least one solid of revolution* generated by the curve whose equation is of the form

$$\pi y^2=\phi(x)=A+Bx+Cx^2+Dx^3\,.$$

As space prevents us discussing all the cases that may arise, we content ourselves by giving three examples as illustrations.

(α) *Volume of an ellipsoid.*—Here $\phi(x)=Bx+Cx^2$.

Let $2a$, $2b$, and $2c$ be the axes of which $2a$ is the greatest, then $h=2a$, $A_1=0_1$, $A_3=0$, and $A_2=\pi bc$;

therefore $\quad\text{volume}=\tfrac{1}{6}h(A_1+4A_2+A_3)=\tfrac{2}{6}a(4\pi bc)=\tfrac{4}{3}\pi abc$,

which agrees with the result in § 104.

(β) *Volume of a sphere.*—Here $\pi y^2=\phi(x)=Bx+Cx^2$.

Let r be the radius of the sphere, then $h=2r$, $A_1=0$, $A_3=0$, and $A_2=\pi r^2$, hence, as before (§ 91),

$$\text{volume of sphere}=\tfrac{1}{6}h(A_1+4A_2+A_3)=\frac{2r}{6}(4\pi r^2)=\tfrac{4}{3}\pi r^3.$$

(γ) *Volume of a right circular cone.*—Here $\pi y^2=\phi(x)=Cx^2$.

Let r = radius of base and h the altitude, then $A_1=0$, $A_3=\pi r^2$, and $A_2=\pi(\frac{1}{2}r)^2$; hence

$$\text{volume of cone}=\tfrac{1}{6}h\{A_1+4A_2+A_3\}=\tfrac{1}{6}h\{\pi r^2+\pi r^2\}=\tfrac{1}{3}h\pi r^2$$

In a similar manner we can determine the volumes of a cylinder, a prolate spheroid, an oblate spheroid, &c.

§ 108. In general, if in any solid we have

$$\phi(x)=A+Bx+Cx^2+Dx^3,$$

where A, B, C, and D are known constants, then, if h be the length of the solid,

$$\begin{aligned}
A_1&=\phi(0)=A,\\
A_2&=\phi(\tfrac{1}{2}h)=A+B(\tfrac{1}{2}h)+C(\tfrac{1}{2}h)^2+D(\tfrac{1}{2}h)^3,\\
A_3&=\phi(h)=A+Bh+Ch^2+Dh^3,
\end{aligned}$$

and therefore

$$\begin{aligned}
\text{volume of solid}&=\tfrac{1}{6}h(A_1+4A_2+A_3)\\
&=Ah+\tfrac{1}{2}Bh^2+\tfrac{1}{3}Ch^3+\tfrac{1}{4}Dh^4.
\end{aligned}$$

I. *Solids of Revolution in General.*

§ 109. *Volume of any Solid of Revolution.*—Let $P_1P_2\;.\;.\;.\;.\;P_n$ (fig. 34) be the generating curve, and $A_1\;.\;.\;.\;.\;A_n$ the axis of revolution. Divide the curve into portions in the points P_2, P_3, &c., and draw the chords and tangents of the small arcs P_1P_2, P_2P_3, &c., then it is evident that the solid generated by the curve is greater than the sum of the conical frusta traced out by the chords and less than the sum of the conical frusta traced out by the tangents. Hence, by increasing the number of chords, namely, by increasing the points of division of the curve, we can make the difference between these sums as small as we please, and therefore by this method we can approximate as closely as we please to the volume of the solid generated.

Assuming that the points P_1, P_2, P_3 are so near each other that the solid generated differs little from the frustum of a cone, and using the same notation as in § 63, we have volume generated by

$$\begin{aligned}
P_1P_2P_3&=\tfrac{1}{6}\pi A_1A_3(s_1^2+4s_2^2+s_3^2)=\tfrac{1}{6}\pi 2A_1A_2(s_1^2+4s_2^2+s_3^2)\\
&=\tfrac{1}{3}\pi a(s_1^2+4s_2^2+s_3^2)\,;
\end{aligned}$$

similarly the volume generated by

$$P_3P_4P_5=\tfrac{1}{3}\pi a(s_3^2+4s_4^2+s_5^2)\,;$$

whence the volume generated by the whole curve $P_1P_2\;.\;.\;.\;.\;P_n$

$$=\tfrac{1}{3}\pi a\left\{s_1^2+s_n^2+2(s_3^2+s_5^2+\;.\;.\;.\;.\;+s_{n-2}^2)+4(s_2^2+s_4^2+\;.\;.\;.\;.\;+s_{n-1}^2)\right\};$$

or (since $\pi s_1^2 = \frac{c_1^2}{4\pi}$, $\pi s_2^2 = \frac{c_2^2}{4\pi}$, &c.)

$$= \frac{1}{\pi}\frac{a}{12}\{c_1^2 + c_n^2 + 2(c_3^2 + c_5^2 + \ldots + c_{n-2}^2) + 4(c_2^2 + c_4^2 + \ldots + c_{n-1}^2)\},$$

a formula more convenient in practice, as it is sometimes more easy to measure equidistant circumferences than equidistant radii.

J. *Theorems of Pappus.*

§ 110. The following general propositions concerning surfaces and solids of revolution, usually called Guldin's theorems, are worth the reader's attention.

If any plane curve revolve about any external axis situated in its plane, then

(α) the surface of the solid which is thereby generated is equal to the product of the perimeter of the revolving curve and the length of the path described by the centre of gravity of that perimeter;

(β) the volume of the solid is equal to the product of the area of the revolving curve and the length of the path described by the centre of gravity of the revolving area.

We content ourselves with an example or two of the application of these theorems, referring to the article INFINITESIMAL CALCULUS for the proofs.

Example 1.—To find the surface and volume of a circular ring.—Let a be the distance of the centre of the generating curve, in this case a circle, from the axis of rotation, and r the radius of the circle, then

$$\text{perimeter of generating curve} = 2\pi r,$$
$$\text{area of generating curve} = \pi r^2, \text{ and}$$

path described by the centre of gravity either of the perimeter or area $= 2\pi a$; hence

$$\text{surface of ring} = 2\pi r \times 2\pi a = 4\pi^2 ra, \text{ and}$$
$$\text{volume of ring} = \pi r^2 \times 2\pi a = 2\pi^2 r^2 a.$$

Example 2.—To find the volume swept out by an ellipse whose axes are $2a$ and $2b$, revolving about an axis in its own plane whose distance from the centre of the ellipse is c.

Here area of generating curve $= \pi ab$,
and path described by centre of gravity of area $= 2\pi c$; hence

$$\text{volume generated} = \pi ab \times 2\pi c = 2\pi^2 abc.$$

Example 3.—A circle of r inches radius, with an inscribed regular hexagon, revolves about an axis a inches distant from its centre, and parallel to a side of the hexagon; to find the difference in area of the generated surfaces and volumes.

$$\text{Here perimeter of circle} = 2\pi r,$$
$$\text{and perimeter of hexagon} = 12 \times r \sin 30° \text{ (§ 17)}$$
$$= 6r;$$
$$\text{also area of circle} = \pi r^2,$$
$$\text{and area of hexagon} = 3r^2 \sin 60° \text{ (§ 18, } \beta)$$
$$= \tfrac{3}{2}\sqrt{3}r^2;$$

hence difference of surfaces generated

$$= 4\pi^2 ra - 12\pi ar = 4\pi ar(\pi - 3);$$

and difference of volumes generated

$$= 2\pi^2 r^2 a - 3\pi r^2 \sqrt{3} a$$
$$= \pi r^2 a(2\pi - 3\sqrt{3}).$$

PART III. GAUGING.

§ 111. By gauging is meant the art of measuring the volume of a cask, or any portion of it. The subject is one of great interest and practical importance, but space will only permit us to discuss it very briefly. If the cask whose capacity we wish to determine be a solid of revolution, then its volume can at once be computed, either exactly or approximately, by the methods already described.

It is usual to divide casks into the following four classes according to the nature of the revolving curve:—

(α) the middle frustum of a spheroid;
(β) the middle frustum of a parabolic spindle;
(γ) two equal frusta of a paraboloid, united at their bases;
(δ) two equal frusta of a cone, united at their bases.

Casks of the second, third, and fourth variety are rarely met with in practice, and we shall accordingly confine our attention to the first kind, which is considered the true or model form of cask.

Let ABCD (fig. 56) be a section of the cask, and assume it to be the middle frustum of a prolate spheroid, then

$$\text{its volume} = \tfrac{1}{3}\pi(2b^2 + b_1^2)k,$$

where $b = OY$, $b_1 = AX$, and $k = XX'$ (§ 99).

YY′ is called the bung diameter, and AB or CD the head diameter.

An imperial gallon contains 277·274 cubic inches, and therefore the number of gallons in the above cask

$$= \frac{\pi(2b^2 + b_1^2)k}{3 \times 277{\cdot}274} = \frac{\pi}{831{\cdot}822}(2b^2 + b_1^2)k.$$
$$= \left(\frac{2d^2 + d_1^2}{1059{\cdot}1}\right)k, \text{ where } d = 2b,\ d_1 = 2b_1;$$

whence we have the rule:—to the square of the head diameter add twice the square of the bung diameter, multiply the sum by the length and divide the result by 1059·1, and the answer is the content in imperial gallons.

Casks as ordinarily met with are not true spheroidal frusta, but it is better to consider them as such, calculate their capacity on this assumption, and then make allowance for the departure from the spheroidal form. The determination of the proper allowance to be made in each case is a matter depending on the skill and experience of the gauger, and proficiency in the art can only be attained by considerable practice.

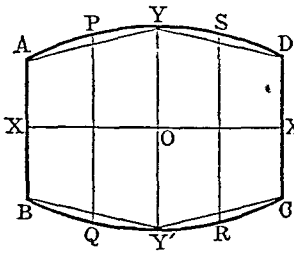

Fig. 56.

§ 112. If the cask be very little curved, we obtain an approximation to its capacity by considering it as made up of two equal frusta of a cone, united at their bases. Hence from § 83 we have

$$\text{volume of cask} = \tfrac{1}{3}\pi h(r_1^2 + r_1 r_3 + r_3^2) \text{ nearly.}$$

Here we neglect the small volumes generated by APY, YSD, BQY′, and Y′RC; and therefore the volume is too small.

If we put $r_1 r_3 = r_1^2$ we obtain

$$\text{volume} = \tfrac{1}{3}\pi h(2r_1^2 + r_3^2),$$

which is a little too large, and therefore the true volume lies between these two limits, and a very close approximation to it is said to be given by the formula

$$\tfrac{1}{3}\pi h\{2r_1^2 + r_3^2 - \tfrac{1}{3}(r_1^2 - r_3^2)\}.$$

§ 113. *Ullage of a Cask.*—The quantity of liquor contained in a cask partially filled and the capacity of the portion which is empty are termed respectively the wet and dry ullage.

(α) *Ullage of a standing cask.*—By means of the method applied in § 105, the following rule is deduced:—

Add the square of the diameter at the surface, the square of the diameter at the nearest end, and the square of double the diameter half-way between; multiply the sum by the length between the surface and the nearest end, and by ·000472.

The product will be the wet or dry ullage according as the lesser portion of the cask is filled or empty.

(β) *Ullage of a lying cask.*—The ullage in this case is found approximately on the assumption that it is proportional to the segment of the bung circle cut off by the surface of the liquor. The rule adopted in practice is

$$\text{ullage} = \tfrac{4}{5} \text{ content} \times \text{segmental area.}$$

(W. T.*)

MENTAL DISEASES. See INSANITY.

MENTON (Ital., *Mentone*), a cantonal capital in the department of Alpes-Maritimes, France, situated 15 miles north-east of Nice, on the shores of the Mediterranean. The town, which has a population of about 8000, rises like an amphitheatre on a promontory by which its semicircular bay (5 miles wide at its entrance, and bounded on the W. by Cape Martin and on the E. by the cliffs of La Murtola) is divided. It is composed of two very distinct portions: below, along the sea-shore, is the town of hotels and of foreigners, which alone is accessible to wheeled vehicles; above is that of the native Mentonese, with steep, narrow, and dark streets, spread over and clinging to the mountain, around the strong castle which was once its protection against the attacks of pirates. Facing the south-east, and sheltered on the north and west by high mountains, the Bay of Menton enjoys a delicious climate, and is on this account much frequented by invalids requiring a mild and equable temperature. The mean for the year is 61° Fahr., exceeding that of Rome or of

Pisa, and equalling that of Naples. Frost occurs on the average only once in ten years; in one particular year the thermometer did not fall below 46° Fahr. In summer the heat is never very great, the temperature rarely exceeding 86° Fahr. Winter and summer are the most agreeable seasons; in autumn the rain storms are accompanied by sudden changes of temperature, and in spring the sea breezes are apt to be violent. Besides the charms of its climate, Menton offers those of an almost tropical vegetation. Lemon-trees, olive-trees, and pines, rising above each other in successive stages, adorn the surrounding slopes. The district produces forty millions of lemons yearly, and this is the principal source of its natural wealth. The olive-trees are remarkable for the great size they have attained in the course of the centuries during which they have continued to bear. Of their wood a multitude of fancy objects are made for sale to strangers.

The origin of Menton is unknown. During the Middle Ages it was successively occupied by the Saracens, the Genoese, and the princes of Anjou. In the middle of the 14th century it was purchased as a single domain by the Grimaldis, lords of Monaco. During the times of the republic and the first empire it belonged to France; but in 1815 it again became the property of the princes of Monaco, who subjected it to such exactions that in 1848 its inhabitants, weary of finding their reasonable demands put off with empty promises, proclaimed their town free and independent, under the protection of Sardinia. Menton, with the neighbouring commune of Roquebrune, was united to France in 1860, at the same time as Nice and Savoy.

MENTZ. See MAINZ.

MENZEL, WOLFGANG (1798–1873), poet, critic, and historian, was born June 21, 1798, at Waldenburg in Silesia, studied at Breslau, Jena, and Bonn, and after living for some time in Aarau and Heidelberg finally settled in Stuttgart, where, from 1830 to 1838, he had a seat in the Würtemberg "landtag." His first work, a clever and original volume of poems, entitled *Streckverse* (Heidelberg, 1823), was followed in 1824–25 by a popular *Geschichte der Deutschen* in three volumes, and in 1829 and 1830 by *Rübezahl* and *Narcissus*, the ballads upon which his reputation as a poet chiefly rests. In 1851 he published the romance of *Furore*, a lively picture of the period of the Thirty Years' War; his other very numerous writings include *Geschichte Europa's*, 1789–1815 (1853), and histories of the German war of 1866 and of the Franco-German war of 1870–71. From 1825 to 1848 Menzel edited a "Literaturblatt" in connexion with the *Morgenblatt*; in the latter year he transferred his allegiance from the Liberal to the Conservative party, and in 1852 his "Literaturblatt" was again revived in that interest. In 1866 his political sympathies again changed, and all his energies were employed to oppose the "particularism" of the Prussian "junkers" and the antiunionism of South Germany. He died on April 23, 1873. His large private library of 18,000 volumes was afterwards acquired for the university of Strasburg.

MEPHISTOPHELES, the name of one of the personifications of the principle of evil. In old popular books and puppet-plays the word appears in various forms,—as Mephistopheles, Mephistophiles, Mephistophilis, and Mephostophilis. In the *Tragical History of Doctor Faustus*, Marlowe writes "Mephistophilis"; in the *Merry Wives of Windsor* we find "Mephistophilus." The etymology of the word is uncertain. According to one theory, it may be taken to represent μηφωστοφίλης; in which case the meaning would be "one who loves not light." Another theory is that the word is a combination of the Latin "mephitis" and the Greek φίλος, signifying "one who loves noxious exhalations." Probably it is of Hebrew origin,—from מֵפִיר, a destroyer, and טֹפֶל, taken to mean a liar. This view is supported by the fact that almost all the names of devils in the magic-books of the 16th century spring from the Hebrew. In the old Faust legends the character of Mephistopheles is simply that of a powerful and wicked being who fulfils Faust's commands in order to obtain possession of his soul. Marlowe attributes to him a certain dignity and sadness, and there can be little doubt that the Mephistophilis of the *Tragical History* suggested some important traits of Milton's Satan. The name has been made famous chiefly by Goethe, whose conception of the character varied at different periods of his career. In the fragment of *Faust* published in 1790, but written many years before, Mephistopheles has a clearly marked individuality; he is cynical and materialistic, but has a man's delight in activity and adventure, and his magical feats alone remind us that he is preternatural. In revising and extending this fragment, which forms the chief portion of the first part of *Faust*, Goethe treated Mephistopheles as the representative of the evil tendencies of nature, especially of the tendency to denial for its own sake, rather than as a living person. This character Mephistopheles maintains in the second part, where, indeed, the name often stands for a pure abstraction.

See Julius Mosen, *Faust*; Düntzer, *Erläuterungen zu Goethe's Werken: Faust*; Vischer, *Goethe's Faust*.

MEQUINEZ (the Spanish form of the Arabic *Miknása*), a town of Morocco, the ordinary residence of the emperor, is situated in a fine hilly country about 70 miles from the west coast and 35 west-south-west of Fez on the road to Sallee, in 34° N. lat. and 5° 35′ W. long. The town-wall, with its four-cornered towers, is kept in good condition; and a lower wall of wider circuit protects the luxuriant gardens with which the outskirts are embellished. In the general regularity of its streets, and in the fairly substantial character of its houses, Mequinez ranks higher than any other town in Morocco; but it possesses few buildings of any note, except the palace, and the mosque of Mulei Ismael, which serves as the royal burying-place. At one time the palace (founded in 1634) was an imposing structure, but the finest part has been allowed to go to ruin. In 1721 Windhus described it as "about 4 miles in circumference, the whole building exceeding massy, and the walls in every part very thick; the outward one about a mile long and 25 feet thick." The best part consisted of oblongs enclosing large open courts or gardens. Mortar or concrete was the principal material used for the walls, but the pillars were in many cases marble blocks of great beauty and costliness (*A Journey to Mequinez*, London, 1725). Most of the inhabitants of Mequinez are connected more or less directly with the court. Their number has been very variously estimated by different travellers. Gråberg de Hemsö gives 56,000 in 1834, Rohlfs in 1861 from 40,000 to 50,000, and Conring in 1880 about 30,000. The town was formerly called Tákarart. Edrisi refers the present name to a Berber chief Meknás.

MERAN, a favourite health resort, and the capital of a district in South Tyrol, Austria, is picturesquely situated at the foot of the vine-clad Küchelberg, on the right bank of the Passer, about half a mile above its junction with the Adige, and 45 miles to the south of Innsbruck. Meran proper consists mainly of one long narrow street, called the Laubengasse, flanked by covered arcades. In a wider sense, the name is often used to include the adjacent villages of Untermais, Obermais, and Gratsch. The most noteworthy buildings are the Gothic church of St Nicholas, with its lofty tower, dating from the 14th and 15th centuries; the Spitalkirche, built in the 15th century, and restored in 1880; and the quaint old Fürstenhaus, or residence of the counts of Tyrol. The town contains a gymnasium, a nunnery and school for girls, an institution for sick priests, and several other charitable establishments.

Meran owes its high reputation as a resort for consumptive and nervous invalids to the purity of its air and its comparative immunity from wind and rain in winter. It stands in 46° 41′ N. lat., at a height of 1050 feet above the sea, and has a mean annual temperature of about 54° Fahr. Meran enjoys three seasons, being also visited in spring for the whey-cure and in autumn for the grape-cure. The arrangements for the comfort of the visitors are very complete; and the environs afford opportunity for numerous pleasant walks and excursions. The favourite promenade of the inhabitants is on a massive dyke, built to protect the town against the encroachments of the Passer. Nearly twenty old castles and chateaus are visible from the bridge over the Passer, the most interesting being Schloss Tyrol, an ancient edifice which has given its name to the entire country. Meran is now frequented by about 6500 patients and 8000 to 9000 passing travellers annually. In 1880 its population, including Obermais and Untermais, amounted to 5334 souls.

Meran is probably the representative of the Roman Urbs Majensis, afterwards known as Mairania. It became a town in 1290, and down to 1490 was the capital of the counts and dukes of Tyrol. The town suffered somewhat during the Peasants' War in the 16th century, and subsequently from destructive floods. As a health-resort it has been known for about forty years. The whole region in which it lies is singularly rich in historic interest.

MERCATOR, GERARDUS (Latinized form of Gerhard Krämer) (1512–1594), mathematician and geographer, was born at Rupelmonde in Flanders, May 5, 1512. Having completed his studies at Louvain, he devoted himself to geography, and, after being for some time attached to the household of Charles V., he was appointed cosmographer to the duke of Juliers and Cleves in 1559, taking up his residence at Duisburg, where he died December 2, 1594. One of his earliest cartographical works was a terrestrial globe (1541), followed in 1551 by a celestial globe. In 1552 he published a treatise *De usu annuli astronomici* (Louvain), and at Cologne in 1569 his *Chronologia, hoc est temporum demonstratio . . . ab initio mundi usque ad Annum Domini* 1568, *ex eclipsibus et observationibus astronomicis, sacris quoque Bibliis*, &c. In the same year was published the first map on Mercator's well-known projection, with the parallels and meridians at right angles, for use in navigation. At Cologne, in 1578, appeared his *Tabulæ geographicæ ad mentem Ptolemæi restitutæ et emendatæ*. The work by which he is chiefly known is his atlas, published in 1594 at Duisburg, in folio, under the title of *Atlas, sive Cosmographicæ meditationes de fabrica mundi.* It contains, besides the maps, cosmographical and other dissertations, some of the theological views in which were condemned as heretical; it was completed by Hondius in 1607. Several of the maps had been previously published separately, the atlas being delayed to allow Ortelius to complete his. Mercator also published in 1592 a *Harmonia Evangeliorum.*

MERCURIAL AIR-PUMP. This name is given to two distinct instruments, one of which is founded on statical, the other on hydrodynamical principles.

1. *The Statical Pump.*—The famous spiritualist Swedenborg was the first to conceive an air-pump in which a mass of mercury, by being made to rise and fall alternately within a vertical vessel, should do the work which in the ordinary instrument is assigned to the piston. He published a description of his pump in 1722; but it is questionable whether his design was ever realized. Of numerous subsequent inventions the only one which, in fact, has survived is the admirably simple and yet efficient instrument first described in 1858, but constructed some time before, by H. Geisler of Bonn, which at once, and justly, met with universal acceptance.

The general scheme of Geisler's pump is shown in fig. 1. A and B are pear-shaped glass vessels connected by a long narrow india-rubber tube, which must be sufficiently strong in the body (or strengthened by a linen coating) to stand an outward pressure of 1 to 1½ atmospheres. A terminates below in a narrow vertical tube *c*, which is a few inches longer than the height of the barometer, and to the lower end of this tube the india-rubber tube is attached which connects A with B. To the upper end of A is soldered a glass two-way stop-cock, by turning which the vessel A can either be made to communicate through *s* and a hole in the hollow cock with the vessel to be exhausted (I., fig. 2), or through *g* with the atmosphere (II., fig. 2), or can be shut off from both when the cock holds an intermediate position. The apparatus, after having been carefully cleaned and dried, is charged with pure and dry mercury, which must next be worked backwards and forwards between A and B to remove all the air-bells. The air is then driven out of A by lifting B to a sufficient level, turning the cock into position II., and letting the mercury flow into A until it gets to the other side of the stop-cock, which is then placed in the intermediate position. Supposing the vessel to be exhausted to have already been securely connected with *b*, we now lower the reservoir B so as to reduce the pressure in A sufficiently below the tension in the gas to be sucked in, and, by turning the cock into position I., cause the gas to expand into and almost fill A. The cock is now shut against both *a* and *b*, the reservoir lifted, the gas contents of A discharged through *a*, and so on, until, when after an exhaustion mercury is let into A, the metal strikes against the top without interposition of a gas-bell. In a well-made apparatus the pressure in the exhausted vessel is now reduced to $\frac{1}{10}$ or $\frac{1}{20}$ of a millimetre, or even less. An absolute vacuum cannot be produced on account of the unavoidable air-film between the mercury and the walls of the apparatus.

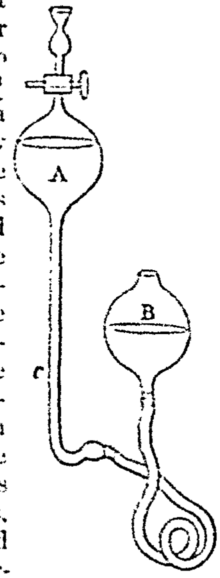

FIG. 1.—Geisler's Mercurial Air-Pump.

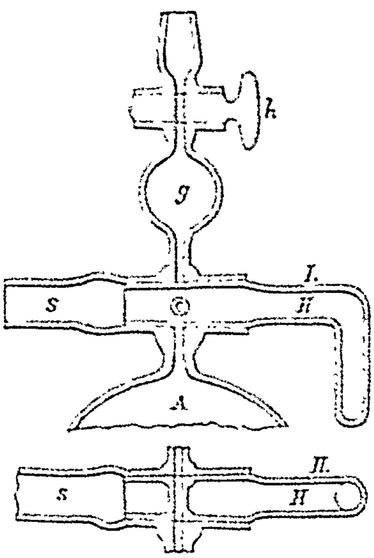

FIG. 2.—Arrangements of Stop-Cock in Air-Pump.

The great advantage of the mercurial over the ordinary air-pump is that it evacuates far more completely than the latter, that it affords direct and unmistakable evidence of the exhaustiveness of its work, and—last not least—that it enables one to transfer the gas sucked out to another vessel without loss or contamination, so that it can be measured and analysed. On account of this latter feature more especially, the instrument is highly valued as an auxiliary in gasometric researches. Without it the researches on which rests our present knowledge of the gases of the blood could not have been carried out. The actual instrument, as constructed for various kinds of work, has of course various complexities of detail omitted in the above description. For these the reader must refer to handbooks of practical physiology.

As it takes a height of about 30 inches of mercury to balance the pressure of the atmosphere, a Geisler pump necessarily is a somewhat long-legged and unwieldy instrument. It can be considerably shortened, the two vessels A and B brought more closely together, and the somewhat objectionable india-rubber tube be dispensed with, if we connect the air-space in B with an ordinary air-pump, and by means of it do the greater part of the sucking and the whole of the lifting work. An instrument thus modified was constructed by Poggendorff (see his *Annalen*, vol. cxxv. p. 151, 1865), and another, on somewhat different principles, by Prof. Dittmar (see the "*Challenger*" *Reports*).

Even a Geisler's stop-cock requires to be lubricated to be absolutely gas-tight, and this occasionally proves a nuisance. Hence a number of attempts have been made to do without stop-cocks altogether. In Töpler's pump[1] this is attained by using both for the inlet and the outlet vertical capillary glass tubes, soldered, the former to somewhere near the bottom, the latter to the top of the vessel. These tubes, being more than 30 inches high, obviously act as efficient mercury-traps; but the already considerable height of the pump is thus multiplied by two. This consideration has led Alexander Mitscherlich (*Pogg. Ann.*, cl. 420, 1873), and quite lately F. Neisen (*Z. f. Instrumentenkunde*, 1882, p. 285) to introduce glass valves in lieu of stop-cocks. As glass floats on mercury, such valves do not necessarily detract from the exhaustive power of the pump.

2. *The Dynamic Pump.*—This was invented in 1865 by H. Sprengel. The instrument, in its original (simplest) form (fig. 3), consists of a vertical capillary glass tube *a* of about 1 mm. bore, provided with a lateral branch *b* near its upper end, which latter, by an india-rubber joint governable by a screw-clamp, communicates with a funnel. The lower end is bent into the shape of a hook, and dips into a pneumatic trough. The vessel to be exhausted is attached to *b*, and, in order to extract its gas contents, a properly regulated stream of mercury is allowed to fall through the vertical tube. Every drop of mercury, as it enters from the funnel, entirely closes the narrow tube like a piston, and in going past the place where the side tube enters entraps a portion of air and carries it down to the trough, where it can be collected. If the vertical tube, measuring from the point where the branch comes in, is a few inches greater than the height of the barometer, and the glass and mercury are perfectly clean, the apparatus slowly but surely produces an almost absolute vacuum.

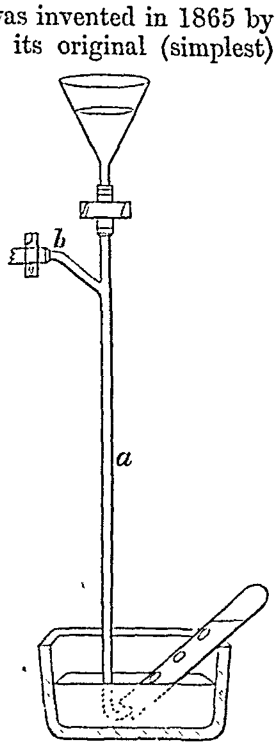

FIG. 3.—Sprengel's Air-Pump.

The great advantages of Sprengel's pump lie in the simplicity of its construction and in the readiness with which it adapts itself to the collecting of the gas. It did excellent service in the hands of Graham for the extraction of gases occluded in metals, and since then has become very popular in gas-laboratories, especially in Britain. Many improvements upon the original construction have been proposed. One of these which deserves mention is to pass the mercury, before it enters the "falling" tube, through a bulb in which a good vacuum is maintained, by means of an ordinary air-pump or a second "Sprengel." (W. D.)

MERCURY was the Roman god who presided over barter, trade, and all commercial dealings. His nature is probably more intelligible and simple than that of any other Roman deity. His very name, which is connected with *merx*, *mercator*, &c., shows that he is the god of merchandise and the patron of merchants. In the native Italian states no merchants and no trade existed till the influence of the Greek colonies on the coast introduced Greek customs into the cities of the land. All the usages and terminology of trade, and all the religious ceremonies connected with it, were borrowed by the Romans from the Greeks. It was no doubt under the rule of the Tarquins, when the prosperity of the state and its intercourse with the outer world were so much increased, that merchants began to ply their trade in Rome. Doubtless the merchants practised their religious ceremonies from the first, but their god Mercurius was not officially recognized by the state till the year 495 B.C. Rome frequently suffered from scarcity of corn during the unsettled times that followed the expulsion of the Tarquins. Various religious innovations were made to propitiate the gods; in 496 the Greek worship of Demeter, Dionysus, and Persephone was established in the city (see LIBER), and in 495 the Greek god HERMES (*q.v.*) was introduced into Rome under the Italian name of Mercurius (Livy, ii. 21, 27). Preller thinks that at the same time the trade in corn was regulated by law, and a regular college of merchants was instituted. This *collegium* was under the protection of the god; their annual festival was on the Ides of May, on which day the temple of the god had been dedicated at the southern end of the *circus maximus*, near the Aventine; and the members were called *mercuriales* as well as *mercatores*. The Ides of May was chosen as the feast of Mercury, obviously because Maia was the mother of Hermes, *i.e.*, of Mercury (see MAIA); and she was worshipped along with her son by the *mercuriales* on this day. According to Preller, this religious foundation had a political object; it established on a legitimate and sure basis the trade between Rome and the Greek colonies of the coast, whereas formerly this trade had been exposed to the capricious interference of the Government officials for the year. Like all borrowed religions in Rome, it must have retained the rites and the terminology of its Greek original (Festus, p. 257). Mercury became the god, not only of the *mercatores* and of the corn trade, but of buying and selling in general; and it appears that, at least in the streets where shops were common, little chapels and images of the god were erected. There was a spring dedicated to Mercury between his temple and the *Porta Capena*; every shopman drew water from this spring on the Ides of May, and sprinkled it with a laurel twig over his head and over his goods, at the same time entreating Mercury to remove from his head and his goods the guilt of all his deceits (Ovid, *Fasti*, v. 673 *sq.*). The art of the Roman tradesman was evidently like that of an Oriental tradesman in modern times, and the word *mercurialis* was popularly used as equivalent to "cheat." In the Latin poets Mercury is often gifted with some of the manifold characters of the Greek Hermes, but this finer conception seems to have had no real existence in Roman religion.

Roman statuettes of bronze, in which Mercury is represented, like the Greek Hermes, standing holding the caduceus in the one hand and a purse in the other, are exceedingly common. The caduceus must have been introduced as a symbol of Mercury at a very early time, for it is found on Italian coins as early as the 4th century before Christ, and we learn that several were kept as sacred objects in the *adytum* of the sanctuary at Lavinium (Dion. Hal., i. 67). But its foreign origin is shown by the fact that, although it was a sign of peace, it was never borne by the *fetiales*, the old Italian heralds. The very name is derived from the Greek κηρύκειον. Preller's view (*Röm. Myth.*) that *mercuriales* and *mercatores* are the same guild is a tempting one, but its truth is very doubtful. Mommsen thinks that *mercuriales* were a purely local guild, viz., the *pagani* of the Circus valley.

MERCURY, in chemistry, is a metal (symbol Hg) which is easily distinguished from all others by its being liquid at even the lowest temperatures naturally occurring in moderate climates. To this exceptional property it owes the synonyms of *quicksilver* in English (with the Germans *quecksilber* is the only recognized name) and of *hydrargyrum* (from ὕδωρ, water, and ἄργυρος, silver) in Græco-Latin.

[1] See *Dingler's Polytechn. Journal*, 1862; an improved form by Bessel-Hagen is described in *Wiedemann's Annalen*, xii. 425, 1881.

This metal does not appear to have been known to the ancient Jews, nor is it mentioned by the earlier Greek writers. Theophrastus (about 300 B.C.) mentions it as a derivative of cinnabar. With the alchemists it was a substance of great consequence. Being ignorant of its susceptibility of freezing into a compact solid, they did not recognize it as a true metal, and yet, on the authority of Geber, they held that mercury (meaning the predominating element in this metal) enters into the composition of all metals, and is the very cause of their metallicity. When, about the beginning of the 16th century, chemistry and scientific medicine came to merge into one, this same mysterious element of "mercury" played a great part in the theories of pathology; and the metal, in the free as in certain combined states, came to be looked upon as a powerful medicinal agent, which position, on purely empirical grounds, it continues to hold to the present day.

Mercury occurs in nature chiefly in the form of a red sulphide, HgS, called cinnabar, which, as a rule, is accompanied by more or less of the reguline metal,—the latter being probably derived from the former by some secondary reaction. The most important mercury mines in Europe are those of Almaden in Spain and of Idria in Illyria; these until lately furnished the bulk of the mercury of commerce, but they are now almost eclipsed by the rich deposits of New Almaden in California. Considerable quantities of mercury are said to be produced in China and in Japan; minor deposits are being worked in the Bavarian Palatinate, in Hungary, Transylvania, Bohemia, and Peru. At Almaden the ore forms mighty veins traversing micaceous schists of the older transition period; in Illyria it is disseminated in beds of bituminous schists or compact limestone of more recent date.

Chemically speaking, the extraction of mercury from its ores is a simple matter. Metallic mercury is easily volatilized, and separated from the gangue, at temperatures far below redness, and cinnabar at a red heat is readily reduced to the metallic state by the action of iron or lime or atmospheric oxygen, the sulphur being eliminated, in the first case as sulphide of iron, in the second as sulphide and sulphate of calcium, in the third as sulphurous acid gas. To the chemical mind a close iron retort would suggest itself as the proper kind of apparatus for carrying out these operations, but this idea is acted upon only in a few small establishments,—for instance, in that of Zweibrücken in the Palatinate, where lime is used as a decomposing agent. In all the large works the decomposition of the cinnabar is effected by the direct exposure of the ore to the oxidizing flame of a furnace, and the mercury vapour, which of course gets diffused through an immense mass of combustion gases, is sought to be recovered in more or less imperfect condensers.

At Almaden this roasting distillation is effected in prismatic furnaces, which, by a second upper (brick) grating are divided into two flats, the lower one serving for the generation of a wood fire, while the upper accommodates the ore, which is introduced through an opening in the dome-shaped roof. To avoid an excessive dilution of the mercury vapour with combustion gases, part of these are led out laterally into a chimney and the rest allowed to strike up through the heap of ore. The large mass of metalliferous vapour produced passes out through a system of pipes inserted laterally into the dome and so arranged that they follow first a descending and then an ascending plane, to lead ultimately into a condensation chamber which communicates in its turn with a chimney. The pipes are formed each of a large number of elongated pear-shaped earthenware adapters (called *aludels*), which are telescoped into one another as in the case of the iodine-distillation apparatus, the joints being luted with clay. The lowest row of aludels, which lie in the line of intersection of the two inclined planes, are pierced with holes below, so that what arrives as liquid mercury there runs out into a gutter leading to a reservoir. What of mercury vapour remains uncondensed in the aludels passes into the chamber, the intention being to have it condensed there; in reality a large proportion of the mercury passes out through the chimney (and through the numerous leaks in the aludels) into the atmosphere to poison the surrounding vegetation and the workmen. Similar furnaces to the Almaden ones are used in Idria and at New Almaden; only the condensation apparatus are a little less imperfect. But in all three places the loss of metal is very considerable; at New Almaden it is said to amount to close upon 40 per cent.

The mercury obtained is purified mechanically by straining it through dense linen bags, and then sent out into commerce in leather bags, or in wrought-iron bottles provided with screw plugs, each holding about 75 ℔ avoirdupois.

According to Balling's *Metallurgische Chemie* (Bonn, 1882), the production of mercury in the years named was as follows:—

Austria, exclusive of Hungary (1880)	369 tons.
Hungary (1879)	180 ,,
Italy (1877)	55 ,,
Spain (1873)	929 ,,
United States (1875)	2054 ,,

Assuming the amount to be the same from year to year, this gives a total of 3587 tons.

The price of the metal is subject to immense fluctuations; it generally ranges from 2s. to 7s. 6d. a pound avoirdupois.

Commercial mercury, as a rule, is very pure chemically, so that it needs only to be forced through chamois leather to become fit for all ordinary applications; but the metal, having the power of dissolving most ordinary other metals, is very liable to get contaminated with these in the laboratory or workshop, and requires then to be purified. For this purpose a great many chemical methods have been proposed, which, however, all come to this, that the base admixtures are sought to be removed by treatment with nitric acid, oil of vitriol, or other agents which act preferably on the impurities. The best of these methods is that of Brühl, who shakes the metal with a solution of 5 grammes of bichromate of potash and a few cubic centimetres of sulphuric acid in one litre of water, until the red chromate of mercury, first produced, has disappeared, and its place been taken by green chromic sulphates. The supernatant liquor and chromic scum are washed away by a powerful jet of water, and the clean metal is dried and filtered through a perforated paper filter. The only really exhaustive method is redistillation out of a glass apparatus. Unfortunately the operation is difficult of execution, as mercury "bumps" badly on boiling; but this can be avoided by distilling the metal in a *perfect* vacuum. An ingenious apparatus for this purpose, in which the distilled metal itself is made to keep up the vacuum, was constructed lately by Leonhard Weber. A U-tube, the limbs of which are longer than the height of the barometer, is filled with pure mercury, and inverted, the one limb being made to dip into a vessel with pure, the other into another containing the impure, mercury. This second limb is inflated above so that the meniscus is about the middle of the bulb. This bulb is heated, and the consequence is that the metal there distils over into the first limb to add to the supply of pure metal, the impure rising up in the second by itself to maintain a constant level. Dewar has modified the apparatus so that there is no need of a supply of pure metal to start with. Absolutely pure mercury does not at all adhere to any surface which does not consist of a metal soluble in mercury. Hence the least quantity of it, when placed on a sheet of paper, forms a neatly rounded-off globule, which retains its form on being rolled about, and, when subdivided, breaks up into a number of equally perfect globules. The presence in it of the minutest trace of lead or tin causes it to "draw tails." A very impure metal may adhere even to glass, and in a glass vessel, instead of the normal convex, form an irregular flat meniscus.

Properties.—The pure metal is silver-white, and retains its strong lustre even on long exposure to ordinary air. At $-38°\cdot8$ C., *i.e.*, $-37°\cdot9$ F. (Balfour Stewart), it freezes,

with considerable contraction, into a compact mass of regular octahedra, which can be cut with a knife and be flattened under the hammer. The specific gravity of the frozen metal is 14·39; that of the liquid metal at 0° C. is 13·595 (water of 4° C. = 1). Under 760 mm. pressure it boils at 357°·3 C. (675°·1 Fahr.) (Regnault). At very low temperatures it seems to be absolutely devoid of volatility (Faraday); but from −13° C. upwards (Regnault) it exhibits an appreciable vapour tension.

The following table gives the tensions "p," in millimetres of mercury of 0° C., for a series of centigrade temperatures "t," according to Regnault:—

t = 0°	10°	20°	50°	100°	150°	200°
p = ·02	·03	·04	·11	·75	4·27	19·90
t = 250°	300°	350°	400°	450°	500°	
p = 75·75	242·1	663·2	1588	3384	6520	

According to the same authority, its average coefficient of expansion k per degree C. is as follows:—

	0–100° C.	0–200° C.	0–300° C.
	k = ·0001815	·0001841	·0001866
or	1/5510	1/5432	1/5359

Its specific heat in the liquid state is ·03332; that of the frozen metal (between −78° and −40° C.) is ·0319 (Regnault). Its electric conductivity is $\frac{1}{57}$ of that of pure silver (Matthiesen). Its conductive power for heat is greater than that of water, and is proved (by Herwig) to be perfectly constant from 40° to 160° C. Its vapour density (air of the same temperature and pressure = 1) is 6·976 (Dumas), or 100·93 for hydrogen = 1. Hence its molecular weight (H_2 = 2) is 201·86. The atomic weight, by chemical methods, was found = 200·0 (Erdmann and Marchand); hence mercury-vapour molecules consist of single atoms. Mercury does not appreciably absorb any chemically inert gas.

Mercury is in constant requisition in the laboratory. It is used for the collecting and measuring of gases, in the construction of thermometers, barometers, and manometers, for the determination of the capacity of vessels, and many other purposes. In medicine it serves for the preparation of mercurial ointment and of "hydrargyrum cum creta" (the chief component of "blue pills"); both are obtained by diligently triturating the metal with certain proportions of grease and chalk respectively until it is "deadened," *i.e.*, subdivided into invisibly small globules (see below).

Alloys.—Mercury readily unites directly with all metals (except iron and platinum) into what are called amalgams. In some cases the union takes place with considerable evolution of heat and large modification of the mean properties of the components. Thus, for instance, sodium when rubbed up with mercury unites with it with deflagration and formation of an alloy which, if it contains more than 2 per cent. of sodium, is hard and brittle, although sodium is as soft as wax and mercury a liquid. Liquid amalgams of gold and silver are employed for gilding and silvering objects of copper, bronze, or other base metal. The amalgam is spread out on the surface of the object by means of a brush, and the mercury then driven off by the application of heat, when a polishable, firmly adhering film of the noble metal remains. Copper amalgam containing from 25 to 33 per cent. of the solid metal, when worked in a mortar at 100° C., becomes highly plastic, but on standing in the cold for ten or twelve hours becomes hard and crystalline. Hence it is used for the stuffing of teeth. A certain amalgam of cadmium is similarly employed.

Oxides.—There are two oxides of mercury, namely, an oxide, Hg_2O, called mercurous, and another, HgO, called mercuric oxide. The latter can be produced directly by keeping the metal for a long time in air at a temperature somewhat below its boiling point, when the oxide is gradually formed as a red powdery solid. This solid has long been known as "red precipitate," or as *mercurius præcipitatus per se.* Priestley made the important discovery that the "precipitate" when heated to dull redness is reduced to metal, with evolution of what has since been known as oxygen gas; but it was reserved for Lavoisier to correctly interpret this experiment, and thus to establish our present views on the constitution of atmospheric air. The oxide is easily prepared by heating any nitrate of the metal as long as nitrous fumes are seen to go off (when it remains as a scaly mass, black when hot, red after cooling), or else by precipitating the solution of a mercuric salt with excess of caustic potash or soda, when it comes down as an amorphous yellow precipitate, which is free of combined water. Mercurous oxide, a black solid, can be obtained only indirectly, by the decomposition of mercurous salts with fixed caustic alkalies. Both oxides are insoluble in water, but dissolve in certain, and combine with all, aqueous acids with formation of mercury salts and elimination of water. Thus, for instance,

$$Hg_2O + 2HNO_3 = H_2O + \underset{\text{Mercurous nitrate}}{Hg_2(NO_3)_2},$$

$$HgO + 2HNO_3 = H_2O + \underset{\text{Mercuric nitrate.}}{Hg(NO_3)_2}.$$

The Nitrates.—When metallic mercury is set aside with its own weight of nitric acid of 1·2 specific gravity, at ordinary temperatures, the normal mercurous salt $Hg_2(NO_3)_2$ is gradually produced, and after a day or two is found to have separated out in colourless crystals. These are soluble (somewhat sparingly) in water acidulated with nitric acid, but are decomposed by the action of pure water, with formation of difficultly soluble basic salts. When this salt (or the metal itself) is treated with excess of nitric acid it is oxidized into mercuric nitrate $Hg(NO_3)_2$, a white crystalline salt, readily soluble in water without decomposition.

The Sulphates.—Cold aqueous sulphuric acid does not act upon mercury, but the hot concentrated acid converts it first into mercurous and then into mercuric sulphate, with evolution of sulphurous acid.

$$Hg_2 + 2H_2SO_4 = 2H_2O + SO_2 + Hg_2SO_4,$$

$$Hg_2SO_4 + 2H_2SO_4 = 2H_2O + SO_2 + 2HgSO_4.$$

Both salts form white crystalline magmas. The mercurous salt is difficultly soluble in water, and consequently producible by precipitation of the nitrate with sulphuric acid. The mercuric salt, when treated with water, is decomposed with formation of a yellow insoluble basic salt, which has long been known as *turpethum minerale.* Its composition is $SO_3 . 3HgO$ when produced by excess of hot water. Mercuric sulphate is of importance chiefly as forming the basis for the manufacture of the two chlorides.

The Chlorides.—These are both extensively used medicinal agents. The mercuric salt, $HgCl_2$, known in medicine as corrosive sublimate, is prepared by mixing the sulphate intimately with common salt, and subjecting the mixture to sublimation, a little binoxide of manganese being added to oxidize the mercurous salt, which is generally present as an impurity. The process is conducted in a glass flask buried in a hot sand-bath. When the decomposition is accomplished, the sand is removed from the upper half of the flask and the temperature raised so that the chloride $HgCl_2$ produced sublimes up and condenses in the upper part as a "sublimate." The salt, as thus produced, forms compact crystalline crusts, which, when heated, melt into a limpid liquid before volatilizing. It is soluble in water, 100 parts of which at 10°, 20°, 100° dissolve 6·57, 7·39, 54 parts of salt. Corrosive sublimate dissolves in 3 parts of alcohol and in 4 parts of ether. This salt, on account of its solubility in water, is a deadly poison. Mercurous chloride, Hg_2Cl_2, better known as "calomel" (from καλός, fair, and μέλας, black, because it becomes dead-black when treated with ammonia, mercuric chloride yielding a white product), is prepared by mixing corrosive sublimate with the proper proportion of metallic mercury ($HgCl_2$: Hg) or mercuric sulphate with salt and mercury in the proportions of $HgSO_4$: Hg : 2NaCl, and subjecting the mixture to sublimation in glass flasks. The salt Hg_2Cl_2 is thus obtained in the form of white, opaque, crystalline crusts, which, when heated, volatilize, without previously melting, into a mixture of $HgCl_2$ and Hg vapour, which, on cooling, recombine into calomel. For medicinal purposes the sublimate is reduced to an impalpable powder, washed with water to remove any corrosive sublimate that may be present, and dried. Being insoluble in water, it acts far less violently on the organism than mercuric chloride does. Its action, no doubt, is due to its very gradual conversion in the stomach into mercury and corrosive sublimate. Finely divided calomel can be produced, without trouble, by the precipitation of a solution of mercurous nitrate with hydrochloric acid or common salt; but this preparation is liable to be contaminated with mercurous nitrate, and, even when pure, has been found to act far more violently than ordinary calomel does. Hence its use is not tolerated by the pharmacopœias. According to Wöhler a mercurous chloride, more nearly equivalent to the sublimed article, is producible by heating corrosive sublimate solution with sulphurous acid—

$$2HgCl_2 + H_2SO_3 + H_2O = H_2SO_4 + 2HCl + Hg_2Cl_2.$$

The writer is unable to say whether Wöhler's calomel has ever found its way anywhere into medicinal practice.

The Iodides.—The mercuric salt HgI_2 is produced in two ways, viz., first by mixing the two elementary components intimately and subjecting the mixture to sublimation, and secondly by precipitating corrosive sublimate solution with its exact equivalent of iodide of potassium. In the first case the salt is obtained in yellow crystals, which, on the slightest touch with a solid body, assume and then permanently retain a rich scarlet colour. The precipitation process at once yields the scarlet salt. The salt is insoluble in water, but soluble in alcohol and in iodide of potassium solution. The mercurous salt Hg_2I_2 is obtained by precipitating mercurous nitrate with iodide of potassium as a dirty-green powder insoluble in water. Both iodides are used medicinally.

The Sulphides.—Mercurous sulphide, Hg_2S, does not seem to exist. The mercuric salt, HgS, exists in two modifications, of which one is amorphous and has a black colour, while the other is crystalline and red. The black one is obtained by precipitation of solutions of mercuric salts with excess of sulphuretted hydrogen, or by direct synthesis. The right proportions of mercury and flowers of sulphur are rubbed together in a mortar until the whole is converted into a jet-black uniform powder. This preparation (the *æthiops mineralis* of the pharmaceutist), however, is apt to be contaminated with uncombined sulphur and mercury. Application of a gentle heat causes exhaustive combination. The red sulphide, HgS, occurs in nature as cinnabar, and can be produced artificially from the black. The artificial preparation, known as vermilion, is highly valued as the most brilliant, stable, and innocuous of all mineral red pigments. Vermilion can be produced from the black sulphide in two ways, viz., first by sublimation, and secondly by treatment of it with fixed alkaline sulphide solution. According to Brunner, 100 parts of mercury are mixed intimately with 38 parts of flowers of sulphur, and the æthiops is digested, with constant agitation, in a solution of 25 parts of potash in 150 parts of water at 45° C. (the water lost by evaporation being constantly replaced), until the preparation has come up to its maximum of fire and brilliancy, which takes a good many hours. Purely sublimed vermilion has a comparatively dull colour, and must be manipulated with alkaline sulphide solution to give it the necessary fire. The action of the alkaline sulphide consists probably in this, that it dissolves successive instalments of the amorphous preparation and redeposits them in the crystalline form.

Mercuric Derivatives of Ammonia.—(1) Recently precipitated oxide HgO is digested, cold, in carbonic-acid-free ammonia, and the mixture allowed to stand for a few days. The liquor is then decanted off, and the precipitate washed with alcohol and then with ether, and dried over sulphuric acid. The product is a yellow solid base ("Millon's base") of the composition

$$N_2H_6 + 4HgO + H_2O = N_2Hg_4O \,.\, 2H_2O + 2H_2O \,.$$

It is insoluble in alcohol and in ether, and requires 13,000 parts of cold water for its solution. It readily unites with all acids, forming salts, which, as a rule, are insoluble in water. Hence all ordinary salt solutions, when shaken with the base, are decomposed with elimination of the base of the salt. Thus, for instance, even such salts as alkaline nitrates, chlorides, or sulphates are decomposed with formation of solutions of caustic alkali.

(2) A body $N_2Hg_4I_2 + 2H_2O$, *i.e.*, of the composition of the iodide corresponding to the oxide in (1), is produced as a brown precipitate when ammonia or an ammonia salt is added to a solution of mercuric iodide in iodide of potassium mixed with large excess of caustic potash or soda ("Nessler's reagent"). In very dilute solutions of ammonia Nessler's reagent produces only a brown or yellow coloration, which, however, is so intense that $\frac{1}{20000000}$th of ammonia in about 50 cubic centimetres of liquid becomes clearly visible.

(3) The chloride $NH_2Hg \,.\, Cl$ of the "ammonium" NH_2Hg is produced as an insoluble white precipitate when ammonia is added to a solution of corrosive sublimate. This substance is known in medicine as infusible white precipitate, in contradistinction to (4).

(4) The fusible white precipitate was at one time supposed to be identical with (3), and is obtained by boiling it with sal-ammoniac solution. Its composition is $NH_2HgCl + NH_4Cl = N_2H_6 \,.\, Hg \,.\, Cl_2$.

Analysis.—Any ordinary solid mercury compound, when heated in a sublimation tube with carbonate of soda, yields a sublimate of metallic mercury, which, if necessary, needs only to be scraped together with a wooden spill to unite into visible globules. From any mercury-salt solution the metal is precipitated by digestion with a piece of bright copper-foil. The precipitated mercury forms a coating on the copper, which becomes silvery on being rubbed with blotting paper. When the quicksilvered copper is heated in a sublimation tube, it reassumes its red colour with formation of a sublimate of mercury.

Solutions of mercurous salts with hydrochloric acid give a white precipitate of calomel, which, after filtration, is easily identified by its becoming jet-black on treatment with ammonia. From mercuric solutions hydrochloric acid precipitates nothing; but stannous chloride, in its twofold capacity as a chloride and a reducing agent, yields a precipitate of calomel. On addition of an excess of reagent the precipitate becomes grey through conversion into finely divided quicksilver. Sulphuretted hydrogen, when added very gradually to an acid mercuric solution, gives at first an almost white precipitate, which, on addition of more and more reagent, assumes successively a yellow, orange, and at last jet-black colour. The black precipitate is HgS, which is identified by its great heaviness, and by its being insoluble in boiling nitric and in boiling hydrochloric acid. A mixture of the two (aqua regia) dissolves it as chloride. (W. D.)

Therapeutics of Mercury.

The use of mercury as a therapeutic agent is of comparatively recent date. To the Greeks and Romans its value was unknown, and the Arabian physicians only used it for skin affections. It was not till the middle of the 16th century that the special properties of mercury were fully appreciated, but since that time the metal has continued to hold a high though fluctuating value as a medicine. At first the metal in a finely divided state or in vapour was used; but very soon its various compounds were found to be endowed with powers even greater than those of the metal itself, and with the discovery of new compounds the number of mercurial medicines has largely increased.

The preparations now in use may be thus classified. (1) Of the preparations containing metallic mercury the chief members are blue pill (pilula hydrargyri), grey powder (hydrargyrum cum creta), and blue ointment (unguentum hydrargyri). The first consists of mercury, liquorice root, and confection of roses, the second of mercury and chalk, the third of mercury, suet, and lard. The power of the three preparations seems to depend on the fine state of subdivision of the mercury they contain; mercury in its ordinary liquid state seems devoid of medicinal properties. It is thought by some that the fine subdivision of the metal leads to the formation of a little oxide, and that the efficacy of the preparations in part depends on this. (2) Three oxides of mercury are employed in medicine,—the red, from which is made red precipitate ointment (unguentum hydrargyri oxydi rubri), the yellow, an allotropic form of the red, and the black oxide. The yellow and black oxides suspended in lime water form respectively yellow and black wash (lotio flava and lotio nigra). (3) The chlorides of mercury form a very important group: calomel (hydrargyri subchloridum) is a white heavy powder; corrosive sublimate (hydrargyri perchloridum) is a heavy crystalline substance. (4) Two iodides are used medicinally; they are known from their colour as the green and red iodides. (5) Nitrate of mercury enters into the composition of a powerful caustic known as the acid nitrate of mercury. It is also the active principle of citrine ointment (unguentum hydrargyri nitratis). (6) In this class only ammoniated mercury and its ointment commonly known as white precipitate ointment, are contained. Of the many compounds not included in the above classification the oleate and albuminate are the most important.

Mercurial preparations are largely employed as external applications. Several of them are potent agents for the destruction of the lower forms of animal life, and hence are employed to destroy parasites having their habitat in skin, hair, and clothing. The white and red precipitate ointments are specially effective in the destruction of pediculi, and blue ointment is occasionally used for the same purpose. Corrosive sublimate is, however, the most energetic of the mercurial parasiticides, and recent observations seem to show that it is superior to almost all other substances as a germ destroyer. It is sometimes used to get rid of ringworm. It should be remembered that corrosive sublimate is a powerful irritant to the skin, and also an active poison.

Acid nitrate of mercury is a caustic, and by it warts and small growths are sometimes removed; it is also one of the caustics occasionally applied to prevent the spread of lupus.

In skin diseases mercurial preparations are largely used, especially in some forms of eczema. A few grains of the red oxide or of ammoniated mercury in an ounce of zinc ointment are often found of great service in this ailment; citrine ointment is also useful.

Calomel ointment is not irritating, but rather tends to soothe. It is therefore sometimes applied to irritable rashes; in pruritus ani it is of special value. Mercurial preparations are not usually found of benefit in scaly eruptions. In acne a weak solution of corrosive sublimate is often most effective.

Preparations of mercury are often used to heal ulcers, especially those of syphilitic origin. Black wash is one of the commonest applications for this purpose. The red oxide ointment is at times employed to stimulate indolent ulcers, and it is capable of removing exuberant granulations (proud flesh), which sometimes retard the healing of wounds.

Mercury is largely used externally to promote the absorption of inflammatory products, especially in the neighbourhood of joints. The blue ointment is frequently employed for this purpose, more rarely a plaster containing mercury or a mercurial liniment. For effecting the absorption of goitre (Derbyshire neck) the ointment of the red iodide is often relied on, especially in India, where it is customary to expose the patient's neck to the sun after rubbing it with the ointment. In enlargements of the liver and spleen the application of mercurial ointment sometimes seems to promote reduction in size.

Taken internally in continued doses, mercury produces a peculiar effect known as salivation. First a metallic taste is experienced; this is followed by soreness of the gums, an undue flow of saliva, and fœtor of the breath. Further administration of the drug may increase greatly the salivary flow, and also lead to swelling of the tongue, ulceration of the mouth, and even disease of the jaw-bone. At the same time the blood becomes impoverished, and feverishness with loss of flesh occurs. A single large dose—rarely too a single small dose—may produce some of the above symptoms. They may also follow the inhalation of the metal or its compounds, or their absorption through the skin. The long-continued inhalation of the vapour of mercury acts likewise on the nervous system, causing a peculiar kind of trembling. Mercurial tremor is sometimes seen in looking-glass makers, often in those who work in quicksilver mines.

Internally mercury is chiefly given for two purposes—(1) to check inflammation and cause the absorption of the products it gives rise to, and (2) to antagonize the syphilitic virus and remove the evils it causes. Some years ago the belief in the power of mercury to control inflammation was almost universal, and it was largely administered in almost all inflammatory affections, but of late it has been much less used, both because it seems doubtful whether it has really the power it was once supposed to have and because of the possibility of evil results from its continued use. In peritonitis and iritis it is still often employed, small doses of calomel being given. Not unfrequently too it is administered in pericarditis and hepatitis, but in pneumonia, pleurisy, and most other inflammatory affections its use is now discarded by many physicians. As an antidote to the syphilitic poison it is still held in high esteem, though opinions vary much as to the extent of its power. There can be little doubt that, given in an early stage of the disorder, it minimizes the secondary symptoms; but it cannot be relied on to prevent their occurrence. It aids in removing the secondary symptoms, and tends to the avoidance of tertiary manifestations, which nevertheless sometimes occur even when mercury has been freely given. The custom of giving mercury till profuse salivation is established has long been abandoned; the aim now is so to give it as to prevent salivation occurring; for this purpose blue pill, calomel, and corrosive sublimate are given in very small doses, but if the gums become tender the dose is decreased or the administration stopped.

Mercurial treatment is sometimes carried out by rubbing the blue ointment into the skin, sometimes by exposing the patient to the fumes of calomel; syphilitic eruptions are often treated by such fumigation. More rarely mercury is introduced by injecting the albuminate or some other preparation under the skin or by means of suppositories. In children grey powder is generally used when mercurial treatment is required. Children bear mercury well.

Blue pill, calomel, and grey powder are often used as purgatives, and a power of promoting the secretion of bile is attributed to them. Experimentally it has not been proved that they stimulate the liver functions, but there is good reason for believing that they promote the expulsion of bile from the body. Grey powder is especially valued as a mild and efficient aperient for children, and is often given in the early stage of diarrhœa to expel the irritating contents of the bowel.

The use of calomel in tropical dysentery, once very prevalent, has within the last few years been abandoned. (D. J. L.)

MERGANSER, a word originating with Gesner (*Hist. Animalium*, iii. p. 129) in 1555, and for a long while used in English as the general name for a group of fish-eating Ducks possessing great diving powers, and forming the genus *Mergus* of Linnæus, now regarded by ornithologists as a Subfamily, *Merginæ*, of the Family *Anatidæ*. The Mergansers have a long, narrow bill, with a small but evident hook at the tip, and the edges of both mandibles beset by numerous horny denticulations, whence in English the name of "Saw-bill" is frequently applied to them. Otherwise their structure does not much depart from the Anatine or Fuliguline type. All the species bear a more or less developed crest or tuft on the head. Three of them, *Mergus merganser* or *castor*, *M. serrator*, and *M. albellus*, are found over the northern parts of the Old World, and of these the first two also inhabit North America, which has besides a fourth species, *M. cucullatus*, said to have occasionally visited Britain. *M. merganser*, commonly known as the Goosander, is the largest species, being nearly as big as the smaller Geese, and the adult male in breeding-attire is a very beautiful bird, conspicuous with his dark glossy-green head, rich salmon-coloured breast, and the upper part of the body and wings black and white. This full plumage is not assumed till the second year, and in the meantime, as well as in the post-nuptial dress, the male much resembles the female, having, like her, a reddish-brown head, the upper parts greyish-brown, and the lower dull white. In this condition the bird is often known as the "Dun Diver." This species breeds abundantly in many parts of Scandinavia, Russia, Siberia, and North America, and of late years has been found to do so in Scotland, usually making its nest in the stump of a hollow tree or under a slab of rock. *M. serrator*, commonly called the Red-breasted Merganser, is a somewhat smaller bird; and, while the fully-dressed male wants the delicate hue of the lower parts, he has a gorget of rufous mottled with black, below which is a patch of white feathers, broadly edged with black. The male at other times and the female always much resemble the preceding. It is more numerous than the Goosander, with a somewhat more southern range, and is not so particular in selecting a sheltered site for its nest. Both these species have the bill and feet of a bright reddish-orange, while *M. albellus*, known as the Smew, has these parts of a lead colour, and the breeding plumage of the adult male is white, with quaint crescentic markings of black, and the flanks most beautifully vermiculated—the female and male in undress having a general resemblance to the other two already described—but the Smew is very much smaller in size, and, so far as is known, it invariably makes its nest in a hollow tree, as ascertained first by Wolley (*Ibis*, 1859, pp. 69 *et seq.*). This last habit is shared by *M. cucullatus*, the Hooded Merganser of North America, in size intermediate between *M. albellus* and *M. serrator*, the male of which is easily recognizable by his broad semicircular crest, bearing a fan-shaped patch of white, and his elongated subscapulars of white edged with black. The conformation of the trachea in the male of *M. merganser*, *M. serrator*, and *M. cucullatus* is very like that of the Ducks of the genus *Clangula*, but *M. albellus* has a less exaggerated development more resembling that of the ordinary *Fuligula*.[1] From the southern hemisphere two species of *Mergus* have been described, *M. octosetaceus* or *brasilianus*, Vieillot (*N. Dict. d'Hist. Naturelle*, ed. 2, xiv. p. 222; *Gal. des Oiseaux*,

[1] Hybrids between, as is presumed, *M. albellus* and *Clangula glaucion*, the common Golden-eye, have been described and figured (Eimbeck, *Isis*, 1831, 300, tab. iii.; Brehm, *Naturgesch. aller Vög. Deutschlands*, p. 930; Naumann, *Vög. Deutschlands*, xii. p. 194, frontispiece; Kjærbölling, *Jour. für Ornithologie*, 1853, Extraheft, p. 29, *Naumannia*, 1853, p. 327, *Ornithol. Danica*, tab. lv., suppl. tab. 29) under the names of *Mergus anatarius*, *Clangula angustirostris*, and *Anas (Clangula) mergoides*, as though they were a distinct species; but the remarks of M. de Selys-Longchamps (*Bull. Ac. Sc. Bruxelles*, 1845, pt. ii. p. 354, and 1856, pt. ii. p. 21) leave little room for doubt as to their origin, which, when the cryptogamic habit and common range of their putative parents, the former unknown to the author last-named, is considered, will seem to be still more likely.

tom. ii. p. 209, pl. 283), inhabiting South America, of which but few specimens have been obtained, having some general resemblance to *M. serrator*, but much more darkly coloured, and *M. australis*, Hombron and Jacquemont (*Ann. Sc. Nat. Zoologie*, ser. 2, xvi. p. 320; *Voy. au Pol Sud, Oiseaux*, pl. 31, fig. 2), as yet known only by the unique example in the Paris Museum procured by the French Antarctic expedition in the Auckland Islands. This last species may perhaps be found to visit New Zealand, and should certainly be looked for there.

Often associated with the Mergansers is the genus *Merganetta*, the so-called Torrent-Ducks of South America, of which three species are said to exist; but they possess spiny tails and have their wings armed with a spur. Whether they should be referred to the *Merginæ* or the *Erismaturinæ*—the Spiny-tailed Ducks proper—is a question that further investigation must decide. (A. N.)

MERGUI, a district of British Burmah, between 9° 58′ and 13° 24′ N. lat. It forms the southernmost district of the Tenasserim division, and is bounded on the N. by Tavoy, E. and S. by Siam, and W. by the Bay of Bengal, with an area of 7810 square miles. Two principal ranges cross Mergui from north to south, running almost parallel to each other for a considerable distance, with the Tenasserim river winding between them till it turns south and flows through a narrow rocky gorge in the westernmost range to the sea. Amongst these mountain ranges and their subsidiary spurs are several fertile plains, densely clothed with luxuriant vegetation. Indeed, the whole district, from the water's edge to the loftiest mountain on the eastern boundary, may be regarded as almost unbroken forest, only 73 square miles being under cultivation. The timber trees found towards the interior, and on the higher elevations, are of great size and beauty, the most valuable being teak, *then-gan* (*Hopea odorata*), *ka-gnyeng* (*Dipterocarpus tuberculatus*), &c. The coast-line of the district, studded with an archipelago of two hundred and seven islands, is much broken, and for several miles inland is very little raised above sea-level, and is drained by numerous muddy tidal creeks. Southwards of Mergui town it consists chiefly of low mangrove swamps alternating with small fertile rice plains. After passing the mangrove limits, the ground to the east gradually rises till it becomes mountainous, even to the banks of the rivers, and finally culminates in the grand natural barrier dividing British Burmah from Assam. The four principal rivers are the Tenasserim, Le-gnya, Pakchan, and Palouk, the first three being navigable for a considerable distance of their course. Coal is found in the district on the banks of the Tenasserim and its tributaries. Gold, copper, iron, and manganese are also found in various parts of the district.

From the notices of early travellers it appears that Mergui, when under Siamese rule, before it passed to the Burmese, was a rich and densely peopled country. On its occupation by the British in 1824–25 it was found to be almost depopulated—the result of border warfare and of the cruelties exercised by the Burmese conquerors. At that time the entire inhabitants only numbered 10,000; in 1876 they had increased to 51,846 (26,767 males and 25,079 females). Classified according to religion, there were—Buddhists, 48,750; Mohammedans, 2533; Hindus, 353; Christians and others, 210. The district contains only one town (Mergui) with more than 5000 inhabitants. Only 73 square miles of the district area were under cultivation in 1876, but this area is steadily though slowly increasing. The principal manufactures are sugar-boiling and tin-smelting. Mergui carries on a flourishing trade with Rangoon, Bassein, and the Straits Settlements. The chief exports consist of rice, rattans, torches, dried fish, areca-nuts, sesamum seeds, molasses, sea-slugs, edible birds' nests, and tin. The staple imports are piece goods, tobacco, cotton, earthenware, tea, and sugar. The imperial revenue in 1876 amounted to £18,208. The climate is remarkably healthy, the heat due to its tropical situation being moderated by land and sea breezes. The rainfall in 1876 amounted to 165¼ inches. The prevalent diseases are simple and remittent fevers, bronchitis, rheumatism, and small-pox.

MERGUI, chief town of the above district, is situated on an island at the mouth of the Tenasserim river. The population (10,731 in 1876–77) consists of many races—Talaings, Burmese, Malays, Bengalis, Madrasis, Siamese, and Chinese. Considerable trade is carried on with other Burmese ports and the Straits Settlements. The harbour admits vessels drawing 18 feet of water.

MÉRIDA, a city of 7390 inhabitants (1877), in the province of Badajoz, Spain, lies about 36 miles by rail eastward from Badajoz, on the Madrid and Badajoz line, on a small eminence on the right bank of the Guadiana. It is connected by a branch line of rail with Llerena on the south-east. The population is mostly agricultural. The city owes its interest entirely to its Roman remains, which are numerous and extensive. Of these one of the most important is the bridge of 81 arches of granite, erected by Trajan; it is 2575 feet long, 26 feet broad, and 33 feet above the bed of the river; it was unfortunately seriously injured during the siege of Badajoz in 1812. Of the colossal wall that formerly surrounded the town all that remains is a fine fragment, built of dressed stone, on the spot formerly occupied by the castellum, and where the provisor of the order of Santiago afterwards had his residence (El Conventual). In the town are some relics of temples of Diana, Mars, Fortuna, Jupiter, and others; and the Arco de Santiago, 44 feet high, also dates from Trajan's time; it has unfortunately been stripped of its marble casing. Of the aqueduct from the laguna of Albuera thirty-seven enormous piers are still standing, with ten arches in three tiers built of brick and granite. To the east of the city is the circus, measuring some 1356 by 335 feet; the eight rows of seats still remain. Further eastward is the almost perfect theatre, and near it are the remains of the amphitheatre, or, as some prefer to call it, naumachia (Baño de los Romanos).

Augusta Emerita was built in 25 B.C. by the emeriti of the fifth and tenth legions who had served in the Cantabrian war under Augustus. It rose to great splendour and importance as the capital of Lusitania. During the Gothic period it became an episcopal see, and several provincial councils known to history were held there. It was taken by Músa in 711, and reconquered by Alphonso in 1228.

MERIDA, the capital of the Mexican state of Yucatan, stands in a great plain in the north of the peninsula, on a surface of limestone rock, about 25 miles from the port of Progreso on the Gulf of Mexico, with which it is connected by a railway opened in 1880. It is a well-built city, with broad streets and squares; and the flat-roofed stone houses, after the style introduced by the Spaniards, give a Moorish colour to the general view. Besides the cathedral, an imposing edifice of the 16th century, the bishop's palace, and the Government house (all of which are situated in the principal square), the most notable building is the Franciscan monastery (1547–1600), which once harboured within its high and turreted walls no fewer than two thousand friars, but has been allowed to fall into complete decay since their expulsion in 1820. For a long time Merida has had the reputation of being one of the principal seats of culture in Mexico; and it possesses, besides the ecclesiastical seminary, schools of law, medicine, and pharmacy, a literary institute, a public library, a theatre, and a considerable number of periodical publications. Commercially it has shared in the prosperity which Yucatan in recent years owes to the development of the Sisal hemp trade; and its manufactures embrace cotton goods, cigars, sugar, and rum. The population, estimated about 1840 as 25,000, was found in 1871 to number 33,025. The Mayas still form numerically the strongest element. Previous to the Spanish conquest the site of Merida was occupied by the Maya town of Tehoo, which contained so great a number of artificial stone-mounds that the new-comers had abundant material for all their buildings. The foundation of the

city dates from 1542, and it was made a bishopric in 1561. Compare Stephen's *Yucatán.*

MERIDEN, a city of the United States, in New Haven county, Connecticut, 18 miles from New Haven by rail. It is a busy manufacturing town; the population has increased from 3559 in 1850 to 7426, 10,495, and 18,340 in 1860, 1870, and 1880. The Britannia Company alone employs upwards of 1000 hands, and sends out every year nearly $3,000,000 worth of Britannia metal and electro-plated goods; and tin-ware, cutlery, brass-work, flint glass, guns, and woollen goods are also manufactured in the town. The State reform school had 307 inmates in 1880. A fortified tavern erected by Belcher in 1660 on the road between Boston and New Haven was the nucleus of Meriden; but the place was not incorporated as a town till 1866, and became a city in 1867.

MÉRIMÉE, PROSPER (1803–1870), novelist, archæologist, essayist, and in all these capacities one of the greatest masters of French style during the century, was born at Paris on September 28, 1803, and died at Cannes on the 23d of the same month sixty-seven years later, having lived just long enough to know that ruin was threatening France. Not many details have been published in reference to his family, but his father seems to have been a man of position and competence. Mérimée had English blood in his veins on the mother's side, and was always considered, at least in France, to look and behave more like an Englishman than a Frenchman. He was educated for the bar, but entered the public service instead. A young man at the time of the romantic movement, he felt its influence strongly, though his peculiar temperament prevented him from joining any of the côteries of the period. This temperament was indeed exhibited by the very form and nature of the works in which he showed the influence of romanticism. Nothing was more prominent among the romantics than the fancy, as Mérimée himself puts it, for "local colour," the more unfamiliar the better. Mérimée exhibited this in an unusual way. In 1825 he published what purported to be the dramatic works of a Spanish lady, Clara Gazul, with a preface stating circumstantially how the supposed translator, one Joseph L'Estrange, had met the gifted poetess at Gibraltar. This was followed by a still more audacious and still more successful *supercherie.* In 1827 appeared a small book entitled *La Guzla* (the anagram of Gazul), and giving itself out as translated from the Illyrian of a certain Hyacinthe Maglanovich. This book, which has greater formal merit than *Clara Gazul*, is said to have taken in Sir John Bowring, a competent Slav scholar, the Russian poet Poushkin, and some German authorities, although not only had it no original, but, as Mérimée declares, a few words of Illyrian and a book or two of travels and topography were the author's only materials. In the next year appeared a short dramatic romance, *La Jacquerie*, in which all Mérimée's characteristics are visible—his extraordinary faculty of local and historical colour, his command of language, his grim irony, and a certain predilection for tragic and terrible subjects which was one of his numerous points of contact with the men of the Renaissance. This in its turn was followed by a still better piece, the *Chronique de Charles IX.*, which stands towards the 16th century much as the *Jacquerie* does towards the Middle Ages. All these works were to a certain extent second-hand, being either directly imitated or prompted by a course of reading on a particular subject. But they exhibited all the future literary qualities of the author save the two chiefest, his wonderfully severe and almost classical style, and his equally classical solidity and statuesqueness of construction. For the latter there was not much opportunity in their subjects, and the former required a certain maturity and self-discipline which Mérimée had not yet given to himself. These were, however, displayed fully in the famous Corsican story of *Colomba*, published in the momentous year 1830. This, all things considered, is perhaps Mérimée's best tale.

He had already obtained a considerable position in the civil service, and after the revolution of July he was *chef de cabinet* to two different ministers. He was then appointed to the more congenial post of inspector of historical monuments. Mérimée was a born archæologist, combining linguistic faculty of a very unusual kind with the accurate scholarship which does not always accompany it, with remarkable historical appreciation, and with a sincere love for the arts of design and construction, in the former of which he had some practical skill. In his official capacity he published numerous reports, some of which, with other similar pieces, have been republished in his works. He also devoted himself to history proper during the latter years of the July monarchy, and published numerous essays and works of no great length, chiefly on Spanish, Russian, and ancient Roman history. He did not, however, neglect novel writing during this period, and numerous short tales, almost without exception masterpieces, appeared, chiefly in the *Revue de Paris.* He travelled a good deal, both for his own amusement and on official errands; and in one of his journeys to Spain, about the middle of Louis Philippe's reign, he made an acquaintance destined to influence his future life not a little—that of Madame de Montijo, mother of the future empress Eugenie. Mérimée, though in manner and language the most cynical of men, was a devoted friend, and shortly before the accession of Napoleon III. he had occasion to show this. His friend Libri was accused of having stolen valuable manuscripts and books from French libraries, and Mérimée took his part so warmly that he was actually sentenced to and underwent fine and imprisonment. He had been elected of the Academy in 1844, and also of the Academy of Inscriptions, of which he was a prominent member. Between 1840 and 1850 he wrote more tales, the chief of which were *Arsène Guillot* and *Carmen.*

The empire made a considerable difference in Mérimée's life. He was not a very ardent politician, but all his sympathies were against democracy, and he had therefore no reason to object to the Bonapartist rule, especially as his habitual cynicism and his irreligious prejudices made legitimism distasteful to him. But the marriage of Napoleon III. with the daughter of Madame de Montijo at once enlisted what was always the strongest of Mérimée's sympathies—the sympathy of personal friendship—on the emperor's side. He was made a senator, and continued to exercise his archæological functions; but his most important rôle was that of a constant and valued private friend of both the "master and mistress of the house," as he calls the emperor and empress in his letters. He was occasionally charged with a kind of irregular diplomacy, and once, in the matter of the emperor's *Cæsar*, he had to pay the penalty frequently exacted from great men of letters by their political or social superiors who are ambitious of literary reputation. But for the most part he was strictly the "ami de la maison." At the Tuileries, at Compiègne, at Biarritz, he was a constant though not always a very willing guest, and his influence over the empress was very considerable and was fearlessly exerted, though he used to call himself, in imitation of Scarron, "le bouffon de sa majesté." His occupations during the last twenty years of his life were numerous and important, though rather nondescript. He found, however, time for not a few more tales, of which more will be said presently, and for two correspondences, which are not the least of his literary achievements, while they have an extraordinary interest of matter. One of these consists

of the letters which have been published as *Lettres à une Inconnue*, the other of the letters addressed to Sir Antonio Panizzi, the late librarian of the British Museum. Various, though idle and rather impertinent, conjectures have been made as to the identity of the *inconnue* just mentioned. It is sufficient to say that the acquaintance extended over many years, that it partook at one time of the character of love, at another of that of simple friendship, and that Mérimée is exhibited under the most surprisingly diverse lights, most of them more or less amiable, and all interesting. The correspondence with Panizzi has somewhat less personal interest. Mérimée made the acquaintance originally by a suggestion that his correspondent should buy for the Museum some MSS. which were in the possession of Stendhal's sister, and for some years it was chiefly confined to correspondence. But Mérimée often visited England, where he had many friends (among whom the late Mr Ellice of Glengarry was the chief), and certain similarities of taste drew him closer to Panizzi personally, while during part of the empire the two served as the channel for a kind of unofficial diplomacy between the emperor and certain English statesmen. These letters are full of shrewd *aperçus* on the state of Europe at different times. Both series abound in gossip, in amusing anecdotes, in sharp literary criticism, while both contain evidences of a cynical and Rabelaisian or Swiftian humour which was very strong in Mérimée. This characteristic is said to be so prominent in a correspondence with another friend, which now lies in the library at Avignon, that there is but little chance of its ever being printed. A fourth collection of letters, of much inferior extent and interest, has been printed by M. Blaze de Bury under the title of *Lettres à une autre Inconnue*. In the latter years of his life Mérimée suffered very much from ill health. It was necessary for him to pass all his winters at Cannes, where his constant companions were two aged English ladies, friends of his mother. The terrible year found him completely broken in health, and anticipating the worst for France. He lived long enough to see his fears realized, and to express his grief in some last letters, and he died on September 23, 1870.

Mérimée's character (which has been unwarrantably slandered by those to whom political differences or his sarcastic intolerance of "pose" in literature made him obnoxious) was a peculiar and in some respects an unfortunate one, but by no means unintelligible, and perhaps in a minor degree not uncommon. Partly by temperament, partly it is said owing to some childish experience, when he discovered that he had been duped and determined never to be so again, not least owing to the example of Beyle, who was a friend of his family, and of whom he saw much, Mérimée appears at a comparatively early age to have imposed upon himself as a duty the maintenance of an attitude of sceptical indifference and sarcastic criticism. He certainly succeeded. Although, as has been said, a man of singularly warm and affectionate feelings, he obtained the credit of being a cold-hearted cynic; and, although he was both independent and disinterested, he was abused as a hanger-on and toad-eater of the imperial court. Both imputations were wholly undeserved, and indeed were prompted to a great extent by the resentment felt by his literary equals on the other side at the cool ridicule with which he met them. But he deserved in some of the bad as well as many of the good senses of the term the phrase which we have applied to him of a man of the Renaissance. He had the warm partisanship and amiability towards friends and the scorpion-like sting for his foes, he had the ardent delight in learning and especially in matters of art and belles lettres, he had the scepticism, the voluptuousness, the curious delight in the contemplation of the horrible, which marked the men of letters of the humanist period. Like them he was a man of the world, and a man who without any baseness liked a king's palace better than a philosopher's hovel. Like them he had an acute judgment in matters of business, and like them a singular consciousness of the nothingness of things. Even his literary work has this Renaissance character. It is tolerably extensive, amounting to some seventeen or eighteen volumes, but its bulk is not great for a life which was not short, and which was occupied at least nominally in little else. About a third of it consists of the letters already mentioned, which will always be to those who delight in personal literature the most attractive part, and which, though in a fragmentary fashion, are really important as throwing side lights on history. Rather more than another third consists of the official work which has been already alluded to—reports, essays, short historical sketches, the chief of which latter is a history of Pedro the Cruel, and another of the curious pretender known in Russian story as the false Demetrius. Some of the literary essays, such as those on Beyle, on Turguenief, &c., where a personal element enters, are excellent. Against others and against the larger historical sketches—admirable as they are—M. Taine's criticism that they want life has some force. They are, however, all marked by Mérimée's admirable style, by his sound and accurate scholarship, his strong intellectual grasp of whatever he handled, his cool unprejudiced views, his marvellous faculty of designing and proportioning the treatment of his work. It is, however, in the remaining third of his work, consisting entirely of tales either in narrative or in dramatic form, and especially in the former, that his full power is perceived. He translated a certain number of things (chiefly from the Russian); but his fame does not rest on these, on his already-mentioned youthful supercheries, or on his later semi-dramatic works. There remain about a score of tales extending in point of composition over exactly forty years, and in length from that of *Colomba*, the longest, which fills about one hundred and fifty pages, to that of *L'Enlèvement de la Redoute*, which fills just half a dozen. They are unquestionably the best things of their kind written during the century, the only *nouvelles* that can challenge comparison with them being the very best of Gautier, and one or two of Balzac. The motives are sufficiently different. In *Colomba* and *Mateo Falcone*, the Corsican point of honour is drawn on; in *Carmen* (written apparently after reading Borrow's Spanish books), the gipsy character; in *La Vénus d'Ille* and *Lokis* (two of the finest of all), certain grisly superstitions, in the former case that known in a milder form as the ring given to Venus, in the latter a variety of the were-wolf fancy. *Arsène Guillot* is a singular satire full of sarcastic pathos on popular morality and religion; *La Chambre Bleue*, an 18th-century *conte*, worthy of Crébillon for grace and wit, and superior to him in delicacy; *The Capture of the Redoubt* just mentioned is a perfect piece of description; *L'Abbé Aubain* is again satirical; *La Double Méprise* (the authorship of which was objected to Mérimée when he was elected of the Academy) is an exercise in analysis strongly impregnated with the spirit of Stendhal, but better written than anything of that writer's. These stories, with his letters, assure Mérimée's place in literature at the very head of the French prose writers of the century. He had undertaken an edition of Brantôme for the Bibliothèque Elzévirienne, but it was never completed.

Mérimée's works have only been gradually published since his death. The latest, *The Letters to Panizzi*, which have also appeared in English, bears date 1881. There is as yet no uniform or handsome edition, but almost everything is obtainable in the collections of MM. Charpentier and Calmann Lévy. (G. SA.)

MERINO. See SHEEP and WOOL.

MERIONETH (Welsh *Meirionydd*), a maritime county of North Wales, is bounded N. by Carnarvon and Denbigh, S.E. by Denbigh and Montgomery, and W. by Cardigan Bay. It is triangular in shape, its greatest length north-east to south-west being 45 miles, and its greatest breadth north-west to south-east about 30 miles. The area is 385,291 acres, or about 600 square miles. Next to Carnarvon, Merioneth is the most mountainous county in Wales. If the scenery is less bold and striking than that of Carnarvon, it excels it in richness, variety, and picturesque beauty. Its lofty mountains are interpenetrated by dark deep dells or smiling vales. The outlines of its rugged crags are softened and adorned by rich foliage. The sea views are frequently fine, and rivers, lakes, and waterfalls add a romantic charm to the valleys. The highest summits in the county are the picturesque Cader Idris (which divides into three peaks,—one, Pen-y-Gadair, having an altitude of 2914 feet), Aran Fawddwy (2955), Arenig-fawr (2818), Moel-wyn (2566), Rhobell-fawr (2360). The finest valleys are those of Dyfi, Dysyni, Talyllyn, Mawddach, and Festiniog. The river Dyfrdwy or Dee rises 10 miles north-west of Bala, and, after passing through Bala Lake, flows north-east by Corwen to Denbighshire. The Dyfi rises in a small lake near Aran Fawddwy, and expands into an estuary of Cardigan Bay. The Mawddach or Maw, from the north of Aran Fawddwy, has a course of 12 miles south-west, during which it is joined by several other streams. The Dwyryd and other streams unite in forming the estuary of Traeth Bach. The finest waterfalls are the

Rhaiadr-y-Glyn near Corwen, Rhaiadr Du, and Pistyll Cain, the latter 150 feet high. The lakes are very numerous, but small, the largest being Bala Lake, or Pimblemere (in Welsh, Llyn Tegid, fair lake), 4 miles long by 1 broad, and Llyn Mwyngil (lake in a sweet nook) in the vale of Talyllyn. Both are much frequented by anglers. On account of frequent indentations the coast-line is about 100 miles long. Sandy beaches intervene between the rocky shores. Frequent shoals and sandbanks render navigation very dangerous. There are only two harbours of importance, Barmouth and Aberdovey.

A mountain tract of the county 15 miles from north to south by 10 from east to west, stretching from the coast inland, is of the Cambrian age, composed of grits, quartzose, and slates, and comprising the Merionethshire anticlinal. This tract is enclosed on the north, east, and south by the Menevian, Lingula, Tremadoc, and Arenig beds, which are pierced by numerous dykes and intrusive masses, mostly greenstone. Rhobell-fawr is one of the greatest igneous masses in the whole area of the Lingula beds. The Arenig beds are interstratified with and overlaid by accumulations of volcanic ashes, felspathic traps, or lava flows, which form the rugged heights of Cader Idris, the Arans, the Arenigs, Manod, and Moel-wyn; and these are in turn overlaid by the Llandeilo and Bala beds, the latter including the Bala limestone. Extensive slate quarries are worked near Festiniog, mostly underground, in strata of the Llandeilo age, giving employment to about 4000 men. Gold, lead, copper, and manganese have been obtained in various places.

Climate and Agriculture.—The climate varies much with the elevation, in some places being bleak and cold, and in others remarkably equable and genial. At Aberdovey it is proverbially mild, and the myrtle grows in the open air. All attempts to introduce fruits have proved abortive in most parts of the county. The soil is generally thin and poor, with fertile tracts in the valleys. A great portion of the moss has been reclaimed within late years.

According to the agricultural returns for 1882, there were 154,406 acres, or considerably less than half the total area, under cultivation. Of this as much as 119,133 acres were permanent pasture, and 13,755 under rotation grasses. Of the 17,312 acres under corn crops, 11,232 were under oats and 4807 under barley. Potatoes occupied 2392 acres, and turnips only 1496 acres. The area under woods extended to 15,049 acres.

The total number of horses in 1882 was 6088. A breed of ponies is peculiar to this county and Montgomeryshire. The rearing of horned cattle and dairy-farming are largely carried on, but the number of cattle (37,643) is considerably under the average of Wales generally. On the other hand the number of sheep in 1882 was 400,553, a larger number than in any other county of Wales, and much beyond the general average in the principality. They are a small hardy breed, which grow heavy fleeces. Goats frequent the loftier crags.

According to the latest return the number of proprietors was 1695, possessing 303,374 acres, with a gross annual value of £183,253. Of the owners 1044, or 62 per cent., possessed less than 1 acre, the average extent of the properties being 189 acres, and the average value per acre a little over 12s. There were ten proprietors who possessed over 5000 acres, viz., Sir W. W. Wynn, 20,295; R. J. L. Price, 17,718; T. P. Lloyd, 16,975; Mrs Kirkby, 13,410; Hon. C. H. Wynn, 10,504; A. J. G. Corbet, 9347; Sir E. Buckley, 8738; W. E. Oakeley, 6018; W. O. Gore, 5497; and R. M. Rickards, 5701.

Manufactures.—Woollen goods are manufactured in various places, especially at Dolgelly. They are principally coarse druggets, kerseymeres, and flannels. The knitting of stockings was a great industry at the close of last century, the value of the sales at Bala being estimated at from £17,000 to £19,000 annually.

Railways.—The Cambrian Railway skirts the coast from Portmadoc to Aberdovey. At Barmouth Junction a branch of the same crosses to Dolgelly, where it is joined by a branch of the Great Western Railway. Another branch of the Great Western unites Bala and Festiniog, and the latter place has railway connexion both with Llandudno Junction and with Portmadoc.

Administration and Population.—Merionethshire comprises five hundreds and thirty-three civil parishes. It has one court of quarter sessions, and the number of petty sessional divisions is six. Ecclesiastically it is partly in the diocese of Bangor, partly in that of St Asaph. The county returns one member to parliament. There is no municipal or parliamentary borough. The towns returned in 1881 as urban sanitary districts are Bala (1653), Barmouth (1512), Dolgelly (2457), Festiniog (11,272), and Towyn (3363). Since 1801 the population has nearly doubled. From 29,506 in that year it had increased in 1851 to 38,963, in 1871 to 46,598, and in 1881 to 54,793, of whom 27,576 were males, and 27,217 females.

History and Antiquities.—Originally Merioneth belonged to the territory of the Ordovices, and under the Romans it was included in *Britannia Secunda.* There are many Celtic, Roman, and mediæval remains. Caer Drewyn on the Dee, near Corwen, was a British camp. There are numerous cromlechs in various parts of the county, especially near the sea-coast. The *Via Occidentalis* of the Romans passed through Merioneth from south to north, and at Tomen-y-Mur was joined by a branch of the South Watling Street, the Castell Tomen-y-Mur being supposed to be identical with the Roman station of Heriri Mons. The immense ruin of Castel-y-Bere was originally one of the largest castles in Wales, but has not been occupied since the time of Edward I. During the Wars of the Roses the castle of Harlech, still a fine ruin, was held by the Lancastrians, and was the last in Wales to surrender. Of ecclesiastical remains the most important is Cymmer Abbey, founded by the Cistercians in 1198, a very fine ruin containing architecture of various periods from Norman to Perpendicular. There are numerous interesting old churches.

MERLIN. See Falcon.

MERMAIDS AND MERMEN, in the popular mythology of England and Scotland, are a class of beings more or less completely akin to man, who have their dwelling in the sea, but are capable of living on land and of entering into social relations with men and women.[1] They are easily identified, at least in some of their most important aspects, with the Old German Meriminni or Meerfrau, the Icelandic Hafgufa, Margygr, and Marmennill (mod. Marbendill), the Danish Hafmand or Maremind, the Irish Merrow or Merruach, the Marie-Morgan of Brittany and the Morforwyn of Wales;[2] and they have various points of resemblance to the vodyany or water-sprite and the rusalka or stream-fairy of Russian mythology. The typical mermaid (who is much more frequently described than the merman) has the head and body of a woman, usually of exceeding loveliness, but below the waist is fashioned like a fish with scales and fins. Her hair is long and beautiful, and she is often represented, like the Russian rusalka, as combing it with one hand while in the other she holds a looking-glass. At other times, like the rusalka, she is seen engaged in the more prosaic occupation of washing or beating clothes; but this, as, for example, in Hugh Miller's terrible Loch Slin legend, is a sign of some impending calamity. For a time at least a mermaid may become to all appearance an ordinary human being; and from a very striking Irish legend ("The Overflowing of Lough Neagh and Liban the Mermaid," in Joyce's *Old Celtic Romances*) it is evident that a human being may also for a time be transformed into a mermaid.

The mermaid legends, both English and other, may be grouped as follows. A. *A mermaid or mermaids either voluntarily or under compulsion reveal things that are about to happen.* Thus the two mermaids (merewîp) Hadeburc and Sigelint, in the *Nibelungenlied*, disclose his future course to the hero Hagen, who, having got possession of their garments, which they had left on the shore, compels them to pay ransom in this way. According to Resenius, a mermaid appeared to a peasant of Samsöe, foretold the birth of a prince, and moralized on the evils of intem-

[1] The name *mermaid* is compounded of the A.-S. *mere*, a lake, and *mægd*, a maid; but, though *mere wif* occurs in Beowulf, *mere-maid* does not appear till the Middle English period (Chaucer, *Romaunt of the Rose*, &c.). In Cornwall the fishermen say *merry-maids* and *merry-men.* The connexion with the sea rather than with inland waters appears to be of later origin. "The Mermaid of Martin Meer" (Roby's *Traditions of Lancashire*, vol. ii.) is an example of the older force of the word; and such "meer-women" are known to the country-folk in various parts of England (*e.g.*, at Newport in Shropshire, where the town is some day to be drowned by the woman's agency).

[2] See Rhys, "Welsh Fairy Tales," in *Y Cymmrodor*, 1881, 1882.

perance, &c. (*Kong Frederichs den andens Krönike*, Copenhagen. 1680, p. 302). B. *A Mermaid imparts supernatural powers to a human being.* Thus in the beautiful story of "The Old Man of Cury" (in Hunt's *Popular Romances of the West of England*, 1871) the old man, instead of silver and gold, obtains the power of doing good to his neighbours by breaking the spells of witchcraft, chasing away diseases, and discovering thieves. John Reid, the Cromarty shipmaster, was more selfish,—his "wishes three" being that neither he nor any of his friends should perish by the sea, that he should be uninterruptedly successful in everything he undertook, and that the lady who scorned his love should scorn it no more. C. *A mermaid has some one under her protection, and for wrong done to her ward exacts a terrible penalty.* One of the best and most detailed examples of this class is the story of the "Mermaid's Vengeance" in Mr Hunt's book already quoted. D. *A mermaid falls in love with a human being, lives with him as his lawful wife for a time, and then, some compact being unwittingly or intentionally broken by him, departs to her true home in the sea.* Here, if its mermaid form be accepted, the typical legend is undoubtedly that of *Melusina*, which, being made the subject of a full-fledged romance by Jean d'Arras, became one of the most popular folk-books of Europe, appearing in Spanish, German, Dutch, and Bohemian versions. Melusina, whose name may be a far-off echo of the Mylitta (Venus) of the Phœnicians, was married to Raymond of Lusignan, and was long afterwards proudly recognized as one of their ancestors by the Luxembourg, Rohan, and Sassenaye families, and even by the emperor Henry VII. Her story will be found in Baring Gould's *Myths of the Middle Ages.* E. *A mermaid falls in love with a man, and entices him to go and live with her below the sea; or a merman wins the affection or captures the person of an earthborn maiden.* This form of legend is very common, and has naturally been a favourite with poets. Macphail of Colonsay successfully rejects the allurements of the mermaid of Corrievrekin, and comes back after long years of trial to the maid of Colonsay.[1] The Danish ballads are especially full of the theme; as "Agnete and the Merman," an antecedent of Matthew Arnold's "Forsaken Merman"; the "Deceitful Merman, or Marstig's Daughter"; and the finely detailed story of Rosmer Hafmand (No. 49 in Grimm).

In relation to man the mermaid is usually of evil issue if not of evil intent. She has generally to be bribed or compelled to utter her prophecy or bestow her gifts, and whether as wife or paramour she brings disaster in her train. In itself her sea-life is often represented as one of endless delights, but at other times a mournful mystery and sadness broods over it. The fish-tail, which in popular fancy forms the characteristic feature of the mermaid, is really of secondary importance; for the true Teutonic mermaid—probably a remnant of the great cult of the Vanir—had no fish-tail;[2] and this symbolic appendage occurs in such remote mythological regions as to give no clue to historical connexion. The Tritons, and, in the later representations, the Sirens of classical antiquity, the Phœnician Dagon, and the Chaldæan Oannes are all well-known examples: the Ottawas and other American Indians have their man-fish and woman-fish (Jones, *Traditions of the North American Indians*, 1830); and the Chinese tell stories not unlike our own about the sea-women of their southern seas (Dennis, *Folklore of China*, 1875).

Quasi-historical instances of the appearance or capture of mermaids are common enough,[3] and serve, with the frequent use of the figure on signboards and coats of arms, to show how thoroughly the myth had taken hold of the popular imagination.[4] A mermaid captured at Bangor, on the shore of Belfast Lough, in the 6th century, was not only baptized, but admitted into some of the old calendars as a saint under the name of Murgen (*Notes and Queries*, Oct. 21, 1882); and Stowe (*Annales*, under date 1187) relates how a man-fish was kept for six months and more in the castle of Orforde in Suffolk. As showing how legendary material may gather round a simple fact, the oft-told story of the sea-woman of Edam is particularly interesting. The oldest authority, Joh. Gerbrandus a Leydis, a Carmelite monk (*ob.* 1504), tells (*Annales*, &c., Frankfort, 1620) how in 1403 a wild woman came through a breach in the dike into Purmerlake, and, being found by some Edam milkmaids, was ultimately taken to Haarlem and lived there many years. Nobody could understand her, but she learned to spin, and was wont to adore the cross. Ocka Scharlensis (*Chronijk van Friesland*, Leeuw., 1597) reasons that she was not a fish because she could spin, and she was not a woman because she could live in the sea; and thus in due course she got fairly established as a genuine mermaid. Vosmaer, who has carefully investigated the matter, enumerates forty writers who have repeated the story, and shows that the older ones speak only of a woman (see "Beschr. van de zoogen. Meermin der stad Haarlem," in *Verh. van de Holl. Maatsch. van K. en Wet.*, part 23, No. 1786). As for the stuffed mermaids which have figured from the days of Bartholomew Fair downwards, it is enough to mention that exhibited in the Turf Coffee-house, London, in 1822, and carefully drawn by Cruikshank (compare Chambers, *Book of Days*).

The best account of the mermaid-myth is in Baring Gould's *Myths of the Middle Ages.* See also, besides works already mentioned, Pontoppidan, who in his logically credulous way collects much matter to prove the existence of mermaids; Maillet, *Telliamed*, Hague, 1755; Grimm, *Deutsche Mythologie*, i. 404, and *Altdän. Heldenlieder*, 1811; Waldron's *Description* and Train's *Hist. and Stat. Acc. of the Isle of Man*; Folklore Society's *Record*, vol. ii.; Napier, *Hist. and Trad. Tales connected with the South of Scotland*; Sébillot, *Traditions de la Haute Bretagne*, 1882, and *Contes des Marins*, 1882. (H. A. W.)

MEROE, in classical geography (Strabo, xvii. 2, 2; Pliny, ii. 73, v. 10; Ptol., p. 201), was the metropolis of Æthiopia, situated on an island of the same name between the Nile and the Astaboras (Atbara). The "island" is only an inaccurate name for the fertile plain between the two rivers. This Meroe, first mentioned by Herodotus (ii. 29 *sq.*), succeeded an older Ethiopian kingdom of Napata lower down the Nile, originally subject to and civilized from Egypt, but which afterwards became independent and even sent forth an Ethiopian dynasty to reign in Egypt, to which the So and Tirhaka of the Bible belonged (see ETHIOPIA). The name of Meroe in the form Merawi is now given to Napata. The later Meroe retained its independence when Egypt fell under foreign sovereigns. Diodorus (iii. 6) describes it as entirely controlled by the priesthood till a native prince Ergamenes destroyed the sacerdotal caste in the time of Ptolemy II. Queen Candace (Acts viii. 27) was probably sovereign of Meroe; see Lepsius's *Letters*, Eng. tr., pp. 196, 206; and comp. Strabo, xvii. 1, 54 for

[3] Compare the strange account of the quasi-human creatures found in the Nile given by Theophylactus, *Historiæ*, viii. 16, pp. 299-302 of Bekker's ed.

[4] See the paper in *Jour. Brit. Arch. Ass.*, xxxviii., 1882, by H. S. Cuming, who points out that mermaids or mermen occur in the arms of Earls Caledon, Howth, and Sandwich, Viscounts Boyne and Hood, Lord Lyttleton, and Scott of Abbotsford, as well as in those of the Ellis, Byron, Phené, Skeffington, and other families. The English heralds represent the creatures with a single tail, the French and German heralds frequently with a double one.

a Queen Candace in Augustus's time when the Romans under Petronius advanced to Napata. Meroe was visited by Greek merchants; and the astronomical expedition of Eratosthenes determined its latitude with great accuracy. An exploring party in the reign of Nero found that the country below Meroe, formerly the site of many towns, had become almost wholly waste (Pliny, vi. 29). From the 6th to the 14th century of our era the Christian (Jacobite) realm of Dongola occupied the place of the older kingdom. The ruins of Meroe and Napata were fully explored by Lepsius in 1844, and the monuments are pictured in his *Denkmäler*.

MERSEBURG, the chief town of a district of the same name in the Prussian province of Saxony, is situated on the river Saale, 10 miles to the south of Halle and 17 to the west of Leipsic. It consists of a quaint and irregularly built old town, with two extensive suburbs, and contains six churches and several schools and charitable institutions. The cathedral is an interesting old pile, with a Romanesque choir of the 11th, a transept of the 13th, and a Late Gothic nave of the 16th century. Among its numerous monuments is that of Rudolph of Swabia, who fell in 1080 in an encounter with his rival Henry IV. It contains two paintings by Lucas Cranach. Contiguous to the cathedral is the Gothic chateau, formerly the residence of the Saxon princes and the bishops of Merseburg. The town-house, the post-office, and the "ständehaus" for the meetings of the provincial estates are also noteworthy buildings. The industries of Merseburg consist of the manufacture of card-board and coloured paper, dyeing, glue-boiling, machine-making, calico-printing, tanning, and brewing. Its population in 1880 was 15,205.

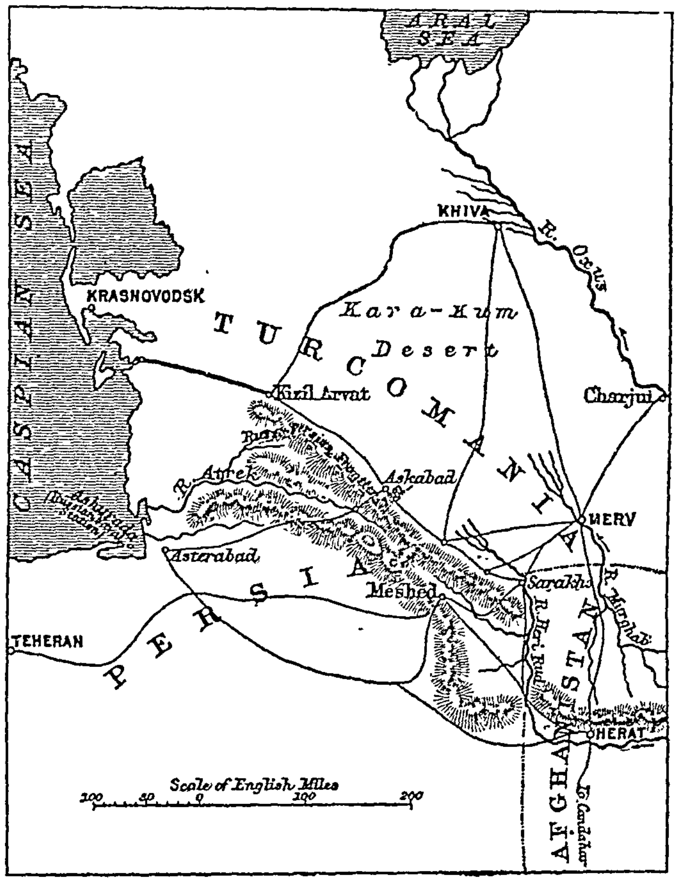
Merseburg (*i.e.*, "march-town") is one of the oldest towns in Germany. From the 9th century down to 1007 it was the capital of a countship of its own name, and from 968 to 1543 it was the seat of a bishop. In the 10th, 11th, and 12th centuries it was a favourite residence of the German emperors, and at this time its fairs enjoyed the importance afterwards inherited by those of Leipsic. The town was repeatedly visited by destructive conflagrations in the 14th to 17th centuries, and also suffered severely during the Thirty Years' War. From 1656 to 1738 it was the residence of the dukes of Saxe-Merseburg. The great victory gained by the emperor Henry I. over the Huns in 933 is believed to have been fought on the Keuschberg near Merseburg.

MERTHYR TYDFIL, or MERTHYR TYDVIL, a parliamentary borough and market-town of Glamorganshire, South Wales, is situated in a bleak and hilly region on the river Taff, and on several railway lines, 25 miles north-north-west of Cardiff and 30 east-north-east of Swansea. The town, which consists principally of the houses of workmen, is for the most part meanly and irregularly built, and at one time, on account of its defective sanitary arrangements, was frequently subject to epidemics of great severity. Within recent years great improvements have taken place, and the town now possesses both a plentiful supply of pure water and an excellent system of sewage. There are also some good streets with handsome shops, while in the suburbs there are a number of private residences and villas inhabited by the wealthier classes. Apart from its extensive iron and steel works, the town possesses no feature of interest. It is situated in the centre of the South Wales coal basin, and the rich coal-mines in the vicinity supply great facilities for the iron industries. At Merthyr Tydfil, which is said to have received its name from the martyrdom of a British saint Tydfil, there were smelting-works at a very early period, but none of any importance until 1755. From about forty years ago until 1875 the manufacture of bar iron developed with great rapidity, but since then the production of steel has largely taken its place. The borough returns two members to parliament. The population of the urban sanitary district in 1871 was 51,949, and in 1881 it was 48,857; the population of the parliamentary borough, which includes the parish of Aberdare and parts of the parishes of Llanwonno and Merthyr Tydfil and of Vainor (Brecon), and has an area of 29,954 acres, was in the same years 97,020 and 91,347.

MERV, MERU, or MAOUR,[1] a district of Central Asia, situated on the border-land of Iran and Turan.

The oasis of Merv lies in the midst of a desert, in about 37° 30′ N. lat. and 62° E. long. It is about 250 miles from Herat, 170 from Charjui on the Oxus, 360 from Khiva, and 175 from Gawars, the nearest point in the newly acquired (1881) Russian territory of Akhal.

The great chain of mountains which, under the name of Paropamisus and Hindu-Kush, extends across the Asiatic continent from the Caspian to China, and forms the line of ethnic demarcation between the Turanian and Indo-Germanic races, is interrupted at a single point; that point is on the same longitude with Merv. Through or near the



Neighbourhood of Merv.

trouée or gap which nature has created flow northward in parallel courses the rivers Heri-rud (Tejend) and Murghab, until they lose themselves in the desert of Kara-kum—that large expanse of waste, known also as Turcomania, which spreads at the northern foot of the mountains, and stretches from the lower Oxus to the Caspian.

Whether as a satrapy of Darius and subsequently as a province of Alexander, whether as the home of the Parthian race, whether as a bulwark against the destructive waves of Mongol invasion, or later as the glacis of Persian Khorasan, the valleys of those rivers—the district of Merv

[1] Merv is the modern Persian name. The river *Margus*, now the Murghab, on which was built the ancient city, is derived from *Margu*, the name of the province as recorded in the Behistan inscriptions of Darius. Spiegel connects the name *Margu* with old Bactrian *meregho*, bird, in allusion to the numerous swarms of birds that gather there. So, too, the river name Murghab means bird-water. The district appears to have been known in the 5th century as Marv-i-rud, so that the river was then the Marv. The name *Merûm* for the district occurs in the Armenian geography ascribed to Moses of Khorene, written probably in the 7th century (ed. Patkanoff). Maour is the Uzbek name, and of comparatively recent date.

—have ever been important outposts on the borders of Iran. In bye-gone epochs their banks have, under powerful rulers, been studded with populous and flourishing cities, which bore the name of "Sovereign of the Universe" (*Merv Shah-i-jehan*), and vied for fame with "Balkh, the Mother of cities"; of late times, with weakness or absence of government, those same banks have become choked with fallen battlements and ruins, the home of the snake and the jackal.

Merv has soared to prosperity or fallen to decay according to her political status at the moment, and history, which repeats itself, may yet have to sing her praises in the future as it has done in the past. All that human life in the desert requires is there,—water in abundance, and a soil unsurpassed for fertility. Good government is alone wanting to turn those natural gifts to full account.

The present inhabitants of the district are Turcomans of the Tekke tribe, who, like the other tribes inhabiting Turcomania, enjoyed until the approach of the Russians virtual independence, and acknowledged allegiance to no one,—a pastoral people who eked out a miserable existence by the trade of passing caravans, and in bad times pillaged the neighbouring and equally barbarous states, to whose reprisals they were in turn subjected.

From the year 1869, the date of the establishment of the Russian military settlement at Krasnovodsk on the east shore of the Caspian, the wave of Russian conquest has gradually swept eastwards along the northern frontier of Persia until it has for the moment stopped at the outermost border of the Akhal Turcoman country, which was incorporated in 1881 by Russia as the result of the defeat of that tribe at Geok Tepe. Among the districts still farther east, to which the Russians give the name of Eastern Turcomania, is that of the Merv Tekke Turcomans, kinsmen of the Akhal Tekkes, the most recent of Russia's subjects. The district of the Merv Tekkes may be taken to be that included between the lower Murghab below Yulutan, where the river enters the plain, and the Persian frontier from Sarakhs to Gawars.

A reference to the map will show the strategical importance of this district, situated at the point of meeting of two lines, of which one is the strategic line of Russian advance on Herat from Krasnovodsk to Sarakhs, and the other the strategic line of advance on the same place from Tashkend through Bokhara. The capital of the district is, moreover, the crossing-point of the Herat-Khiva and Meshed-Bokhara trade routes.

Consequently this district, a solitary oasis in a vast desert, guarantees to its possessor the command of an important avenue between north and south, and, in the event of its falling into Russian hands, will give that power in addition a valuable link in the chain of connexion between her recent acquisitions on the Persian frontier and those in Turkestan, the forging of which has been persistently advocated by Russian writers for years past. One of these, Colonel Veniukoff, frankly admits that it is the political results—"the consolidation of friendly relations with the Turcomans"—and not commercial interests merely, that are primarily looked to, and openly states that the forward movement in Central Asia "cannot end otherwise than by the annexation to Russia of the whole of Turan."

Whether by design or by the force of circumstances, the recommendations of those writers have been translated into facts, and Russia with her advanced post at Askabad is now within 400 miles of Herat, which Sir Henry Rawlinson designates as the key of India. The occupation of the Merv Tekke country would bring Russia to within 250 miles of Herat. From Askabad she is in connexion with the Caspian by a good line of communication, part of which from the sea to Kizil Arvat) is by rail; and hence facilities are offered for bringing up not only the resources of the Caucasus but of the whole of European Russia. While Russian troops are within 400 miles of Herat, the British troops at Quetta are more than 500 miles from Herat.[1]

These remarks serve to explain the very natural suspicion with which Great Britain has regarded the occupation one after another of important strategical points along that route by which alone Russia can strike at India,—the same line by which Napoleon meditated a Russo-French invasion in the early part of this century.

In the matter of Merv and the neighbouring Turcoman districts diplomacy has not been idle. As early as 1869, when an interchange of opinions was taking place between the Russian and British Governments with respect to the demarcation of a neutral zone between the two empires, Great Britain objected to the Russian proposal that this zone should be Afghanistan, "because of the near approach to India that would be thereby afforded to Russian troops from the direction of the Kara-kum, the home of the Turcomans, of which Merv is the central point." In the following year a Russian diplomatist remarked to the British ambassador at St Petersburg, when discussing the Afghan frontier, that great care would be required in tracing a line from *Khoja Saleh* on the *Oxus* to the south, as Merv and the country of the Turcomans were becoming "commercially important." About the same time Russia intimated that, if the amir of Afghanistan claimed to exercise sovereignty over the Tekkes, his pretensions could not be recognized. After the Russian campaign against Khiva in 1873, and the subsequent operations against the Turcomans, the English foreign secretary early in 1874 called attention "to the fears expressed by the amir of Afghanistan as to the complications in which he might become involved with Russia were the result of a Russian expedition against Merv to be to drive the Turcomans to take refuge in the province of Badghees in Herat." In reply to this communication Prince Gortschakoff repeated the assurance that the imperial Government "had no intention of sending any expedition against the Turcomans, or of occupying Merv." In 1875 the operations of General Lomakin on the northern frontier of Persia led to representations being made by the British ambassador at the court of St Petersburg. To these Russia replied that the czar had no intention of extending his frontiers on the side of Bokhara or on the side of Krasnovodsk. Notwithstanding the oft-repeated assurances to the contrary, large annexations have been since made in Turcomania by the Russians, and these proceedings, clearly indicating the persistent prosecution of a concerted plan, have naturally tended to disturb the harmonious relations which should subsist between the two great civilizing powers of the East.

Settlements and Inhabited Centres.—Of towns or even villages, fixed centres of habitation, there are none, according to Mr O'Donovan, the latest European traveller to Merv. The present political and military capital of Merv is Koushid Khan Kala, a fort which serves rather as a place of refuge against sudden attacks than as a habitation. It is situated on the east bank of the most westerly branch of the Murghab, about 25 miles below the dam at Porsa Kala. In form it is oblong, measuring 1¾ miles long by ¾ mile broad, is constructed entirely of earth, revetted on the exterior slope with sun-dried brick; the ramparts are 40 feet high, and are 60 feet at the base. The fort is built in a loop of the river, which protects it on two sides; between it and the river is an "obah," or nomad village of huts and tents, some thousand in number, disposed in rows, but there is no town or settlement.

Twenty-five miles east of Koushid Khan Kala lie the ruins of the Greek city of Antiochia Margiana, showing traces of a high civilization. According to Strabo (xi. 2) the Merv oasis at this period was surrounded with a wall measuring 1500 stadia (185 miles). Mr O'Donovan found the trace of the fort of Iskander to have been quadrangular, with a length of side of 900 yards. This was probably the fort built by Alexander, about 328 B.C., on his return from

[1] *Concurrently with the consolidation of her position in Turcomania*, Russia has of late been showing less military activity on the side of her Turkestan district. It is probable that her recent explorations at the sources of the Oxus have demonstrated the impracticability of directing any offensive movement against India from that side. Hence the line of strategical advance has been shifted from Tashkend to Tiflis.

Sogdiana after the capture of Bessus. The city was destroyed in 666 A.D. by the Arabs, who built a new one, afterwards known as Sultan Sanjar, about 1000 yards away, and occupying an area, according to Mr O'Donovan, of about 600 yards square. The towers are still extant, and inside can be seen the ruins of a most elaborate tomb, in which the supposed bones of Sultan Sanjar are enshrined. It has always been a place of pilgrimage for the faithful. Not far to the south-west lies the site of the last city of Merv, that which existed up to a hundred years ago, when it was laid waste by the Bokharians. It bears the name of its gallant defender Bairam Ali.

These three ruins are all that remain of that which flourished of yore as "sovereign of the universe."

At the time of the visit of Burnes, Abbott, Shakespear, and Taylour Thomson, about the fourth decade of the century, Merv was under the jurisdiction of Khiva, and the administrative centre was at Porsa Kala, where the dam is situated. This place is now also a waste of mud ruins, uninhabited.

Rivers.—The Heri-rud (or Tejend, as the river is named below Sarakhs) runs a course of some 280 miles within Afghan borders. On reaching the Persian frontier it turns north and forces a channel through the mountain chain near Sarakhs. Beyond Sarakhs the river is Turcoman on both banks, runs close to the Khelat mountains, and in the latitude of Askabad loses itself in the marshes formed by the spring floods. It is probably the Ochus of ancient geography, which watered Nissa, once the capital of Parthia, and joined the Oxus just before the latter river disembogued into the Caspian (Rennell's *Herodotus*). The Tejend is fordable at all points below Sarakhs except in the early spring after the melting of the snows. On the road from Meneh to Merv the river is sluggish, 50 yards wide and 4 feet deep in February. The river-bed is sunk 12 to 15 feet below the level of the surrounding country, and has immense quantities of drift wood on its banks; trees and luxuriant herbage clothe the immediate borders. At midsummer the river runs nearly dry, and does not reach Sarakhs. The Kashaf-rud, which flows near Meshed, is one of its chief affluents.

The Murghab takes its rise in the northern slopes of the Paropamisus, and runs parallel to the Heri-rud at a distance of 70 miles from it. On this river lies the plain or oasis of Merv, irrigated by means of an elaborate system of dams and canals cut from the main river. Beyond the limits of the oasis the Murghab "hides its streams in the sand," like the Tejend. The river at Porsa Kala (near the principal dam) is 80 yards wide, at Koushid Khan Kala 30 to 40 yards wide. In summer it is much swollen by the melting of the snows, and its stream is then barely fordable. The water is yellow in colour from suspended matter.

Formerly a great deal of the country, now a waste, between the two rivers was also cultivated by the agency of water derived from canals cut from the Tejend. These canals extended to Kucha Kum in the desert, rendering the journey between the two rivers much easier than in the present day. From the Murghab was also cut, among others, the Kara-i-ab canal, which ran for a distance of 40 miles towards the Tejend. Recent explorers affirm that there is no reason why these canals should not be again filled from those rivers, when the intervening country, "an argillaceous expanse" (O'Donovan), would become culturable.

Communication.—Merv is surrounded on all sides by desert. On the north, west, and east this desert is sandy and arid; water is exceedingly scarce, the wells being sometimes 60 or 70 miles apart, and easily choked. To the south of Merv, between the rivers Murghab and Tejend, there are traces of past cultivation, of irrigating canals, and of considerable settlements. Between the Tejend and Askabad the road lies through a populous well-cultivated country (Persian territory) by way of Kahka and Lutfabad.

There are no roads in Merv,—nothing but mere tracks. Many wide and deep irrigating canals have to be crossed; bridges are few and bad. The inhabitants cross by inflated skins.

The following tracks lead to the Persian frontier from Merv:—(1) *via* Mahmur or Chungul to Lutfabad—eight days on camels; (2) *via* Shahidli to Mehna—120 miles; (3) *via* Shahidli to Fort Cherkeshli and Meshed,—for 85 miles between the Murghab and Tejend there is scarcely any water; (4) *via* Sarakhs to Meshed, 9 or 10 marches for camels, and, according to Petrusevitch, without water between Merv and Sarakhs—120 miles.

To the Afghan frontier lead (1) the track *via* Sarakhs and up the Heri-rud to Herat—fit for a coach, according to Sir Charles MacGregor and Mr Lessar; and (2) a practicable track, used by Abbott and Shakespear, up the Murghab and Kushk rivers.

To the Oxus in Bokharian territory lead several tracks, the chief of which is that to Charjui—nine marches for camels. Water is scarce.

To Khiva by the direct track is 360 miles. Water is scarce.

Population.—The Turcomans, according to Sir Henry Rawlinson and others, are descendants of the Ghúz or Komani, a race of Turks who migrated westward from their homes in the Altai before the Christian era, and penetrated even to the Danube. From subsequent intermixture with Persian and Caucasian peoples, they exhibit variations from the true Tartar type. According to Baron de Bode the Turcoman closely resembles both in appearance and in speech the Nogai Tartar and the Tartar of Kasan on the Volga.

They are an independent race, as wild and free as their native desert, brave and very impatient of control—"Wild warriors in stormy freedom bred" (Moore). They have a very evil reputation for brigandage and murder, so much so that the Bokharians and Khivans have a proverb—"If you meet a viper and a Mervi, commence by killing the Mervi and then despatch the viper." Of late years a change for the better has taken place, and recent travellers among them state that the Mervis show an inclination to lead a more settled life and to establish an elementary form of government (Medjliss), and that it is no longer accounted an honour among them to kill their neighbours. Opium smoking and arrack drinking are apparently widespread vices (O'Donovan); at the same time they are described as clever and intelligent.

The Merv Tekkes (like the Akhal Tekkes) are classed in two great divisions—the Toktamish and the Otamish. Each of these divisions consists of two clans, and each clan is subdivided into families. The two clans of the Toktamish are called Beg and Wakil; those of the Otamish, Suchmuz and Bukshi. The clans of Beg and Wakil are the most powerful, and occupy that part of the oasis which lies on the right or east bank of the Murghab. The Suchmuz and Bukshi have their tents on the left or west bank.

There is no machinery of government, and no taxes are levied. Whatever government there be is of a patriarchal nature. Each family has a *ketkhoda* (patriarch), who represents the family in matters of policy, but can only act in accordance with the wishes of the clan. The *aksakals*, or grey beards, are also useful in settling intertribal disputes, but they are tolerated only so long as they do not act in opposition to the tribesmen. For external affairs and in time of war the *ketkhodas* exercise a certain amount of power. The authority of *ketkhodas* and *aksakals* is, however, overriden by the laws of custom or usage (*deb*) and the less respected laws of religion. The injunctions of deb are paramount. It sanctions the *alaman*, or plundering raid, and in general regulates the Turcoman's daily life; its prescriptions are more binding than those of the Koran.

The Tekkes marry young. The father purchases for his twelve-year-old son a child-wife for 500 to 2000 krans (£20 to £80). A young widow of twenty-five is much more valuable, but a woman over forty is not worth the price of a camel. On the conclusion of the bargain, the priest reads a prayer from the Koran, and the marriage becomes valid.

The dress of the men consists of a long tunic of coarse crimson silk reaching below the knees, with a white sash through which is stuck a dagger; an outer robe of brown camel-hair cloth, a huge sheepskin hat, trousers and slippers or amber-coloured knee-boots, complete the costume. The women are exceedingly fond of trinkets, rings, and amulets, which accompany their movements with a sound as it were of bells. Their dress consists of the same red silk robe as the men wear, with a sash round the waist, and high-heeled boots, red or yellow.

The religion is Suni Mohammedan; their language Jagatai or Oriental Turk.

The numbers of Merv Tekkes on the Murghab and Tejend are variously estimated, but may be stated approximately at 40,000 tents, including 5000 tents of the Salor tribe. These 40,000 tents represent a population of 200,000 to 250,000 souls. The Salors and Sariks at Yulutan and Panjdeh, higher up the Murghab, are given at 11,000 tents, or some 60,000 souls.

Products, Arts, and Manufactures.—The country in all times has been renowned throughout the East for its fertility. Strabo tells us "that it was not uncommon to meet with a vine whose stock could hardly be clasped by two men with outstretched arms, while

clusters of grapes might be gathered two cubits in length." The Arab traveller Ibn Haukal, writing in the 10th century, remarks that "the fruits of Merv are finer than those of any other place, and one cannot see in any other city such palaces with groves and streams and gardens." A local proverb says, "Sow a grain to reap a hundred." All cereals and many fruits grow in great abundance.

The Turcomans possess a famous breed of horses,—not prepossessing in appearance, being somewhat leggy and long in the back and neck, but capable of accomplishing long distances—50 or 60 miles—for several days in succession, and with very little food. Their great peculiarity appears to be their hairlessness; the coat is very fine, the mane and tail very scanty. This breed of horses, as well as the wealth of the Merv Tekkes in camels and flocks, is fast disappearing.

The Turcomans are noted as excellent workers in silver and as armourers, and their carpets are superior to Persian. They also make felts and a rough cloth of sheep's wool.

One of the chief occupations of the male sex is the repair of the dams and the clearing of the canals, upon the efficiency of which their existence is dependent. The services of a large number of workmen are always held in readiness for the purpose. In 1878 the unusual mass of water in the Murghab carried away the dam, and the drying up of some of the canals nearly led to a failure of the crops.

Climate.—The position of Merv, in the midst of sandy deserts in the heart of Asia, makes the climate in the heat of summer most oppressive. The least wind raises clouds of fine sand and dust, which fill the air, render it so opaque as to obscure the noonday sun, and make respiration difficult. In winter the climate is very fine. Snow falls rarely, and melts at once.

History.—The name Merv, or some similar form, occurs at a very early period in the history of the Aryan race. Under Mouru we find it mentioned with Bakhdi (Balkh) in the geography of the Zend Avesta (*Vendidad*, fargand i., ed. Spiegel), which dates probably from a period anterior to the conquest of Bactria by the Assyrians, and therefore at least one thousand two hundred years before the Christian era. Under the name of Margu it occurs in the cuneiform inscriptions of Darius Hystaspis, where it is referred to as forming part of one of the satrapies of the ancient Persian empire (*Inscriptiones Behistani*, ed. Kossowicz). It afterwards became a province (Μαργιανή) of the Græco-Syrian, Parthian, and Persian kingdoms. On the Margus—the Epardus of Arrian and now the Murghab—stood the capital of the district, Antiochia Margiana, so called after Antiochus Soter, who rebuilt the city founded by Alexander the Great. About the 5th century, during the dynasty of the Sasanids, Merv was the seat of a Christian archbishopric of the Nestorian Church. In the middle of the 7th century the flood of Arab conquest swept over the mountains of Persia to the deserts of Central Asia. Merv was occupied 666 A.D. by the lieutenants of the caliph Othman, and was constituted the capital of Khorasan. From this city as their base the Arabs, under Kuteibe bin Muslim, early in the 8th century brought under subjection Balkh, Bokhara, Ferghana, and Kashgaria, and penetrated into China as far as the province of Kan-su. In the latter part of the 8th century Merv became obnoxious to Islam as the centre of heretical propaganda preached by Mokannah (Haschem ben Hakem), the "veiled prophet of Khorasan," who claimed to be the incarnation of the Deity. In 874 Arab rule in Central Asia came to an end. During their dominion Merv, like Samarkand and Bokhara, became one of the great schools of science, and the celebrated historian Yakut studied in its libraries. About 1037 the Seljukian Turks crossed the Oxus from the north and raised Toghrul Beg, grandson of Seljuk, to the throne of Persia, founding the Seljukian dynasty, with its capital at Nishapur. A younger brother of Toghrul, Daoud, took possession of Merv and Herat. Toghrul was succeeded by the renowned Alp Arslan (the great lion), whose sway was so vast that, according to tradition, no fewer than twelve hundred kings, princes, and sons of kings and princes did homage before his throne. Alp Arslan was buried at Merv. It was about this time that Merv reached the zenith of her glory. During the reign of Sultan Sanjar of the same house, towards the middle of the 11th century, Merv was overrun by the Turcomans of Ghúz, and the country was reduced to a state of misery and desolation. These Turcomans, the ancestors of the present tribes of Turcomania, were probably introduced into the country by the Seljukian Turks as military colonists. They formed the van of their armies, and rendered efficient service so long as the dynasty lasted, and afterwards took part in the wars of Tamerlane.

In 1221 Merv opened its gates to Toolai, son of Jenghiz, khan of the Mongols, on which occasion the inhabitants, to the number of 700,000, are said to have been butchered. From this time forward Merv, which had been the chief city of Khorasan, and was popularly supposed to contain a million inhabitants, commenced to languish in obscurity. In the early part of the 14th century Merv was again the seat of a Christian archbishopric of the Eastern Church. On the death of the grandson of Jenghiz Khan Merv became included in the possessions of Toghluk Timur Khan (Tamerlane), in 1380. In 1505 the decayed city was occupied by the Uzbeks, who five years later were expelled by Ismail Khan, the founder of the Suffavean dynasty of Persia. Merv thenceforward remained in the hands of Persia until 1787, when it was attacked and captured by the emir of Bokhara. Seven years later the Bokharians razed the city to the ground, broke down the dams, and converted the district into a waste. About 1790 the Sarik Turcomans pitched their tents there. When Sir Alexander Burnes traversed the country in 1832, the Khivans were the rulers of Merv, the nomad population being subject to them. About this time the Tekke Turcomans, then living at Orazkala on the Heri-rud, were forced to migrate northward in consequence of the pressure from behind of the Persians. The Khivans contested the advance of the Tekkes, but ultimately, about the year 1856, the latter became the sovereign power in the country, and have ever since resisted all attempts at reconquest.

Authorities.—Besides the standard travels of Wolff, Ferrier, Vambery, Burnes, Abbott, Mouravieff, and others, the following works and papers of more recent date may be consulted with advantage:—Sir H. Rawlinson's *England and Russia in the East*; O'Donovan's correspondence with the *Daily News*, 1880-81; O'Donovan's "Merv," *Proc. Roy. Geog. Soc.*; Col. Stewart's "Country of the Tekke Turcomans," *Proc. Roy. Geog. Soc.*, with excellent map; "The New Russo-Persian Frontier, 1881," *Proc. Roy. Geog. Soc.*; Girard de Rialle, *Mémoire sur l'Asie Centrale*; Sir H. Rawlinson, "Road to Merv," *Proc. Roy. Geog. Soc.*; Col. Baker's *Clouds in the East*; Captain Napier's "Reports," *Jour. Roy. Geog. Soc.*; Hutton's *Central Asia*; Marvin's *Merv*; Col Potto's *Steppe Campaigns*; Sir Charles MacGregor's *Journey through Khorassan*; Boulger's *England and Russia in Central Asia*; Captain Butler's *Communications to the Public Press*; Lessar's "Journeys," *Proc. Roy. Geog. Soc.*; O'Donovan's *Merv Oasis*; Papers on the Turcomans, &c., by Col. Petrusevitch, *Proc. Imp. Russ. Geog. Soc.*, Caucasus section; Col. Kostenko's "Turkestan," *Jour. R. U. S. Instn.*; Schuyler's *Turkistan*; correspondence on Central Asia presented to parliament, &c. (F. C. H. C.)

MÉRYON, CHARLES (1821–1868). The name of Méryon is associated with that spirited revival of etching in France which took place in the middle of the 19th century,—say from 1850 to 1865,—but it is rather by the individuality of his own achievements, and the strength of his artistic nature, than by the influence he exercised that Méryon best deserves fame. No doubt his work encouraged others to employ the same medium of expression, and so great was his own perfection of *technique* that he may well have been made a model; but, after all, the medium he selected, and in which he excelled, was but the accident of his art; he was driven to it in part by stress of circumstances—by colour blindness; and, even with colour blindness, his extraordinary certainty of hand and his delicate perception of light, aided by his potent imagination, would have made him a great draughtsman not alone upon the copper.

Charles Méryon was born in Paris in 1821. His father was an English physician, his mother a French dancer. It was to his mother's care that Méryon's childhood was confided. She was supplied with money, and she gave the boy passionate affection, if not a wise training. But she died when he was still very young, and Méryon in due time entered the French navy, and in the corvette "Le Rhin" made the voyage round the world. He was already a draughtsman, for on the coast of New Zealand he made pencil drawings which he was able to employ, years afterwards, as studies for etchings of the landscape of those regions. The artistic instinct developed, and, while he was yet a lieutenant, Méryon left the navy. Finding that he was colour-blind, Méryon determined to devote himself to etching. He entered the work-room of one Bléry, from whom he learnt something of technical matters, and to whom he always remained grateful. Méryon was by this time poor. It is said that he might have had assistance from his kindred, but he was too proud to ask it. And thus he was reduced to the need of executing for the sake of daily bread much work that was wholly mechanical and irksome. Resolutely, though unwillingly, he became the hack of his art, doing frequently, from the day when he was first a master of it to the day when insanity disabled him, many dull commissions which paid ill, but paid better than his original works. Among learner's work, done for his own advantage, are to be counted some studies after the

Dutch etchers such as Zeeman and Adrian van de Velde. Having proved himself a surprising copyist, he proceeded to labour of his own, and began that series of etchings which are the greatest embodiments of his greatest conceptions—the series called "Eaux-fortes sur Paris." These plates, executed from 1850 to 1854, are never to be met with as a set; they were never expressly published as a set. But they none the less constituted in Méryon's mind an harmonious series. For him their likenesses and their contrasts were alike studied; they had a beginning and an end; and their differences were lost in their unity.

Besides the twenty-two etchings "sur Paris" characterized below, Méryon did seventy-two etchings of one sort and another,—ninety-four in all being catalogued in Wedmore's *Méryon and Méryon's Paris*; but these include the works of his apprenticeship and of his decline, adroit copies in which his best success was in the sinking of his own individuality, and dull and worthless portraits chiefly of forgotten celebrities. Yet among the seventy-two prints outside his professed series there are at least a dozen that will aid his fame. Three or four beautiful etchings of Paris do not belong to the series at all. Two or three etchings, again, are devoted to the illustration of Bourges, a city in which the old wooden houses were as attractive to him for their own sakes as were the stone-built monuments of Paris. But generally it was when Paris engaged him that he succeeded the most. He would have done more work, however,—though he could hardly have done better work,—if the material difficulties of his life had not pressed upon him and shortened his days. He was a bachelor, unhappy in love, and yet, it is related, almost as constantly occupied with love as with work. The depth of his imagination and the surprising mastery which he achieved almost from the beginning in the technicalities of his craft were appreciated only by a few artists, critics, and connoisseurs, and he could not sell his etchings, or could sell them only for about 10d. a piece. The fact that his own original work was of incalculably greater value than his best copies of his most celebrated forerunners had not yet impressed itself upon anybody. Disappointment told upon him, and, frugal as was his way of life, poverty must have told on him. He became subject to hallucinations. Enemies, he said, waited for him at the corners of the streets; his few friends robbed him or owed him that which they would never pay. A very few years after the completion of his Paris series, he was lodged in the madhouse of Charenton. Its order and care restored him for a while to health, and he came out and did a little more work, but at bottom he was exhausted. In 1867 he returned to his asylum, and died there in 1868. In the middle years of his life, just before he was placed under confinement, he was much associated with Bracquemond and with Flameng,—skilled practitioners of etching, while he was himself an undeniable genius,—and the best of the portraits we have of him is that one by Bracquemond under which the sitter wrote that it represented "the sombre Méryon with the grotesque visage." And it did.

There are twenty-two pieces in the Eaux-fortes sur Paris. Some of them are insignificant. That is because ten out of the twenty-two were destined as headpiece, tailpiece, or running commentary on some more important plate. But each has its value, and certain of the smaller pieces throw great light on the aim of the entire set. Thus, one little plate—not a picture at all—is devoted to the record of verses made by Méryon, the purpose of which is to lament the life of Paris. The misery and poverty of the town Méryon had to illustrate, as well as its splendour. The art of Méryon is completely misconceived when his etchings are spoken of as views of Paris. They are often "views," but they are so just so far as is compatible with their being likewise the visions of a poet and the compositions of an artist. It was an epic of Paris that Méryon determined to make, coloured strongly by his personal sentiment, and affected here and there by the occurrences of the moment,—in more than one case, for instance, he hurried with particular affection to etch his impression of some old-world building which was on the point of destruction. Nearly every etching in the series is an instance of technical skill, but even the technical skill is exercised most happily in those etchings which have the advantage of impressive subjects, and which the collector willingly cherishes for their mysterious suggestiveness or for their pure beauty. Of these, the Abside de Notre Dame is the general favourite; it is commonly held to be Méryon's masterpiece. Light and shade play wonderfully over the great fabric of the church, seen over the spaces of the river. As a draughtsman of architecture, Méryon was complete; his sympathy with its various styles was broad, and his work on its various styles unbiassed and of equal perfection—a point in which it is curious to contrast him with Turner, who, in drawing Gothic, often drew it with want of appreciation. It is evident that architecture must enter largely into any representation of a city, however much such representation may be a vision, and however little a chronicle. Besides, the architectural portion even of Méryon's labour is but indirectly imaginative; to the imagination he has given freer play in his dealings with the figure, whether the people of the street or of the river or the people who, when he is most frankly or even wildly symbolical, crowd the sky. Generally speaking, his figures are, as regards draughtsmanship, "landscape-painter's figures." They are drawn more with an eye to grace than to correctness. But they are not "landscape-painter's figures" at all when what we are concerned with is not the method of their representation but the purpose of their introduction. They are seen then to be in exceptional accord with the sentiment of the scene. Sometimes, as in the case of La Morgue, it is they who tell the story of the picture. Sometimes, as in the case of La Rue des Mauvais Garçons,—with the two passing women bent together in secret converse,—they at least suggest it. And sometimes, as in L'Arche du Pont Notre Dame, it is their expressive gesture and eager action that give vitality and animation to the scene. Dealing perfectly with architecture, and perfectly, as far as concerned his peculiar purpose, with humanity in his art, Méryon was little called upon by the character of his subjects to deal with Nature. He drew trees but badly, never representing foliage happily, either in detail or in mass. But to render the characteristics of the city, it was necessary that he should know how to pourtray a certain kind of water—river-water, mostly sluggish—and a certain kind of sky—the grey obscured and lower sky that broods over a world of roof and chimney. This water and this sky Méryon is thoroughly master of; he notes with observant affection their changes in all lights.

Méryon's excellent draughtmanship, and his keen appreciation of light, shade, and tone, were, of course, helps to his becoming a great etcher. But a living authority, himself an eminent etcher, and admiring Méryon thoroughly, has called Méryon by preference a great original engraver,—so little of Méryon's work accords with Mr Haden's view of etching. Méryon was anything but a brilliant sketcher; and, if an artist's success in etching is to be gauged chiefly by the rapidity with which he records an impression, Méryon's success was not great. There can be no doubt that his work was laborious and deliberate, instead of swift and impulsive, and that of some other virtues of the etcher—"selection" and "abstraction" as Mr Hamerton has defined them—he shows small trace. But a genius like Méryon is a law unto himself, or rather in his practice of his art he makes the laws by which that art and he are to be judged. He was a great etcher, and by his most elaborate labour he seemed somehow to ensure the more completely for his picture that virtue of unity of impression which, it may well be admitted, oftener belongs to rapid than to deliberate work. In Méryon's etchings the hand-work never seems to be in arrear of the thought. As long as the hand-work must continue, the thought and passion are retained. Méryon knows the secrets of his craft as well as did the older masters of it; but he turns them to his own purposes. He is unexcelled in strength and in precision, nor is he often rivalled in delicacy. These qualities, and others more distinctly technical, which it would take too long to insist on here, students find in his etchings. But the incommunicable charm of Méryon's prints and their lasting fascination are due to the fact that, behind all technical qualities, and as their very source and spring, there lies the potent imagination of the artist, poetical and vivid, directing him what to see in his subject, and how to see it. (F. WE.)

MESCHERYAKS, or MESCHERS, a people inhabiting eastern Russia. Nestor regarded them as Finns, and even now part of the Mordvinians (of Finnish origin) call themselves Meschers. Klaproth, on the other hand, supposed they were a mixture of Finns and Turks, and the Hungarian traveller Reguli discovered that the Tartarized Meschers of the Obi closely resembled Hungarians. They formerly occupied the basin of the Oka (where the town Meschersk, now Meschovsk, has maintained their name) and of the Sura, extending north-east to the Volga. After the conquest of the Kazan empire by Russia, part of

them migrated north-eastwards to the basins of the Kama and Byelaya, and thus the Meschers divided into two branches. The western branch became Russified, so that the Mescheryaks of the governments of Penza, Saratoff, Ryazan, and Vladimir have adopted the customs, language, and religion of the conquering race; but their ethnographical characteristics can be easily distinguished in the Russian population of the governments of Penza and Tamboff. The eastern branch has taken on the customs, language, and religion of Bashkirs, with whom their fusion is still more complete. They can be distinguished from their neighbours only by their more peaceful character. This Bashkir-Mescheryak branch was estimated by Rittich in 1875 to number 138,000. They make 6 per cent. of the population of the government of Upa, and 22 per cent. in the district of Birsk. The number of the western Mescheryaks is unknown, and could hardly be estimated on account of their mixture with Russians. It is only in the government of Penza that they have maintained their national features; there they make 3 per cent. of the population.

MESCHOVSK, a district town of Russia, in the government of Kaluga, 45 miles to the south-west of the capital of the province. It is an old town supposed to date from the 13th century, and it is often mentioned in Russian annals under the names of Mezetsk, Mezechevsk, or Meschorsk. About the end of the 14th century it was embraced in Lithuania, and it was ceded to the Moscow "great principality" in 1494. It was often pillaged by Tartars in the 16th century, and during the great disturbances of 1610 all its inhabitants were killed by the Zaporoghi Cossacks, and the fort was taken by Poles, who returned it to Russia only after the treaty of Deulin. The country round Meschovsk is not fertile; but, from its position on old established routes to the south, the town has become a centre of considerable trade. Its annual fair, which takes place on the grounds of the very old Petrovsk monastery, is important to the surrounding districts for the export sale of horses, grain, hemp, hempseed oil, and coarse linen, and for the import trade in cottons, woollens, and earthen and glass wares, the whole turn-over reaching about £100,000. Population, 7400.

MESHED (properly Mesh-hed, *i.e.*, "place of martyrdom," "shrine"), a city of northern Persia, capital of Khorásán, 472 miles east of Tehrán, 201 miles north-west of Herat, 36° 17′ 40″ N., 52° 35′ 29″ E., lies on a plain watered by the Keshaf-rúd, a tributary of the Heri-rúd, and is surrounded by mud walls 4 miles in circumference, with a dry ditch 40 feet deep at some points, which could be flooded from the neighbouring reservoir and watercourses. Within this enclosure is a strong citadel, with good walls 25 feet high, residence of the prince governor of Khorásán. There are five gates, from one of which, the Bala Khíabán, the Khíabán main street runs right through the city, forming a fine boulevard planted with plane and mulberry trees, and with a stream of dirty water running down its whole length. In the centre is an open parallelogram 160 yards by 75, encircled by double-storied cloisters, and pierced on the long side by a high arched porch leading directly to the great mosque, whose gilded dome rises above the shrine of the famous Imám Rizá.[1] The marble tomb of the saint, which is the most venerated spot in the whole of Persia, and yearly visited by from 80,000 to 100,000 pilgrims, is surrounded by a silver railing, and approached by a flight of inlaid marble steps. Eastwick, the only European before O'Donovan who penetrated as far as the parallelogram, describes the mosque as large enough to contain three thousand people. It is flanked by two gilded minarets, one of which, 120 feet high, is extremely beautiful, with an exquisitely carved capital, built by Sháh Abbás. The façade is entirely covered with blue and white enamelled tiles. To the mosque are attached as many as two thousand attendants and retainers of all sorts, including no less than five hundred mollahs. Beyond the dome is Gauhar Sháh's handsome mosque, surmounted by an immense blue dome, and also flanked by two minarets. In the main street is a public kitchen supported by the enormous revenues of the shrine, where eight hundred devotees are daily supplied with food gratuitously. The only other notable buildings in the place are some colleges and twenty-two caravanserais, one of which is of great size. Meshed does a considerable local and transit trade to the yearly value of about 600,000 tománs, and its bazaars are always well stocked with silks, velvets, felts, cottons, shawls, carpets, lacquer work, lambskins, hardware, glass, china, and other goods from South Persia, India, Turkestan, and Russia. The European trade is now entirely controlled by Russia, and European manufactured articles are mostly all from that country. The chief manufactures are silk, satin, velvet, and checked-cotton fabrics, carpets, shawls, noted sword blades, shagreen, and turquois jewellery. Within the enclosures are extensive cemeteries far exceeding the local requirements, large numbers of the faithful being brought from all parts of the Shí'a world to be buried in the vicinity of Rizá's shrine under the belief that their eternal salvation is thereby ensured.

Some 10 miles west of Meshed is a powder factory, formerly under Colonel Dolmage, where powder of excellent quality is produced. The district, although fertile, does not produce sufficient for the inhabitants, so that much grain has to be imported from Kurdistán and Nisháp-úr. The climate is very severe in winter, with much snow; in summer it is less sultry than might be expected, the temperature ranging from 76° F. to 90° or 92° F., and in exceptional years 94° to 98° F. The population is variously estimated at from 45,000 (Connolly) and 60,000 (Ferrier) to 80,000 and 100,000 (Eastwick). The settled residents, exclusive of pilgrims and foreign traders, are estimated by O'Donovan at 50,000.

The main caravan routes from Khiva, Bokhara, Samarkand, and Herat converge at Meshed, whence lines of traffic radiate to Kúchan for the Atrek valley and the Caspian, to Nishápúr and Bostam for Tehrán, to Tabas for Isfahán, to Khaf for Sístán and Kirmán. It thus occupies a position in north-eastern Persia analogous to that of Tabríz in the north-west.

MESHED-ALI, *i.e.*, the shrine of the "martyr" Ali, is a town of Asiatic Turkey, province of Baghdad, 50 miles south of Kerbela, close to the ruins of Kufa, and 2 miles west of the Hindíye branch of the Euphrates, the reputed burial-place of the caliph Ali.[2] It stands on the east scarp of the Syrian desert, and is enclosed by nearly square brick walls flanked by massive round towers dating from the time of the caliphs. Under the gilded dome of the great mosque, which occupies the centre of the town, is the shrine of Ali, which is held by the Shí'a as at least as holy as the Kaaba itself. Any Moslem buried within sight of the dome being certain of salvation, large numbers of bodies are yearly sent from all parts for interment here. Besides the mosque with its richly decorated façade, the only noteworthy building is a good bazaar supplied from Baghdad and Basra. The town itself, which Lady Anne

[1] 'Alí Riẓá (or el-Riḍá), the eighth imám of the Shí'a, is the 'Alí ibn Músá from whom the party of Alides had such hopes under the caliphate of Mamún (see MOHAMMEDANISM). He died at Ṭús, 818 A.D., and was buried by Mamún's orders in the vicinity of that town beside the grave of Hárún el-Rashíd. To the Alides he was a martyr, being believed to have been poisoned by the caliph. Ibn Batúta, who describes both shrines (iii. 77 *sq.*), tells how the pious visitors to the shrine of 'Alí ibn Músá used to spurn with their feet the tomb of Rashid. In his time a considerable town had been formed around the shrine under the name of Meshhed el-Riḍá and ultimately the new town eclipsed the older city of Ṭus.

[2] Whether the place really contains the grave of Ali was long disputed, and the story given in defence of its claims is doubtless apocryphal. The dome was built under the Abbasids, and the resting-place of the caliph unknown or concealed under the Omayyads (Ibn Ḥaukal, p. 163).

Blunt describes as "an ideal Eastern city, standing in an absolute desert, and bare of all surroundings but its tombs," consists of narrow gloomy streets lined by houses closely packed together. The locality is properly named Najaf, and gives its name to the neighbouring lake, a large depression filled by an eruption of the river, and ranging from 6 to 20 feet in depth. The accumulated treasures of the shrine were carried off by the Wahhábites when they captured this place early in the present century. The population is estimated at 7000, including several Indian Mohammedans under the protection of the British resident at Baghdad.

The aspect of the shrine in the 14th century is described by Ibn Batúta, i. 414 *sq.* A plan of the town and description of its splendour before the Wahhábites pillaged it is given by Niebuhr. See also Ibn Jubair, p. 214; P. Teixeira, *Itin.*, cap. iv.

MESMER, MESMERISM. See vol. xv. p. 277.

e Plate II. MESOPOTAMIA, the "country between the rivers," is a purely geographical expression, the countries which it comprehends never having formed a self-contained political unity.[1] It was first introduced by the Greeks at or after the time of Alexander, but probably had its origin in the earlier Aramæan name *bêth nahrîn* (the country between the rivers), to which again corresponds the Biblical *Aram Naharayim*.[2] As early as 700 B.C. "the country of two rivers" is mentioned on the Egyptian monuments under the name Naharina, but no such designation appears in the cuneiform inscriptions (though the territory formed part of the Assyrian as it afterwards did of the Persian empire). The most settled period in the history of Mesopotamia was probably under Persian-Greek rule. Xenophon applies the name Syria to the extremely fertile district which he traversed after having crossed the Euphrates at Thapsacus. The country beyond the Araxes (Chaboras ?) he calls Arabia,—a desert region in which his army had to suffer great hardships until it reached the "gates of Arabia." Even in later times Mesopotamia was included under the name Assyria, or was reckoned part of Babylonia.

These statements of Xenophon already indicate a demarcation of the territory afterwards called Mesopotamia, as well as its division into two sections. The fertile portion, inhabited by agricultural Aramæans, stretched from the Euphrates to the Chaboras; the desert portion, the home of wandering tribes, extended to the Tigris. It would be rash, however, to conclude from this that Mesopotamia designated the whole territory between the Euphrates and Tigris; indeed it is possible that *Aram Naharayim*, the Aram of the country of the two rivers, originally meant only the main portion of the fertile country inhabited by Syrians. In this case the two boundary rivers must have been, not the Euphrates and the Tigris, but the Euphrates and the Chaboras. After the final occupation of the country by the Romans (156 A.D.), the political province of Mesopotamia was practically confined to this more limited district. Though in ordinary usage the Euphrates and Tigris are considered as the two rivers which bound Mesopotamia, the one bank of the river cannot be geographically separated from the other, and consequently narrow strips of country on the right bank of the Euphrates and on the left bank of the Tigris must be reckoned to the country "between" the rivers. On the other hand, the country between the sources of the Euphrates and the Tigris has from early times been reckoned not to Mesopotamia but to Armenia. In this direction the Masius range forms the proper boundary, and it is only on rare occasions that theoretical geographers extend the name Mesopotamia over the more northern districts, Sophene, &c. Purely theoretical too, and not to be approved, is the extension of the definition so as to include the land of Babylonia ('Irák 'Arabi), that is, the country as far south as the confluence of the Euphrates and Tigris, or even as far as their embouchure in the Persian Gulf.

From what has been said it appears that Mesopotamia reaches its northern limits at the points where the EUPHRATES (*q.v.*) and the Tigris break through the mountain range and enter the lowlands. In the case of the Euphrates this takes place at Sumeisát (Samosata), in that of the Tigris near Jezíret ibn 'Omar (Bezabdá) and Mosul (Nineveh). Consequently the irregular northern boundaries are marked by the lowland limits of those spurs of the Taurus mountains known in antiquity as Mons Masius and now as Ḳaraje Dágh and Ṭúr 'Abdín. Towards the south the ancient boundary was the so-called Median Wall, which, near Pirux Shapur, not much to the south of Hít (the ancient Is), crossed from the Euphrates in the direction of Ḳadisiya (Opis) to the Tigris. There the two rivers approach each other, to diverge again lower down. At the same place begins the network of canals connecting the two rivers which rendered the country of Babylonia one of the richest in the world; there too, in a geological sense, the higher portion of the plain, consisting of strata of gypsum and marl, comes to an end; there at one time ran the line of the sea-coast; and there begin those alluvial formations with which the mighty rivers in the course of long ages have filled up this depressed area. Mesopotamia thus forms a triangle lying in the north-west and south-east direction, with its long sides towards the north and south-west. It extends from 37° 30′ to about 33° N. lat. and from 38° to 46° E. long., and has an area of some 55,200 square miles. The points at which the rivers issue from among the mountains have an absolute altitude of between 1000 and 1150 feet, and the plain sinks rapidly towards the southern extremity of Mesopotamia, where it is not more than about 165 feet above the sea. As a whole the entire country consists of a single open stretch, save that in the north there are some branches of the Taurus—the Nimrúd Dágh near Orfá, the long limestone range of 'Abd-el 'Azíz, running north-north-west, and farther to the east the Sinjar range, also of limestone, 7 miles broad and 50 miles long, running north-north-east. Between these two ranges—near the isolated basaltic hill of Tell Kókab (Hill of Stars)—runs the defile by which the waters of the Chaboras, swollen by the Jaghjagha and other affluents from the Masius, find their way into the heart of Mesopotamia. The Khábúr proper, the ancient Chaboras, which rises in the three-hundred copious fountains of Rás-'ain (the ancient Rhesæna), and ultimately falls into the Euphrates near Karkísiyá (Circesium), forms the boundary between the two, or more correctly the three, great divisions of Mesopotamia. These divisions are (1) the northern country to the west of the Khábúr, (2) the northern country to the east, and (3) the steppe-land. In the country to the north-west of the Khábúr we must probably, as already mentioned, recognize the true ancient *Aram Naharayim*. Under the dominion of the Seleucids it bore the name of Osrhoene, or better Orrhoene, and was for a time the seat of a special dynasty which at a later date at any rate was Arabian (Abgar). The capital of this kingdom was Orfa (Roha), the Edessa of the Greeks and Romans, the Orrhoi of the Syrians; it was at a later date a Roman colony, and bore also the name of Justinopolis. This once flourishing city lies on the small river Daisan (the ancient Scirtus). South of Edessa lie

---

[1] Μεσοποταμία, more exactly ἡ μέση τῶν ποταμῶν, scil. χῶρα or Συρία.

[2] In the more recent parts of Genesis Padan Aram takes the place of Aram Naharayim. But this perhaps is the name of a smaller district in the neighbourhood of Harran.

the ruins of Harran (see vol. xi. p. 454). In the Mongolian period Harran fell into decay, and at present it is a mere heap of ruins. A third town of this region is Serug (Gen. xi. 20); in the Greek period it was called Batne, but the Syrians retained the name Serug, which is still in use (Serúj). The town lies between Harran and the Euphrates, in a plain to which it gives its name. On the left bank of the Euphrates lay Apamea (the modern Birejik), connected with Zeugma on the other side by a bridge, and farther south, at the mouth of the Bilechas (modern Belik), was the trading town and fortress Nicephorium, founded by command of Alexander, and completed by Seleucus Nicator, in memory of whose victory it was named. From the emperor Leo it received the designation Leontopolis. The spot is now known as Raḳḳa (see below). Farther up the fruitful valley of the Belik lay the town of Ichnæ (Chne). Farther south lay Circesium (*Chaboras* of Ptolemy, *Phaleg* of Isidor), not to be identified, as is usually assumed, with Carchemish; from the time of Diocletian it was strongly fortified. The site is at present occupied by a wretched place of the name Karkísiyá. Carchemish probably lay near the bridge of Membij, the present Kalat el-Nejm.

In ancient times a highly flourishing district must have stretched along the river Chaboras (Khábúr) to its principal source at Rás-ain ("Fountain-head," Syr. *Rîsh'aina*, the Rhesæna of Ptolemy), a town which was for some time called Theodosiopolis, because after 380 A.D. it was extended and embellished by Theodosius. Justinian fortified it. The strip of completely desert country which now stretches along the lower course of the Khábúr was called in antiquity Gauzanitis, and corresponds to the Gozan of 2 Kings xviii. 6 (Guzana or Guzanu in the cuneiform inscriptions).

The country to the east of the upper Khábúr is in many respects similar to that which has just been described. As the watershed of the Tigris is not far distant, the Masius range sends down into Mesopotamia only insignificant streams, the most important being the Hermas, the Mygdonius of the Greeks. On its banks was situated Nisibis, the chief city of the district, which commanded the great road at the foot of the mountains leading through the steppe, which here from the scarcity of water comes close up to the edge of the hills. In the old Assyrian empire Nasibina was the seat of one of the four great administrative officials. In the time of the Seleucids the site was occupied by the flourishing Greek colony of Antiochia Mygdonia; but the new designation, transferred to the river and the vicinity of Nisibis from the Macedonian district of Mygdonia, afterwards passed out of use. Nisibis was an important trading city, and played a great part in the wars of the Romans against the Persians. Captured by Lucullus, surrendered by Tigranes, recovered by Trajan, again abandoned by Hadrian, once more occupied under Lucius Verus, and strongly fortified by Severus, it was at length raised to be the capital of the province, and remained the frontier fortress of the Romans till in the time of Jovian it was ceded to the Persians. After the loss of Nisibis the emperor Anastasius in 507 founded to the north-west the fortress of Daræ or Daras (the modern Dárá), also called Anastasiopolis, which from the reign of Justinian, who increased its strength, remained for a time the residence of the *dux Mesopotamiæ*. Besides these strongholds, many fortified posts were established by the Byzantine empire in this district. Antoninopolis must be mentioned as an important town; this was refortified by Constantine under the name of Constantia, and has left its ruins near Tela between Harran and Nisibis. Mardin too was a fortress of a similar kind, and the town of Singara, at the southern foot of the mountain of the same name, was an advanced post of the Roman power.

The south or steppe portion of Mesopotamia was from early times the roaming-ground of Arabic tribes; for Xenophon gives the name of Arabia to the district on the left bank of the Euphrates to the west of the Khábúr; and elsewhere it is frequently stated that the interior at a distance from the rivers was a steppe inhabited by Arabes Scenitæ (Tent Arabs). Along the bank of the two great rivers ran a belt of cultivated country, and the rocky islands of the Euphrates were also occupied by a settled population. On the Euphrates, beginning towards the north, we must mention first Zaitah or Zautha, south-east of Circesium; next Corsothe, at the mouth of the Mascash; then Anatho or Anathan, the modern Ana; and finally Is (Hít). On the Tigris the point of most importance is Carnæ (Καιναί of the *Anabasis*), south from the mouth of the Great Zab near the present Ḳal'at Sherḳát; and not far distant towards the interior was Atræ or Hatræ, also called Hatra, the chief town of the Arab tribe of the Atreni. It was besieged without success by Trajan and Severus; by the 4th century it was already destroyed; but the interesting ruins, which can scarcely be visited owing to the plundering habits of the Bedouins, still bear the name of El-Ḥadhr. They lie in the heart of the steppe, and were formerly well supplied with water.

All these districts came in 640 A.D., or perhaps a little earlier, into the power of the Arabs, who named them Jezíra (island) or Jezíret Aḳúr,[1] and divided them according to tribes into three portions, the land of Bekr, of Rebí'a, and of Modhar. The district of Modhar ran along the side of the Euphrates, and its chief towns were Orfa and Raḳḳa; the district of Rebí'a comprised the plain of Mosul as far as the country on the Khábúr (chief towns Mosul and Nisibis), and the district of Bekr (Diyár Bekr) the more mountainous country to the west of the upper Tigris (chief town Amid or Diarbekr). In general the Arabs consider a part of the mountain territories which lie between the two rivers to belong to Jezíra, as is best seen from the following notice given by Abulfeda:—

"El-Jezíra is the land between the Tigris and the Euphrates, yet many places on the other side of the Euphrates, which properly belong to Syria, are also included, as well as places and even districts on the east side of the Tigris. The exact boundary line thus runs from Malatia by Sumeisát, Ḳal'at er-Rúm (Rum-Kala of the maps), and Bire (Birejik) to the point opposite Membij, and then by Bális, Er-Rakka, Karkísiyá, Er-Rahaba (on right bank), and Hít to Anbár. Here the Euphrates ceases to form the boundary, which runs across to the Tigris in the direction of Tekrít, and ascends the Tigris as far as Es-Sinn (Senna) to El-Ḥadítha and Mosul, thence to Jezíret ibn 'Omar, then to Diarbekr, and so back to Malatia."

From the Arabic geographers and travellers we gain the impression that a great part of Mesopotamia, with the exception of the southern steppe of course, must at that time have been in a very flourishing condition; the neighbourhood of Nisibis especially is celebrated as a very paradise. In fact it is only since the Turkish conquest of the country under Sultan Selim in 1515 that it has turned into a desert and gradually lost its fertility. As the nomadic Arabs have continually extended their encroachments, agriculture has been forced to withdraw into the mountains; and this is especially true of the western portions of Mesopotamia, the district of Rás-ain, and the plain of Harran and Serúj, where huge mounds give evidence that the whole country was once covered with towns and villages. Under the Turks El-Jezíra does not form a political unity, but belongs to different pashaliks.

From this brief survey it appears that Mesopotamia, like Syria, constitutes an intermediate territory between the great eastern and western monarchies,—Syria inclining

[1] Philostratus (*c.* 200 A.D.) already reports that the Arabs called Mesopotamia νῆσος.

more to the west, and Mesopotamia to the east. In virtue of its position it frequently formed both the object and the scene of contest between the armies of those mighty monarchies, and it is wonderful how a country so often devastated almost always recovered. The roads, it is true, which traversed the territory were not mere military highways, but the main routes of traffic for Central Asia, Western Asia, and Europe. It is only in modern times, and since these lines of commercial intercourse have ceased to be followed, that the general condition of things has been so entirely altered.

The number of roads which in ancient times traversed the country was very considerable; the Euphrates formed not a barrier but a bond between the nations on either side; at many places there were at least boat-bridges (zeugma) across. One of the most important of the ancient crossing-places must be sought, where in fact it still exists, at Birejik, the ancient Apamea-Zeugma. From this point a great road led across to Edessa (Orfa); there it divided into two branches, the northern going by Amid (Diarbekr) and the other by Mardin and Nisibis to Mosul (Nineveh). In quite recent times, in order to avoid the direct route across the desert and through the midst of the Bedouins, the post-road makes a great circuit from Nisibis by Jezíret ibn ʿOmar to Mosul. A second route crossed the Euphrates somewhat more to the south, and joined the other *via* Harran and Rhesæna. The principal crossing of the earlier times (Xenophon) was at Thapsacus, almost opposite Rakka; and it will be remembered also how important a part Thapsacus (Tiphsah) plays in the Old Testament. Sometimes a route along the Euphrates to Babylonia was followed, as is still frequently done by caravans at the present day; but even in ancient times this course was attended by more or less difficulty, the country being occupied by the chiefs of independent Arab tribes, with whom the travellers had to come to terms.

The ancient condition of things must consequently be considered as essentially analogous to that of the present day; the central districts away from the rivers were occupied at certain seasons, according as they yielded pasture, by nomadic cattle-grazing tribes, the physical character of the country being then and now the same on the whole as that of the Syrian desert, which belongs not to Syria but properly to Arabia. On the banks of the rivers were settled half-nomadic Arab tribes,—tribes, that is, which were more or less on the way to the agricultural stage, or which, having become altogether agricultural, had nevertheless, owing to frequent intercourse with the Bedouins, lost little of their original character, and even maintained their independence. The same movement takes place over and over again: Arab tribes migrating from Arabia, that *officina gentium*, gradually settle down wherever circumstances prove favourable, and by this very change in their mode of life make their first step towards civilization. In this way a continual stream of Arabs has flowed into the civilized countries of Mesopotamia. On the Assyrian monuments are figures of Arabs riding on camels; evidently the Assyrians had carried on war against the Bedouins settled in their territory. At an early period the Ṭai Arabs were the neighbours of the Aramæans, and consequently all Arabs bear in Syriac the name of Tayóyé. The district between Mosul and Nisibis received the name Béth ʿArbáyé from its being occupied by Arabs. These Ṭai Arabs, whose original home was Central Arabia, are still settled partly near Nisibis and partly east of Mosul; but they have to some extent lost their old noble Bedouin manners. The wandering Arab tribe which at the present time is dominant in Mesopotamia is the Shammar; they have driven back the Aneze, the most powerful tribe of the Syrian desert. It is only two or three generations ago that the Shammar came from Nejd; but they have already broken up into two great parties. The head of the one division is Ferhán, who has more or less completely submitted to the Turks, and has consequently obtained the title of pasha; to him adhere the Shammar tribes between Mosul and Baghdad, and those also to the east of the Tigris. The head of the tribes who roam over the greater part of Mesopotamia—pasturing their camels and sheep to the east of the Chaboras in the colder season and to the north in the hotter—is the chivalrous Fáris. These western tribes are totally independent of the Turkish Government, and have offered determined opposition to the attempts of the authorities at Dér to force them to a settled way of life; they still lay the peasants of Mesopotámia under contribution by exacting Khuwwe, "brother-money," or a portion of grain. The Shammar live in almost perpetual feud with their relations to the east, and especially with the Aneze on the Syrian bank of the Euphrates, the so-called Shámiye. Many other Bedouin tribes might here be mentioned; but it may be enough to name the Delém on the Euphrates as an example of a tribe just in process of becoming agricultural. In the northern parts of Mesopotamia there are a number of tribes of mingled Kurds and Arabs which have to a greater or less degree abandoned their tents for fixed habitations and the tillage of the ground; such are the Beraziye near Orfa, the Milliye between Orfa and Mardin, and the Kíkíye nearer Mardin and also in the neighbourhood of Mosul. It is extremely hard to obtain trustworthy statistical information about the number of the Bedouins; the Shammar may have a total strength of some 3500 tents. In the difficult contests which it has to carry on with those independence-loving tribes, the Turkish Government acts in general on the principle *divide et impera*.

The Kurdish element only appears sporadically in the true Mesopotamian plain; but the Yezidis, who form the population of the Sinjar range, may be referred to this stock. He who encounters the uncanny figure of one of these people will hardly be able to restrain a slight shudder, especially if he remembers the graphic descriptions of the Yezidi robbers in Morier's *Ayesha*. Of the old Aramæan peasantry there are no longer any important remains in the plain, the Aramæans having withdrawn farther into the Kurdish highlands, where, in spite of their wild Kurdish neighbours, they are more secure from exactions of every kind. The plain of the northern country of the two rivers was at one time richly cultivated, and owed its prosperity to this industrious people, who formerly played so distinguished a part as a connecting link between the Persians and the Roman empire and afterwards between the Western and the Arabian world, and whose highest culture was developed in this very region. Quite otherwise is it now. In the plain there are almost no remains of the common Aramæan tongue. Apart from the scattered areas in which Kurdish prevails, the ordinary language is a vulgar Arabic dialect; but both Kurdish and Aramæan (Syriac) have exercised an influence on the speech of the Arab peasant. Finally it must be mentioned that certain Turcoman hordes roam about the Mesopotamian territory.

In climate and in the character of its soil, as well as in its ethnographic history, Mesopotamia holds an intermediate position. In this aspect also we must maintain the division into two quite distinct zones. The southern half consists mainly of grey, dreary flats covered with selenite; and gypsum everywhere makes its appearance a little below the surface; bitumen is not unfrequent, and here and there it rises in petroleum wells. In the solid strata of gypsum and marl the rivers have carved out valleys, from a quarter to half a mile broad and from 40 to 50 or even 100 feet deep, which with their arable soil contrast with the barren surface of the more elevated desert (chól). Especially below Bális there are marl-hills capped with gypsum, and alluvial plains (so-called *háwís*) of considerable extent

have been formed. The banks of the rivers are there lined with a luxuriant growth of tamarisks. Occasional swamps and small lagoons occur; and the marl shows a more or less marked efflorescence of salt. In this part of the country frost is rare even in winter; in summer the heat is of extraordinary intensity, and during the whole season from May to the close of October it is but slightly modified by the night-dews. During the sand storms which frequently blow from the West Arabian desert, the temperature may rise to 50° C. (122° Fahr.), and this same excess of heat will then prevail through seven degrees of latitude in the whole valley of the Euphrates and Tigris from the Persian Gulf to the foot of the mountains. For, considering the strong radiation which takes place over what is now the uniform surface of the Mesopotamian soil with its almost complete absence of evaporation, there is nothing to hinder this warm zone extending in summer to the upper half of the country. In winter, on the other hand, this latter region has quite a different climate. From the mild coasts of the Mediterranean the cold increases from west to east. In the spurs of the Taurus, consequently, the winter cold extends far to the south, and the influence of the snow-covered ridges spreads far into the Mesopotamian plain. Snow and ice are thus not unfrequent in the higher part of the plain, and the temperature may fall as low as −10° C. (14° Fahr.), especially if the cold north winds are blowing. That inland region too is cut off from the influence of the mild air of the Mediterranean by the coast ranges. For this reason the vegetation is of a less southern character than that of the Mediterranean countries in the same latitude. In the spring the green is soon parched out of existence. In this way the northern district of Mesopotamia combines strong contrasts, and is a connecting link between the mountain region of western Asia and the desert of Arabia. On the other hand the country to the south of Mesopotamia, or 'Irák, has a warm climate, and towards the Persian Gulf indeed the heat reaches the greatest extremes.

In Upper Mesopotamia, strictly so called, agriculture has suffered an extraordinary decline; in spite of excellent soil, very little of the land is turned to account. In the western district the fertile red-brown humus of the Orfa plain, derived from the lime of Nimrúd Dágh, extends to about 12 miles south of Harran. With a greater rainfall, and an artificial distribution of the water such as existed in olden times, agriculture would flourish. If spring rains are only moderately abundant, wheat and barley grow to a great height, and yield from thirty to forty fold. Rice is also grown in the richly watered hill-encircled district of Serúj and on the banks of the Khábúr. Next, millet and sesamum are the chief crops,—the latter being grown for the sake of its oil, as the olive does not succeed in this region. The abundance of wheat may be estimated from the fact that during Layard's residence in Mosul a camel-load of 480 lb was worth four shillings. Durra (*Holcus Sorghum* and *H. bicolor*), lentils, pease, beans, and vetches are also grown, as well as cotton, safflower, hemp, and tobacco. *Medicago sativa* furnishes fodder for horses. Among the fruits the most noteworthy are the cucumbers, melons, and water-melons planted in great abundance on the banks of the smaller streams. The figs of the Sinjar mountains are celebrated for their exceptional sweetness. Timber trees are few; plane trees and white poplars are planted along the streams, and a kind of willow and a sumach flourish on the banks of the Euphrates. The palm-trees which appear on the banks of both the rivers farther south do not come so far north. On account of the hot dry summer the orange does not succeed. Of the great forest which existed (?) near Nisibis in the time of Trajan no trace remains; but the slopes both of the Masius mountains and of the Jebel 'Abd-el 'Aziz, as well as, more especially, those of the Sinjar range, are still covered with wood.

The wide treeless tracts of the low country of Mesopotamia are covered with the same steppe vegetation which prevails from Central Asia to Algeria, but there is an absence of a great many of the arborescent plants that grow in the rockier and more irregular plateaus of western Asia and especially of Persia. This comparative poverty and monotony of the flora is partly due to the surface being mainly composed of detritus, and partly to the cultivation of the country in remote antiquity having ousted the original vegetation and left behind it what is really only fallow ground untouched for thousands of years. Endless masses of tall weeds, belonging to a few species, cover the face of the country,—large *Cruciferæ*, *Cynareæ*, and *Umbelliferæ* disputing the possession of the soil in company with extraordinary quantities of liquorice (*Glycyrrhiza glabra* and *echinata*) as well as *Lagonychium* and the white ears of the *Imperata*. In autumn the withered weeds are torn up by the wind and driven immense distances. Among the aromatic plants, which even Xenophon mentions in Mesopotamia, the first place belongs to the species of wormwood (*Artemisia*), which cover wide areas, and the second to *Labiatæ*, such as species of thyme and *Salvia*, which, however, become rarer in the low country. With few exceptions there are none but cultivated trees, and these are confined to the irrigated districts on the Euphrates and the Shatt; a few willows, a *Pyrus*, tamarisks, a *Rhus*, a *Rubus*, on the banks of the rivers, and the willow-like *Populus euphratica*, which grows from Dzungaria to Morocco, make up the list of the indigenous kinds. In the wide belt of swamp which lines the Shatt el-'Arab in the low country of 'Irák 'Arabi there are boundless reaches of gigantic sedge inhabited by a rich fauna, especially of birds such as pelicans and flamingoes. From the south, or in other words from the true desert and oasis country of Arabia, the date-palm spreads up the valley to some little distance above Baghdad; and especially along the Shatt it yields rich crops of fruit, which are exported to India. With the exception of a few truffles, capers, liquorice, and such like, there are few wild food-plants. The cycle of vegetation begins in November. The first winter rains clothe the plain with verdure, and by the beginning of the year a number of bulbous plants are in bloom—*Amaryllidæ*, *Liliaceæ*, and *Colchicum*. The full summer development is reached in June; and by the end of August everything is burnt up.

The lion is said to roam as far as the Khábúr; but in any case it is at least much less frequent than in the time of the Assyrians, when the lion-hunt was a recognized form of sport. The wild ass too is very rare; but on the other hand wild swine, hyænas, jackals, cheetahs, and foxes are extremely abundant. Wolves are said to exist in the plain, and among others a variety of black wolf (*Canis lycaon*). Particularly numerous in the steppe are the antelope species; and herds of gazelles are frequently met with. Beavers are said to have been observed on the Euphrates. Jerboas, moles, porcupines, and especially the common European rat, abound in the desert; bats are numerous; and the long-haired desert hare is also found. Among the domestic animals in this steppe country the camel holds the first place; and next come goats and sheep; but the Bedouin sheep is not the ordinary fat-tailed variety. The common buffalo is often kept by the Arabs and Turcomans on the Euphrates and the Tigris; and on the Euphrates we also find the Indian zebu, which is still more frequent in the districts farther to the south. Bird-life is very rare in the southern parts of the plain; though on the Euphrates there are vultures, owls, ravens, &c., as well as falcons (? *Tinnunculus alaudarius*) which are trained to hunt. Among game-birds are some kinds of doves, francolins, partridges, wild ducks and geese, and in the steppe bustards. The ostrich seems almost to have disappeared. Large tortoises are numerous.

In conclusion it is necessary in supplement to the article IRAK to say something of the district of Babylonia, often (though wrongly) included under the name Mesopotamia. Here we have to do with a fundamentally different region, for it consists in the main of alluvial formations, a few scattered reaches of sand only now and then appearing in the level depression not filled up by the alluvium. The mass of solid matter which the rivers bring down and deposit is very considerable; it has been ascertained that the maximum proportion for the Euphrates in the month of January is $\frac{1}{80}$, and at other times $\frac{1}{200}$; for the Tigris the maximum is $\frac{1}{100}$. As regards the physical character of the alluvia, in the most northerly portion the soil is pebbly, the pebbles consisting almost solely of variously coloured flints and occasional small fragments of gypsum. This is succeeded by a continuous formation of clayey soil, in part argillaceous and argillo-calcareous, but covered with mould and sand, or the more tenacious clay of frequent inundations.

In general, the northern plains of the interior have a slight but well-defined southerly inclination with local depressions. The territory undulates in the central districts, and then sinks away into mere marshes and lakes. The clay, of a deep blue colour, abounds with marine shells, and shows a strong efflorescence of natron and sea-salt, the latter derived from the decomposition of vegetable matter. When the soil is parched up the appearance of the mirage (seráb) is very common. As extensive inundations in spring are caused by both the rivers, especially the Tigris, great alterations must have taken place in this part of the country in the course of thousands of years. It has been asserted that in former times the alluvial area at the mouth of the river increased one mile in the space of thirty years; and from this it has been assumed that about the 6th century B.C. the Persian Gulf must have stretched from 45 to 55 miles farther inland than at present. The actual rate of increase at the present time is about 72 feet per annum. For this reason we cannot decide much in regard to the former physical configuration of southern Babylonia; but it is at least certain that the Euphrates and the Tigris reached the sea as independent rivers. Ritter estimates that in the time of Alexander the Great the embouchures were still separated by a good day's journey; and, though they cannot now be traced, great alterations have probably taken place in the upper portions of the rivers as well as in the country near the mouths. Assyriologists tell us that more than thirty-five canals are known by name from the Babylonian period; but it is extremely difficult, or rather it has proved hitherto impossible, to identify them either with those actually existing or with those mentioned in classical authors, in the Babylonian Talmud, or in Arabian writers. To the west of the Euphrates was to be found the Pallacopas channel, and we still have the Hindiye channel in the same quarter. The country between the rivers more particularly was traversed by such secondary branches. Beginning

from the Euphrates we must mention the Saklawíye channel (Nahr 'Isá), the Nahr Melik, the Nahr Zemberáníye, and especially the Nahr-en-Níl, constructed by the famous Omayyad governor Hajjáj. Eastwards from the Tigris strikes the great Nahrawan channel; and right through the country of the two rivers runs the Shatt-el Hai from Kút-el-'Amára, almost due south to the Euphrates, parallel with the Shatt-el-Kehr. Many of these have been silted up; from those, however, which are still maintained there is derived a considerable revenue, and by the restoration of many of the old channels, traces of which are met with at every step, the country might be again raised to that condition of high civilization which it enjoyed not only in antiquity but partly even in the time of the later caliphs. The classical writers are unanimous in their admiration of this country; and it is at least certain that nowhere else in the whole world was the principle of the application of canals to the exigencies of agriculture worked out so successfully. The most luxuriant vegetation was diffused over the whole country; and three crops were obtainable in the year. It is this alone which makes it intelligible how this region in the most remote antiquity attained a high civilization, and for centuries played, it may be said, one of the principal parts in the history of the world. In the matter of civilization, indeed, no country of the ancient world was its equal; a multitude of great cities once flourished within its borders. Even the Arabic writers are unanimous in regard to the extremely favourable influence which the character of the country exercised on the intellectual activity, spirit, and capacity of its inhabitants. We need not here discuss the question recently started as to whether the Biblical garden of Eden is to be sought in this locality, two canals of the Euphrates and Tigris being identified with the Gihon and Pison of Gen. ii.; but it is certain at least that this lower country of the two rivers might well pass in antiquity for the *ne plus ultra* of civilization, and exercised the most powerful political and intellectual influence on the surrounding regions. The question often raised as to whether the Semites were derived from this district may also be left untouched. From the Bible we know that an ancient name of the district was Shinar, though this has not hitherto been discovered in the cuneiform inscriptions. The name Kush is applied in the Bible to its oldest non-Semitic inhabitants. The northern half of the country was called Akkad, the southern Sumer. But it must not be forgotten that the rivers never formed ethnographic and political boundaries; and thus Sumer extended to the coast of the Persian Gulf and Akkad as far as the Lower Zab, the eastern affluent of the Tigris. As a less ancient designation of the whole country may be reckoned *mat Kalda*, the country of the Chaldæans (Hebr., *erets Kasdîm*); originally Kalda is said to have designated central Babylonia. Of still later date is the name derived from the capital, the country of Babel (*erets Bábel*), as an equivalent of which *mât Bâbîlû* appears in the cuneiform inscriptions (in the Darius lists *Babîru*). From this was developed the Greek designation Babylonia, Βαβυλωνία (as early as Xenophon). That the country was densely peopled may be gathered from the fact that about 704 B.C. eighty-nine fortified towns and eight hundred and twenty smaller places in the Chaldæan country were captured during one military expedition. Of separate districts of the country we may mention Karduniash, the district in the vicinity and especially to the north of Babylon; and southward by the sea-coast the important country of Bít Yakín, governed by kings of its own. At a later date we find on the coast and at the mouth of the Pallacopas canal the maritime town of Teredon, which is also mentioned by the classical writers. Besides Babylon and Borsippa, the larger cities were the double city of Sippar (Sefarvayim, 2 Kings xvii. 24, 31) and Akkad on the left bank of the Euphrates on the present Nahr 'Isá; Erech, *i.e.*, Warka, on the left bank of the Euphrates; Ur on the Pallacopas, not far from the place where the Shatt-el-Hai falls into the Tigris; Nippur, *i.e.*, Tell Niffer; Kutha (2 Kings xvii. 24), Kalne (Gen. x. 10), in the north, Opis at the junction of the Adhem (Physcus) with the Tigris. Huge mounds give evidence of the extent of these cities. A number of the canals were navigable, and at the same time, when the bridges were destroyed, they formed defensive moats against the incursion of enemies from the north. And the same purpose was served by the great wall (afterwards the Median Wall of the Greeks) which ran across the country from river to river between the points of their nearest approach.

During the period of Greek domination a Greek city, Seleucia, which afterwards attained great prosperity, was founded by Seleucus I. in an extremely favourable situation on the right bank of the Tigris. In the south of the country, too, there was a Greek seaport town first called Alexandria on the Tigris and afterwards Antiochia. After the conquest of Babylonia by the Parthians (130 B.C.) a small Arabian kingdom grew up in those parts called Characene or Mesene, after the town of Charæ or Maisan. It was under Parthian and for a time under Roman supremacy. The city of Vologesia, founded by Vologeses to the south-west of Babylon, near Ullais, in the neighbourhood of the later Kúfa, was one of the capitals of the Parthian power. In the time of the Sasanids, too, as well as in that of the Parthians, the country of the lower Euphrates and Tigris played a leading part; it formed in fact the main centre of the Persian kingdom. The city of Ctesiphon, founded by the Greeks on the east side of the Tigris opposite Seleucia, was the winter residence of the Parthian kings, and the imperial capital of the Sasanids. Under the name of Madáin (The Cities) it continued to flourish till the rise of Baghdad in the 9th century. The neighbourhood of Ctesiphon was called in the time of the Sasanids Súristán, a translation of the Aramæan designation Bêth-Arâmâyê, "country of the Syrians," for the land was mainly occupied by Aramæans. By a notable substitution the Arabs afterwards gave the name Nabat, *i.e.*, Nabatæans, to these Aramæan peasantry, who, it may be added, were already found in these parts at the time of the Babylonian empire.

On the west side of the Tigris the Arab kingdom of Híra formed the bulwark of the Sasanid power. As the result mainly of the battle of Kadisiya (east of Híra) in 635 A.D., the whole of this wealthy country fell into the hands of the Moslems, and it soon constituted the centre of their power, especially when the Abbasids, with true political insight, transferred thither the capital of the empire and founded Baghdad. The chief cities of the older Arabic period were Kúfa (in the neighbourhood of the earlier Híra to the south of ancient Babylon) and Basra (or BUSSORAH, *q.v.*) in the neighbourhood of the earlier Maisan. After these two cities the country was divided into the Sawád, "rich arable district," of Basra and that of Kúfa. Sawád was also employed as a name for the whole country; and more or less identical with this designation is the name 'Irák still in use. Sometimes also the term Sawád-el-'Irák is employed; but at a later date the country is distinguished as 'Irák 'Arabi (Arabian 'Irák) from the Persian 'Irák 'Ajemi to the east, the ancient Media. The Arabian geographer Yákút makes the distinction that the country called Sawád reaches farther to the north (viz., to the district of the Upper Záb).

Abulfeda gives the boundaries of 'Irák as follows:—"In the west of the country lie El-Jezíra and the desert, in the south the desert, the Persian Gulf, and Khuzistán, in the east the mountain country as far as Holwán (near the principal pass through the Zagrus range). Thence the boundary runs again towards Mesopotamia. Thus the greatest breadth of 'Irák is in the north, and its narrow extremity is formed by the island 'Abbádán in the Shatt-el-'Arab (the united Euphrates and Tigris) to the south of Basra." From what has been said it appears that 'Irák extended far beyond the country between Euphrates and Tigris. Abulfeda says clearly that 'Irák lies on the Tigris as Egypt on the Nile; for according to this view the Tigris flows through the middle of the country. 'Irák consequently lies between 30° and 34° 30′ N. lat. and between 44° and 48° 30′ E. long.; of its area it is impossible to form an estimate under such varying conditions. For some details see BAGHDAD.

From the union of the rivers upwards, in the case of the Euphrates as far as 26° N. lat. (above Rakka), in that of the Tigris to 35° N. lat., the valleys are known as *ez-zór*, the depression, in opposition to the more elevated desert-plateau. It has been surmised that in this name is to be recognized the Dúra of the Old Testament (Daniel iii. 1).

Very little of the ancient condition of the country has been preserved; and there are now but few remains of ancient buildings, scarcity of stone having all along led to the use of bricks. 'Irák has played its part. It is only by the expenditure of immense sums, far beyond the financial capacity of the Turkish Government, that the ancient canals could be restored and the swamps formed by them drained. The whole land falls into two unequal portions,—an extensive dry steppe with at any rate a healthy desert climate, and an unhealthy region of swamps. There is a good deal more agriculture along the Euphrates than along the Tigris; but swamps, with almost impenetrable reed thickets, composed of a kind of *Agrostis*, are at the same time much more extensive. The slightly more elevated districts are the special habitat of the date palm, which by itself forms dense groves bordering the banks particularly on the lower Euphrates, for a distance of several days' journey. This part of the country consequently has a somewhat monotonous but in its own way imposing aspect. A luxuriant vegetation of water-plants is to be found in the swamps, which are the haunt of numerous wild beasts—wild swine, lions, different kinds of aquatic animals and birds. The swamps are inhabited by a wild race of men, dark of hue, with many negroes amongst them. They live in reed huts, and cultivate rice; and they weave straw mats. In the main they keep pretty free both of the Turkish Government and of the semi-Bedouins and Bedouins of 'Irák. The Khazael especially who dwell to the south of ancient Babylon often give the Government trouble, through their passion for independence. Less turbulent are the Bedouins in the interior of the country—the Zobeid, the Afaij, and the Abu Muhammed; but on the other hand the Beni Lám (7500 tents strong), who occupy the great tract of country east of the Tigris to the south of Baghdad, have often been a source of great annoyance to the pashas of that city. A still more difficult task is the management of the Shammar, who come and pitch their tents to the south-east of Baghdad; and also the Muntefitch on the southern Euphrates put the whole ad-

ministrative and diplomatic skill of the Turkish officials to the test. The Turkish influence has here made at one time great advance and at another lost all the ground it had gained,—the rich and powerful sheikhs of the Muntefitch sometimes becoming for a season rulers over the whole of Southern 'Irák and even over the town of Basra. The present writer once visited the great sheikh Násir in his camp near Súk-esh-Shiyúkh; and he received the impression of having to do with a very remarkable and astute personage.

The old Syrian population of 'Irák has almost entirely disappeared; the few remnants left are distinguished by a special religion, in regard to which see the article MANDÆANS. Ethnographically the country is subject to a double influence. On the one hand the connexion with Nejd, the central plateau of Arabia, continues uninterrupted; the emigration from that region being mainly directed towards 'Irák and Jezíra. In Baghdad even, the 'Agél-Bedouins from Central Arabia have a quarter of their own. With the earnings obtained in these rich districts the emigrants return to their homes. But quite as strong at least is the influence of Persia. Persian customs are in fashion; in Baghdad there is an important Persian quarter; and Kerbela and Meshed 'Ali to the west of the Euphrates may be considered regular Persian "enclaves." In these places are buried the son-in-law of Mohammed, the caliph Ali, and his son Hosein (in Kerbela), the chief saints of the Shiite sect; and their tombs are not only shrines of pilgrimage to the living, but the dead are brought by countless caravans from Persia to be buried in ground which they have made holy. The neighbourhood of Kerbela reeks with the odour of corpses; and from the midst of them pestilence has often begun its march. Throughout the whole of 'Irák the Shiites have many adherents,—for example, the Khazael already mentioned. Persian influence prevails on the Arab population of 'Irák, and the intermingling of the races can still be very clearly traced; in this distant corner of the Turkish empire a more international tone prevails than in any other district. And, however small when compared with former times the commercial and intellectual intercourse of various nations in these regions may be at the present day, the attentive observer must notice that such intercourse does still exist, though within restricted limits. No trace, indeed, is to be found of that rich intellectual development which was produced in the time of the caliphs through the reciprocal action of Persian and Arabic elements. Still the quickwittedness of the inhabitants of 'Irák makes a decided impression on the traveller passing through Asiatic Turkey; and one might venture to prophesy that the country might to some extent recover its former position in the world, especially if English influence from India were more widely extended, and should lead to the construction of a railway. The trade which passes through 'Irák is even now not unimportant; horses, for example, are exported in considerable numbers from southern 'Irák to India. But it might be very much improved, as the country, it is said, could support five hundred times as many inhabitants as it actually contains. There is also a considerable export of dates, a fruit which forms the chief sustenance of a great number of the inhabitants; and the breeding of cattle (especially buffaloes) is extensively carried on. Only a few steamboats as yet navigate the majestic rivers. Communication by water is carried on by means of the most primitive craft. Goods are transported in the so-called "terrades," moderately big high-built vessels, which also venture out into the Persian Gulf as far as Kuwét. Passengers are conveyed, especially on the Euphrates, in the *meshhúf*, a very long and narrow boat, mostly pushed along the river bank with poles. The Mesopotamian "kelleks"—rafts laid on goatskin bladders—come down as far as Baghdad, where round boats made of plaited reeds pitched with asphalt are in use. At Basra, on the other hand, we see the "belem," boats of a large size, having the appearance of being hollowed out of tree trunks, and partly in fact so constructed. Throughout 'Irák in general Indian influence is partially at work; in the hot summer months, for instance, when the natives live in underground apartments (serdáb), the Indian punkah is used in the houses of the rich. As regards language, the local Arabic dialect has evidently been affected on the one hand by Persian, on the other by the Bedouin forms of speech.

MESSENE, the chief city of Messenia, founded, under the auspices of Epaminondas, as a bulwark against the Spartans. After the battle of Leuctra that general sent to all the exiled Messenians,—in Africa, Sicily, or Italy,—and invited them to return to the land of their fathers. Many came with eagerness, and in 369 B.C. the city was built by the combined army of Thebans under Epaminondas and Argives under Epiteles, assisted by the Messenians themselves. The site was chosen in conformity with a vision which appeared to Epaminondas, and the walls were raised to the sound of flutes playing the airs of Sacadas and Pronomus. The citadel was erected on the summit of Mount Ithome, and the city on its southern slope and in the adjoining valley. City and citadel were enclosed by a wall 47 stadia in length. Near the centre of the city was the agora, with a famous spring called Arsinoe, and various temples and statues, among the latter an iron statue of Epaminondas. The Hierothysion contained many statues of gods and heroes, among them a bronze statue of Epaminondas. In the gymnasium were statues of Hermes, Hercules, and Theseus by Egyptian artists. In the stadium was a bronze statue of the great hero Aristomenes, who had a sepulchral monument elsewhere in the city. On the summit of the citadel was a famous spring called Clepsydra, and near it a temple of Zeus Ithomatas, with a statue by the famous Argive artist Ageladas, executed originally for the Messenian Helots who settled in Naupactus (see MESSENIA). It was in honour of this statue that the festival of the Ithomæa was performed.

The situation of Messene is one of the finest and most romantic in the world. The view of Mount Ithome, with its level summit and its ancient and mediæval ruins, as one issues from the Langadha Pass in the Taygetus mountains, is beautiful beyond description. And the view from the summit of the mountain itself, which rises, steep and rugged, to the height of 2631 feet, and is crowned by the ruins of fortifications of Cyclopean workmanship, is enchanting, hardly equalled by any other in Greece. Near the middle of the ruins of the lower city stands a wretched village named Mavrommáti (Black Eye), so called from the Turkish name of the spring Arsinoe, which still flows as plentifully as in the old days. These ruins are the most imposing in Greece, and furnish the finest existing specimen of Hellenic military architecture. Almost the entire circuit of the ancient walls can be traced, and in some places they are standing to their full height. They are built of large hewn stones laid in beautifully regular layers without mortar, and are surmounted by towers, of which there seem to have been originally over thirty. Seven of these are still in a good state of preservation, and bear testimony to the thoroughness of the great enterprise undertaken by Epaminondas. Two gates can still be distinguished, one on the slope of Mount Ithome, the other (the northern or Megalopolis gate) on the north side. The latter is a dipylon or double gate, opening into a circular enclosure 62 feet in diameter. The walls of this enclosure are built with extreme care, and the soffit stone of the inner portal, which has been partly moved from its place, reminds one of the lintel of the so-called treasury of Atreus at Mycenæ. It is 18 ft. 8 in. × 4 ft. 2 in. × 2 ft. 10 in. Within the town several ancient sites can still be distinguished—the stadium, the theatre, and several temples.

MESSENIA (in Homer Messene), a state of Greece, and the most westerly of the three peninsulas of the Peloponnesus. Its area is a little over 1160 square miles. It is separated from Elis and Arcadia on the north by the river Neda and the Nomian mountains, and from Laconia on the east by the lofty range of Taygetus. The other sides are washed by the sea, which indents its shores with four gulfs or bays,—Messenia, Phœnicus, Pylus, and Cyparissus. On its south-west corner are the Œnussæ Islands, and opposite the bay of Pylus (Navarino) the famous Sphacteria. The interior is divided by mountain chains into fertile plains, watered by rivers, the chief of which is the Pamisus (with its tributaries Leucasia, Charadrus, Amphitus, and Aris), falling into the Messenian Gulf. The great valley

of this river is divided, near Mount Ithome, into two distinct parts, the plain or basin of Stenyclarus on the north, and the plain of Macaria, so called from its extreme fertility, on the south. The climate is delightful.

The earliest inhabitants of Messenia were Leleges, whose capital was at Andania. After these came Ætolians, whose chief centre was at Pylus. After the Dorian conquest the country was divided by Cresphontes into five parts, whose chief cities were respectively Stenyclarus, Pylus, Rhion, Hyamia, and Mesola. The towns of Messenia were not numerous. Homer mentions Pylus (the seat of the Thessalian Neleids), Amphigeneia (possibly the same as Ampheia), Dorion, Æpeia (possibly Methone), Œchalia, Pharæ, Antheia (probably the later Thuria), Pedasus, and Ira (the later Abia). Other important towns were Asine, Corone, Limnæ, Carnasium, Cyparissia, and, finally, Messene.

Of the history of Messenia before the Dorian invasion little is known except a few fables related by Pausanias. Two generations after the Trojan war, the country was invaded by the Dorians, who expelled the Neleids and conferred the sovereignty upon Cresphontes, who seems to have been a popular king. Perhaps for this reason he was put to death by the chiefs along with all his sons except Æpytus. Æpytus was restored to the throne by the Arcadians, took vengeance for his father's death, and became very popular. His line lasted through several generations. We know little of the subsequent history of Messenia until the date of the Messenian wars, waged against Sparta. The ostensible and immediate causes of these wars are variously assigned; but the true cause was the cupidity of Sparta. Our chief trustworthy authority for the history of them is the old elegiac poet Tyrtæus; but so little is known about them that it is a matter of doubt in which of them the great hero Aristomenes won his fame. The date of the first was from 743 to 724, of the second from 685 to 668 or, according to others, from 648 to 631 B.C. Ithome was the centre of action in the first, Eira in the second. The result of these wars was the complete subjugation of Messenia to Sparta. Its territory was parcelled out among Spartans, and its towns handed over to Periœci and Helots. Many of the inhabitants took refuge in Arcadia, but still more in Italy and Sicily. A very large number settled in Rhegium, whose chiefs for many generations were of Messenian stock. About 200,000 remained behind in bondage. After the second war a large number of Messenians settled on the Sicilian coast at Zancle, to which they subsequently gave the name Messana (see MESSINA). In 464 B.C. the Messenian Helots, taking advantage of an earthquake at Sparta, revolted, and, though they were finally compelled to surrender in 455, they did so only on condition of being allowed to retire to Naupactus on the Corinthian Gulf. This city had been offered them as a residence by the Athenians, ever glad to favour the foes of Sparta. Here the Messenians remained for sixty years, until the loss of the battle of Ægospotami deprived them of the protection of the Athenians. They were then driven out, and had to find homes in Cephallenia and Zacynthus, or among their kinsmen in Rhegium and Messana. Some even went to Africa, and took up their abode at Euesperidæ or Hesperidæ, afterwards called Berenice. Things remained in this condition until 369 B.C., when Epaminondas, having broken the power of Sparta, rent from her Messenia, and, collecting from all quarters the descendants of the exiled inhabitants, helped them to found the city of MESSENE (*q.v.*). Sparta never gave up her claim to Messenia, and made many attempts to reconquer it, but without success. The Messenians maintained their independence until 146 B.C., when, with the Achæans, they were reduced under the power of Rome. From that time they fall into the background of history. In the Middle Ages the country, like the rest of the Peloponnesus, was largely overrun by Slavic tribes, as is shown by the numerous Slavic local names occurring in it. At the establishment of Greece as a kingdom, Messenia was constituted into a province, with a governor or nomarch residing at Kalamata (officially Kalamai), the ancient Pharæ. The country, though beautiful and fertile, is still in a deplorably backward condition, and the population is sparse and semi-barbarous. Agriculture languishes, and the roads and bridges are few and bad. More deeds of violence occur in Messenia than in any other part of Greece. With the exception of Kalamata, it contains no town of importance. Navarino, on the Gulf of Pylus, was the scene of the destruction of the Turkish fleet in 1827.

MESSIAH (Dan. x. 25, 26), MESSIAS (John i. 41; iv. 25), are transcriptions (the first form modified by reference to the etymology) of the Greek Μεσσίας (Μεσίας, Μεσσείας), which in turn represents the Aramaic מְשִׁיחָא (*mĕshîḥâ*), answering to the Hebrew הַמָּשִׁיחַ, "the anointed."[1] The Hebrew word with the article prefixed occurs in the Old Testament only in the phrase "the anointed priest" (Lev. iv. 3, 5, 16; vi. 22 [15]), but "Jehovah's anointed" is a common title of the king of Israel, applied in the historical books to Saul and David, in Lam. iv. 20 to Zedekiah, and in Isa. xlv. 1 extended to Cyrus. In the Psalms corresponding phrases (My, Thy, His anointed)[2] occur nine times, to which may be added the lyrical passages 1 Sam. ii. 10, Hab. iii. 13. In the intention of the writers of these hymns there can generally be no doubt that it refers to the king then on the throne, or, in hymns of more general and timeless character, to the Davidic king as such (without personal reference to one king);[3] but in the Psalms the ideal aspect of the kingship, its religious importance as the expression and organ of Jehovah's sovereignty, is prominent. When the Psalter became a liturgical book the historical kingship had gone by, and the idea alone remained, no longer as the interpretation of a present political fact, but as part of Israel's religious inheritance. It was impossible, however, to think that a true idea had become obsolete merely because it found no expression on earth for the time being; Israel looked again for an anointed king to whom the words of the sacred hymns should apply with a force never realized in the imperfect kingship of the past. Thus the psalms, especially such psalms as the second, were necessarily viewed as prophetic; and meantime, in accordance with the common Hebrew representation of ideal things as existing in heaven, the true king remains hidden with God. The steps by which this result was reached must, however, be considered in detail.

The hope of the advent of an ideal king was only one feature of that larger hope of the salvation of Israel from all evils, the realization of perfect reconciliation with Jehovah, and the felicity of the righteous in Him, in a new order of things free from the assaults of hostile nations and the troubling of the wicked within the Hebrew community, which was constantly held forth by all the prophets, from the time when the great seers of the 8th century B.C. first proclaimed that the true conception of Jehovah's relation to His people was altogether different from what was realized, or even aimed at, by the recognized civil and religious leaders of the two Hebrew kingdoms, and that it could become a practical reality only through a great deliverance following a sifting judgment of the most terrible kind. The idea of a judgment so severe as to render possible an entire breach with the guilty past, and of a subsequent complete realization of Jehovah's kingship in a regenerate nation, is common to all the prophets, but is expressed in a great variety of forms and images, conditioned by the present situation and needs of Israel at the time when each prophet spoke. As a rule the prophets directly connect the final restoration with the removal of the sins of their own age, and with the accomplishment of such a work of judgment as lies within their own horizon; to Isaiah the last troubles are those of Assyrian invasion, to Jeremiah the restoration follows on the exile to Babylon; Daniel connects the future glory with the overthrow of the Greek monarchy. The details of the prophetic pictures show a corresponding variation; but all agree in giving the central place to the realization of a real effective kingship of Jehovah; in fact the conception of the religious subject

---

[1] The transcription is as in Γεσσούρ, Γεσσίρ for גְּשׁוּר, *Onomastica*, ed. Lag., pp. 247, 281, Βασ. β ii. 3. For the termination *ας* for חא, see Lagarde, *Psalt. Memph.*, p. VII.

[2] The plural is found in Psalm cv. 15, of the patriarchs as consecrated persons.

[3] In Ps. lxxxiv. 9 [10] it is disputed whether the anointed one is the king, the priest, or the nation as a whole. The second view is perhaps the best.

moulded that hope into certain fixed forms which were taken with a literalness not contemplated by the prophets themselves. It was, however, only very gradually that the figure and name of the Messiah acquired the prominence which they have in later Jewish doctrine of the last things and in the official exegesis of the Targums. In the very developed eschatology of Daniel they are, as we have seen, altogether wanting, and in the Apocrypha, both before and after the Maccabee revival, the everlasting throne of David's house is a mere historical reminiscence (Sirach xlvii. 11; 1 Mac. ii. 57). So long as the wars of independence worthily occupied the energies of the Palestinian Jews, and the Hasmonæan sovereignty promised a measure of independence and felicity under the law, in which the people were ready to acquiesce, at least, till the rise of a new prophet (1 Mac. xiv. 41), the hope that connected itself with the house of David was not likely to rise to fresh life, especially as a considerable proportion of the not very numerous passages of Scripture which speak of the ideal king might with a little straining be applied to the rising star of the new dynasty (comp. the language of 1 Mac. xiv. 4–15). It is only in Alexandria, where the Jews were still subject to the yoke of the Gentile, that at this time (*c.* 140 B.C.) we find the oldest Sibylline verses (iii. 652 *sq.*) proclaiming the approach of the righteous king whom God shall raise up from the East (Isa. xli. 2) to establish peace on earth and inaugurate the sovereignty of the prophets in a regenerate world. The name Messiah is still lacking, and the central point of the prophecy is not the reign of the deliverer but the subjection of all nations to the law and the temple.[1]

With the growing weakness and corruption of the Hasmonæan princes, and the alienation of a large part of the nation from their cause, the hope of a better kingship begins to appear in Judæa also; at first darkly shadowed forth in the *Book of Enoch* (chap. xc.), where the white steer, the future leader of God's herd after the deliverance from the heathen, stands in a certain contrast to the inadequate sovereignty of the actual dynasty (the horned lambs); and then much more clearly, and for the first time with use of the name Messiah, in the *Psalter of Solomon*, the chief document of the protest of Pharisaism against its enemies the later Hasmonæans. The struggle between the Pharisees and Sadducees, between the party of the scribes and the party of the Hasmonæan aristocracy, has been described in ISRAEL (vol. xiii. p. 423 *sq.*). It was a struggle for mastery between a secularized hierarchy on the one hand, to whom the theocracy was only a name, and whose whole interests were those of their own selfish politics, and on the other hand a party to which God and the law were all in all, and whose influence depended on the maintenance of the doctrine that the exact fulfilling of the law according to the precepts of the scribes was the absorbing vocation of Israel. This doctrine had grown up in the political nullity of Judæa under Persian and Grecian rule, and no government that possessed or aimed at political independence could possibly show constant deference to the punctilios of the schoolmen. The Pharisees themselves could not but see that their principles were politically impotent; the most scrupulous observance of the Sabbath, for example—and this was the culminating point of legality—could not thrust back the arms of the heathen. Thus the party of the scribes, when they came into conflict with an active political power, which at the same time claimed to represent the theocratic interests of Israel, were compelled to lay fresh stress on the doctrine that the true deliverance of Israel must come from God and not from man. We have seen indeed that the legalism which accepted Jehovah as legislator, while admitting that his executive sovereignty as judge and captain of Israel was for the time dormant, would from the first have been a self-destructive position without the complementary hope of a future vindication of divine justice and mercy, when the God of Israel should return to reign over his people for ever. Before the Maccabee revival the spirit of nationality was so dead that this hope lay in the background; the ethical and devotional aspects of religion under the law held the first place, and the monotony of political servitude gave little occasion for the observation that a true national life requires a personal leader as well as a written law. But now the Jews were a nation once more, and national ideas came to the front. In the Hasmonæan sovereignty these ideas took a political form, and the result was the secularization of the kingdom of God for the sake of a harsh and rapacious aristocracy. The nation threw itself on the side of the Pharisees; but it did so in no mere spirit of punctilious legalism, but with the ardour of a national enthusiasm deceived in its dearest hopes, and turning for help from the delusive kingship of the Hasmonæans to the true kingship of Jehovah, and to His vicegerent the king of David's house. It is in this connexion that the doctrine and name of the Messiah appear in the *Psalter of Solomon*. The eternal kingship of the house of David, so long forgotten, is seized on as the proof that the Hasmonæans have no divine right.

"Thou, Lord, art our king for ever and ever. . . . Thou didst choose David as king over Israel, and swarest unto him concerning his seed for ever that his kingship should never fail before Thee. And for our sins sinners (the Hasmonæans) have risen up over us, taking with force the kingdom which Thou didst not promise to them, profaning the throne of David in their pride. But Thou, O Lord, will cast them down and root out their seed from the land, when a man not of our race (Pompey) rises up against them. . . . Behold, O Lord, and raise up their king the Son of David at the time that Thou hast appointed, to reign over Israel Thy servant; and gird him with strength to crush unjust rulers; to cleanse Jerusalem from the heathen that tread it under foot, to cast out sinners from Thy inheritance; to break the pride of sinners and all their strength as potter's vessels with a rod of iron (Ps. ii. 9); to destroy the lawless nations with the word of his mouth (Isa. xi. 4); to gather a holy nation and lead them in righteousness. . . . He shall divide them by tribes in the land, and no stranger and foreigner shall dwell with them; he shall judge the nations in wisdom and righteousness. The heathen nations shall serve under his yoke; he shall glorify the Lord before all the earth, and cleanse Jerusalem in holiness as in the beginning. From the ends of the earth all nations shall come to see his glory and bring the weary sons of Zion as gifts (Isa. lx. 3 *sq.*); to see the glory of the Lord with which God hath crowned him, for he is over them a righteous king taught of God. In his days there shall be no unrighteousness in their midst; for they are all holy, and their king the anointed of the Lord (χριστὸς κύριος, mistranslation of משיח יהוה). He shall not trust on horses and riders and bowmen, nor heap up gold and silver for war, nor put his confidence in a multitude for the day of war. 'The Lord is king,' that is his hope. . . . He is pure from sin to rule a great people, to rebuke governors and destroy sinners by his mighty word. In all his days he is free from offence against his God, for He hath made him strong by the Holy Spirit. . . . His hope is in the Lord; who can do aught against him? Strong in deeds and mighty in the fear of the Lord, he feedeth the flock of the Lord in truth and righteousness, and suffereth not one of them to stumble in the pasture. . . . So it beseemeth the king of Israel whom God hath chosen to lead the house of Israel. . . . God hasten His mercy on Israel to deliver them from the uncleanness of profane foes. The Lord is our king for ever and ever."—*Psalt. Sol.* xvii.

This conception is traced in lines too firm to be those of a first essay; it had doubtless grown up as an integral part of the religious protest against the Hasmonæans. And while the polemical motive is obvious, and the argument from prophecy against the legitimacy of a non-Davidic dynasty is quite in the manner of the scribes, the spirit of theocratic fervour which inspires the picture of the Messiah is broader and deeper than their narrow legalism. In a word, the Jewish doctrine of the Messiah marks the fusion of Pharisaism with the national religious feeling of the

[1] In *Sibyll.*, iii. 775, νηόν must undoubtedly be read for υἱόν.

Maccabee revival. It is this national feeling that, claiming a leader against the Romans as well as deliverance from the Sadducee aristocracy, again sets the idea of the kingship rather than that of resurrection and individual retribution in the central place which it had lost since the captivity. Henceforward the doctrine of the Messiah is at once the centre of popular hope and the object of theological culture. The New Testament is the best evidence of its influence on the masses (see especially Matt. xxi. 9); and the exegesis of the Targums, which in its beginnings doubtless reaches back before the time of Christ, shows how it was fostered by the Rabbins and preached in the synagogues.[1] Its diffusion far beyond Palestine, and in circles least accessible to such ideas, is proved by the fact that Philo himself (*De Præm. et Pœn.*, § 16) gives a Messianic interpretation of Num. xxiv. 27 (LXX.). It must not indeed be supposed that the doctrine was as yet the undisputed part of Hebrew faith which it became when the fall of the state and the antithesis to Christianity threw all Jewish thought into the lines of the Pharisees. It has, for example, no place in the *Assumptio Mosis* or the *Book of Jubilees*. But, as the fatal struggle with Rome became more and more imminent, the eschatological hopes which increasingly absorbed the Hebrew mind all group themselves round the person of the Messiah. In the later parts of the *Book of Enoch* (the "symbols" of chaps. xlv. *sq.*) the judgment day of the Messiah (identified with Daniel's "Son of Man") stands in the forefront of the eschatological picture. Josephus (*B. J.* vi. 5, § 4) testifies that the belief in the immediate appearance of the Messianic king gave the chief impulse to the war that ended in the destruction of the Jewish state; after the fall of the temple the last apocalypses (*Baruch*, 4 *Ezra*) still loudly proclaim the near victory of the God-sent king; and Bar Cochebas, the leader of the revolt against Hadrian, was actually greeted as the Messiah by Rabbi Akiba (comp. Luke xxi. 8). These hopes were again quenched in blood; the political idea of the Messiah, the restorer of the Jewish state, still finds utterance in the daily prayer of every Jew (the *Sh'mônê Esrê*), and is enshrined in the system of Rabbinical theology; but its historical significance was buried in the ruins of Jerusalem.[2]

But the proof written in fire and blood on the fair face of Palestine that the true kingdom of God could not be realized in the forms of an earthly state, and under the limitations of national particularism, was not the final refutation of the hope of the Old Testament. Amidst the last convulsions of political Judaism a new and spiritual conception of the kingdom of God, of salvation, and of the Saviour of God's anointing, had shaped itself through the preaching, the death, and the resurrection of Jesus of Nazareth. As applied to Jesus the name of Messiah lost all its political and national significance, for His victory over the world, whereby He approved himself the true captain of salvation, was consummated, not amidst the flash of earthly swords or the lurid glare of the lightnings of Elias, but in the atoning death through which He entered into the heavenly glory. Between the Messiah of the Jews and the Son of Man who came not to be ministered to but to minister, and to give his life a ransom for many, there was on the surface little resemblance; and from their standpoint the Pharisees reasoned not amiss that the marks of the Messiah were conspicuously absent from this Christ. But when we look at the deeper side of the Messianic conception in the *Psalter of Solomon*, at the heartfelt longing for a leader in the way of righteousness and acceptance with God which underlies the aspirations after political deliverance, we see that it was in no mere spirit of accommodation to prevailing language that Jesus did not disdain the name in which all the hopes of the Old Testament were gathered up. The kingdom of God is the centre of all spiritual faith, and the perception that that kingdom can never be realized without a personal centre, a representative of God with man and man with God, was the thought, reaching far beyond the narrow range of Pharisaic legalism, which was the last lesson of the vicissitudes of the Old Testament dispensation, the spiritual truth that lay beneath that last movement of Judaism which concentrated the hope of Israel in the person of the anointed of Jehovah.

It would carry us too far to consider in this place the details of the Jewish conception of the Messiah and the Messianic times as they appear in the later apocalypses or in Rabbinical theology. See for the former the excellent summary of Schürer, *NTliche Zeitgeschichte*, §§ 28, 29 (Leipsic, 1874), and for the latter, besides the older books catalogued by Schürer (of which Schoettgen, *Horæ*, 1742, and Bertholdt, *Christologia Judæorum*, 1811, may be specially named), Weber, *Altsynagogale Theologie* (Leipsic, 1880). For the whole subject see also Drummond, *The Jewish Messiah* (London, 1877), and Kuenen, *Religion of Israel*, chap. xii. For the Messianic hopes of the Pharisees and the *Psalter of Solomon* see especially Wellhausen, *Pharisäer und Sadducäer* (Greifswald, 1874). In its ultimate form the Messianic hope of the Jews is the centre of the whole eschatology, embracing the doctrine of the last troubles of Israel (called by the Rabbins the "birth pangs of the Messiah"), the appearing of the anointed king, the annihilation of the hostile enemy, the return of the dispersed of Israel, the glory and world-sovereignty of the elect, the new world, the resurrection of the dead, and the last judgment. But even the final form of Jewish theology shows much vacillation as to these details, especially as regards their sequence and mutual relation, thus betraying the inadequacy of the harmonistic method by which they were derived from the Old Testament and the stormy excitement in which the Messianic idea was developed. It is, for example, an open question among the Rabbins whether the days of the Messiah belong to the old or to the new world (הָעוֹלָם הַזֶּה or הָעוֹלָם הַבָּא), whether the resurrection embraces all men or only the righteous, whether it precedes or follows the Messianic age. Compare MILLENNIUM.

We must also pass over the very important questions that arise as to the gradual extrication of the New Testament idea of the Christ from the elements of Jewish political doctrine which had so strong a hold of many of the first disciples—the relation, for example, of the New Testament Apocalypse to contemporary Jewish thought. A word, however, is necessary as to the Rabbinical doctrine of the Messiah who suffers and dies for Israel, the Messiah son of Joseph or son of Ephraim, who in Jewish theology is distinguished from and subordinate to the victorious son of David. The developed form of this idea is almost certainly a product of the polemic with Christianity, in which the Rabbins were hard pressed by arguments from passages (especially Isa. liii.) which their own exegesis admitted to be Messianic, though it did not accept the Christian inferences as to the atoning death of the Messianic king. That the Jews in the time of Christ believed in a suffering and atoning Messiah is, to say the least, unproved and highly improbable. See, besides the books above cited, De Wette, *Opuscula*; Wünsche, *Die Leiden des Messias*, 1870. The opposite argument of King, *The Yalkut on Zechariah* (Cambridge, 1882), App. A, does not really prove more than that the doctrine of the Messiah Ben Joseph found points of attachment in older thought. (W. R. S.)

MESSINA, a city and seaport at the north-east corner of Sicily, capital of the province of the same name,[3] is

[1] The Targumic passages that speak of the Messiah are registered by Buxtorf, *Lex. Chald.*, s.v.

[2] False Messiahs have continued from time to time to appear among the Jews. Such was Serenus of Syria (*circa* 720 A.D.). Messianic hopes were active at the time of the fall of the Omayyads, and led to a serious rising under Abu 'Isa of Ispahan, who called himself forerunner of the Messiah. The false Messiah David Alrui (Alroy) appeared among the warlike Jews in Azerbijan in the middle of the 12th century. The Messianic claims of Abraham Abulafia of Saragossa (born 1240) had a cabalistic basis, and the same studies encouraged the wildest hopes at a later time. Thus Abarbanel calculated the coming of the Messiah for 1503 A.D.; the year 1500 was in many places observed as a preparatory season of penance; and throughout the 16th century the Jews were much stirred and more than one false Messiah appeared. For the false Messiah Sabbathai, see vol. xiii. p. 681.

[3] The province occupies the north-east corner of the island, and is 60 miles in length by 30 in breadth. It is chiefly occupied with mountain ranges and valleys; there are few plains. The largest river is the

situated on the Straits of Messina (at this point about 4 miles wide), 8 miles north-west of Reggio and 130 miles east by north of Palermo, in 38° 15′ N. lat., 15° 30′ E. long. The town is built between the sea and a range of sharp and rugged hills, called the Dinnamare, 3707 feet at their highest point. It runs in a semicircle round the harbour, and presents a picturesque appearance from the sea, as the houses rise in tiers upon the slope of a hill, and behind are the wooded mountains.

Messina is the second town of Sicily in importance and in size. Its population was 97,074 in 1850, 111,854 in 1871, and 126,497 in 1881. It is an archiepiscopal see, and has a university, founded by the Jesuits in 1548, with a public library of 56,000 volumes.

The excellence of its harbour makes Messina an important trading town. The harbour is formed by a tongue of low land which runs out from the shore in the form of a sickle, and encloses a round basin, open to the north only, where the entrance channel is about 500 yards wide. This basin is 1¼ miles in circumference, and is of such depth that the largest vessels are able to use it. It is estimated that 1300 steamers, with a total of 1,000,000 tons burthen, and 9000 sailing ships, with a total of 500,000 tons burthen, enter the port yearly. The exports of Messina consist chiefly of oranges, lemons, raisins, wine, oil, liquorice, and hides. There is no prominent manufacture; but silk stuffs are made in considerable quantities. Many of the inhabitants are engaged in fishing, chiefly for tunny. Sword-fish also are captured with the harpoon in the Straits during July and August. Coral fishery is a trade of the people. The hills behind Messina produce a strong dark wine, inferior to that which is made in other parts of the island.

Messina has few buildings of importance or antiquity. The sieges and earthquakes from which the town has suffered destroyed most of its monuments. After the great earthquake in 1783 the city was almost entirely rebuilt. The cathedral, the principal building, is a church of the Norman period. It was begun in 1098 by Count Roger I., and finished by his son Roger II. The church is in the form of a Latin cross, 305 feet long and 145 feet wide in the transepts. The lower half of the façade is encrusted with slabs of red and white marble. It has three Gothic portals, with pointed arches and rich ornamentation, belonging to the period of the Anjou dynasty. The nave contains twenty-six columns of Egyptian granite, said to have been brought from an ancient temple of Poseidon which stood near the Faro. The mosaics of the apses date from the year 1330. In the choir are the sarcophagi of the emperor Conrad IV. (d. 1254), of Alphonso the Generous (d. 1458), and of Antonia, widow of Frederick III. of Aragon. In 1254 the cathedral was seriously damaged by fire; in 1559 the campanile was burned down; in 1783 the earthquake overthrew the campanile and the transept. The building therefore offers a mixture of styles,—first Norman, then Gothic, then Early Renaissance, finally Barocco and Modern Gothic.

The history of Messina begins very early. It is said to have been founded, on the site of a more ancient Sicilian town, by pirates from Cumæ, in 732 B.C. It took its earlier name of Zancle (a sickle) from the shape of its harbour. The number of its inhabitants was increased by an influx of Chalcidians under Cratæmenes; and in 649 B.C. the town was sufficiently prosperous and populous to establish a colony at Himera. The Samians occupied Zancle for a short time after Miletus had been captured by the Persians in 494 B.C. In the following year the city fell into the hands of Anaxilas, tyrant of Rhegium, who introduced a population of Messenians, from Messenia in the Peloponnesus; and they changed the name of the place to Messana, in the Doric pronunciation, to remind them of their fatherland. The sons of Anaxilas were expelled from the government of Messina in 466 B.C., and a republic established; and this government was continued until Messina fell into the hands of the Carthaginians during their wars with Dionysius the elder of Syracuse (396 B.C.). The Carthaginians destroyed the city; but Dionysius recaptured and rebuilt it. During the next fifty years Messina changed masters several times, till Timoleon finally expelled the Carthaginians in 343 B.C. In the wars between Agathocles of Syracuse and Carthage, Messina took the side of the Carthaginians. Agathocles's mercenaries, the Mamertines, treacherously seized the town in 288 B.C. and held it. They came to war with Hiero II. of Syracuse, after Agathocles's death; and Hiero's allies, the Carthaginians, helped him to reduce Messina. The Mamertines appealed for help to Rome, which was granted, and this led to a collision between Rome and Carthage, which ended in the First Punic War. At the close of that war, in 241 B.C., Messina became a possession of the Romans. During the civil wars which followed the death of Julius Cæsar, Messina held with Sextus Pompeius; and in 35 B.C. it was sacked by Octavian's troops. After Octavian's proclamation as emperor he founded a colony here; and Messina continued to flourish as a trading port. In the division of the Roman empire it belonged to the emperors of the East; and in 547 A.D. Belisarius collected his fleet here before crossing into Calabria. The Saracens took the city in 831 A.D.; and in 1061 it was the first permanent conquest made in Sicily by the Normans under Roger d'Hauteville. In 1190 Richard Cœur de Lion with his crusaders passed six months in Messina. He fell out with Tancred, the last of the Hauteville dynasty, and sacked the town. In 1194 the city, with the rest of Sicily, passed to the house of Hohenstaufen under the emperor Henry VI., who died there in 1197. At the time of the Sicilian Vespers (1282), which drove the French out of Sicily, Messina bravely defended itself against Charles of Anjou, and repulsed his attack. Peter I. of Aragon, through his commander Ruggiero di Loria, defeated the French off the Faro; and from 1282 to 1713 Messina remained a possession of the Spanish royal house. In 1571 the fleet fitted out by the Holy League against the Turk assembled at Messina, and in the same year its commander, Don John of Austria, celebrated a triumph in the city for his victory at Lepanto. Don John's statue stands in the Piazza dell' Annuziata. For one hundred years, thanks to the favours and the concessions of Charles V., Messina enjoyed great prosperity. But the internal quarrels between the Merli, or aristocratic faction, and the Malvezzi, or democratic faction, fomented as they were by the Spaniards, helped to ruin the city (1671–78). The Messinians suspected the Spanish court of a desire to destroy the ancient senatorial constitution of the city, and sent to France to ask the aid of Louis XIV. in their resistance. Louis despatched a fleet into Sicilian waters, and the French occupied the city. The Spaniards replied by appealing to Holland, who sent a fleet under Ruyter into the Mediterranean. The French admiral, Duquesne, defeated the combined fleet of Spain and Holland, but, notwithstanding this victory, the French suddenly abandoned Messina in 1678, and the Spanish occupied the town once more. The senate was suppressed, and Messina lost its privileges. This was fatal to the importance of the city, and it never recovered. In 1743 the plague carried off 40,000 inhabitants. The city was partially destroyed by earthquake in 1783. During the revolution of 1848 against the Bourbons of Naples, Messina was bombarded for three consecutive days. In 1854 the deaths from cholera numbered about 15,000. Garibaldi landed in Sicily in 1860, and Messina was the last city in the island taken from the Bourbons and made a part of united Italy under Victor Emmanuel.

Messina was the birthplace of the following celebrated men: Dicæarchus, the historian (*cir.* 322 B.C.); Aristocles, the Peripatetic; Euhemerus, the rationalist (*cir.* 316 B.C.); Stefano Protonotario, Mazzeo di Ricco, and Tommaso di Sasso, poets of the court of Frederick II. (1250 A.D.); and Antonello da Messina, the painter (1447–99), five of whose works are preserved in the university gallery. During the 15th century the grammarian Constantine Lascaris taught in Messina; and Bessarion was for a time archimandrite there.

METALLURGY, a branch of applied science whose object is to describe and scientifically criticize the methods used industrially for the extraction of metals from their ores. Of the large number of metals enumerated in the handbooks of chemistry, the vast majority, of course, lie outside its range; but it is perhaps as well for us to point out that in metallurgic discussions even the term "metallic," as applied to compounds, has a restricted meaning, being exclusive of all the light metals, although one of these, namely aluminium, is being manufactured industrially. The following table enumerates in the order of their importance the metals which our subject at present

Alcantara. The chief towns are Messina, Castroreale, Mistretta, Patti, and Milazzo. The population in 1854 was 380,279, in 1871 420,649, and in 1881 467,233.

is understood to include: the second column in each case gives the chemical characters of the native compounds utilized, italics indicating ores of subordinate importance. The term "oxide" must be understood to include carbonate, hydrate, and occasionally (when marked in the table with *) silicate.

Metal	Character of Ores.
Iron	Oxides, *sulphide.*
Copper	Complex sulphides, also oxides, *metal.*
Silver	Sulphide and reguline metal, *chloride.*
Gold	Reguline metal.
Lead	Sulphide and basic-carbonate, *sulphate*, &c.
Zinc	Sulphide, oxide *
Tin	Oxide.
Mercury	Sulphide, reguline metal.
Antimony	Sulphide.
Bismuth	Reguline metal.
Nickel and cobalt	Arsenides
Platinum and platinum metals	Reguline.
Aluminium	Oxide,* sodio-fluoride.

excess of unburned oxygen; or it is meant to deoxidize ("reduce") the ore, when the draught must be restricted so as to keep the ore constantly wrapped up in combustible flame gases (carbonic oxide, hydrogen, marsh-gas, &c.). The vast majority of the chemical operations of metallurgy fall into this category, and in these processes other metal-reducing agents than those naturally contained in the fire (or wind) are only exceptionally employed.

2. *Amalgamation.*—The ore by itself (if it happens to be a reguline one), or the ore plus certain reagents (if it does not), is worked up with mercury so that the metal is obtained ultimately as an amalgam, which can be separated mechanically from the dross. The purified amalgam is subjected to distillation, when the mercury is recovered as a distillate while the metal remains.

3. *Wet Processes.*—Strictly speaking, certain amalgamation methods fall under this head; but, in its ordinary acceptance, the term refers to processes in which the metal is extracted either from the natural ore, or from the ore as it is after roasting or some other preliminary treatment, by means of an aqueous acid or salt solution, and from this solution precipitated—generally in the reguline form—by some suitable reagent.

Few methods of metal extraction at once yield a pure product. What as a rule is obtained is a more or less impure metal, which requires to be "refined" to become fit for the market. We now pass to the individual consideration of the several steps referred to.

Comminution of Ores.—Assuming the ore to be given in the shape of large lumps, these must first be broken up into small stones (of about the size of those used for macadamizing a road) before they can go to the grinding-mill. This formerly used to be done by handwork; nowadays it is preferably effected by means of an American invention called the stone-breaker (fig. 1). This consists essentially of two substantial vertical iron plates; one is fixed, the other is connected with an excentric worked by an engine so as to alternately dash against and recede from the former. The lumps of ore, in passing through this jaw-like contrivance, are broken up into smaller fragments fit for

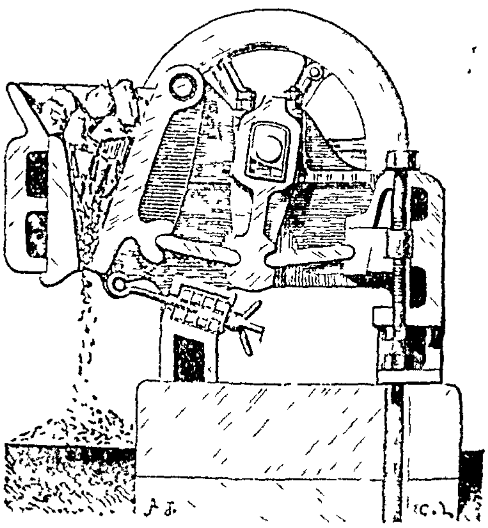

Fig. 1.—American Stone-Breaker.

the mill. For the production of a coarse powder revolving cylinders are often employed. Two cylinders of equal diameter and length, made of iron, steel, or stone, are suspended by parallel axes in close proximity to each other. The width of the slit between them can be made to vary according to the requirements of the case. The cylinders are made to revolve in opposite directions, so that the stones when run into the groove formed by their upper halves are drawn between them and are crushed into bits of a size depending on the least *distance between the two surfaces* Exceptionally hard stones might bring the machine to a standstill or cause breakages; hence only one of the two axes of rotation is absolutely fixed; the cushions of the other are only held in relatively fixed positions, each between a couple of guiding rails, by means of powerful springs at their backs. The springs are made of alternate disks of india-rubber and sheet-iron, and *yield appreciably only* to very strong pressures. When an exceptionally hard stone comes on, they yield

and allow it to pass through uncrushed. Sometimes two sets of cylinders are arranged one above the other, so that the grit from the upper falls into the jaws of the lower set to receive further comminution. The diameter of the cylinders is from a foot to a yard, their length from 9 inches to a yard, the velocity of a point on the periphery a foot to a yard per second. The quantity of ore reduced per hour per horse-power is about 5 cubic feet for quartz or other hard minerals, and about 14 cubic feet for minerals of moderate hardness.

For the production of a relatively fine powder the pounding-mill is frequently used, which, in its action, is analogous to a mortar and pestle. The mortar is a rectangular trough, while the pestle is replaced by a parallel set of heavy metal or metal-shod beams, which (by means of a revolving cylinder with cogs catching projections on the beams) are lifted up in succession and then let fall by their own weight so as to pound up the ore in the trough. The ore is supplied from a prismatic reservoir with a sloping bottom leading into a canal through which the stones slide into the trough. A current of water, which constantly flows into the trough from below, lifts up the finer particles and carries them away over the edge of the trough into a settling tank.

The object pursued in powdering an ore is to prepare it for being purified by washing. But the velocity with which a solid particle falls through water depends on its size as well as on its specific gravity—an increase in either accelerating the fall: hence, where the difference in specific gravity between the things to be separated is small, the washing must be preceded by a separation of the ore-powder into portions of approximately equal fineness. This is often effected by passing the ore through a system of sieves of different width of mesh superposed over one another, the coarser sieve always occupying the higher position. Sometimes the sieves are made to "go dry," sometimes they are aided in their action by a current of water which, more effectually than mere shaking, prevents adherence of dust to coarser parts.

Another contrivance is the "Drum" (fig. 2). A long perforated circular cylinder made of sheet-iron, open at both ends, is suspended, in a sloping position, by a revolving shaft passing through its axis. The size of the perforations is generally made to increase in passing from the upper to the lower belts of the cylinder. While the drum

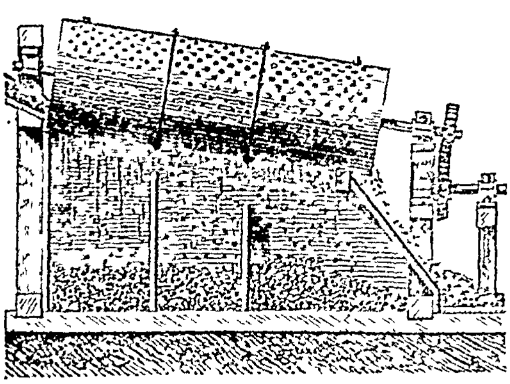

FIG. 2.—Drum.

is revolving, the ore, suspended in water, flows in at the upper end, and in travelling down it casts off first its finest and then its coarser parts, the coarsest only reaching the exit at the lower end. The several grades of powder produced fall each into a separate division of the collecting tank.

The drum, of course, is subject to endless modifications. A very ingenious combination is H. E. Taylor's "Drum Dressing Machine" (fig. 3). It consists of three truncated cone-shaped drums D, fixed co-axially to the same horizontal revolving shaft,

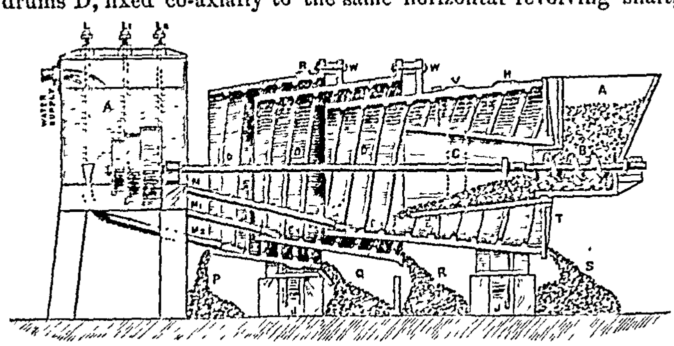

FIG. 3.—Taylor's Drum Dressing Machine.

so that the narrow end of No. 1 projects into the wider end of No. 2, and No. 2 similarly into No. 3. The drums are not perforated, but are armed inside with screw-threads formed of strips of sheet metal fixed edgeways to the drum. The ore grit to be dressed is placed in a hopper A, and from it, by a worm B fixed to the revolving shaft, is being screwed forward into a short fixed truncated cone C projecting into the revolving drum No. 1, into which it flows in a constant current. The rotary motion of the drum tends to convey the ore along the spiral path prescribed by the screw-thread towards the other end, and from it into drum No. 2, and so on. But the ore in each drum meets with a jet of water E impelling it the opposite way, and the effect is that, in each drum, the lighter parts follow the water, and with it run off over the entrance edge to be collected in a special tank, while the coarser parts roll down the spiral path toward the next drum to undergo further parting. The tank or pit for drum 1 receives the finest and lightest parts, that of drum 2 a heavier, that of drum 3 a still heavier portion, while only the very heaviest matter finds its way out of the exit end of No. 3 into a fourth receptacle.

Of the large number of other ore-dressers, only two need be mentioned here.

The "Clausthal Turn-Table" consists of a circular table, the surface of which rises from the periphery towards the centre so as to form a very flat cone of about 170°, which is fixed co-axially to a vertical rotary shaft. At the apex of the table, surrounding the shaft, but independent of its motion, there is a circular trough of sheet zinc, divided into two compartments; one receives a stream of water carrying the ore, the other a supply of pure water. A large annular trough of sheet zinc is placed below the periphery of the table, so as to receive whatever may fall over the edge. It also is divided into compartments, as shall be explained further on. Supposing the table to be at rest, a sector of about 60° of it would be constantly run over by the ore-mud out of the first compartment of the upper trough. This mud current would suffer partial separation into heavier and lighter parts,—rich ore resting in the higher and poorer in the lower latitudes, and a still poorer ore falling over the periphery into the lower trough. The same happens with the moving table; only each sector of such partially analysed ore undergoes further purification by passing through about 90° of water-shower. After passing this, it meets with a perforated fixed water-pipe going up radially to about half the radius of the table. This pipe also carries sweeping brushes, so that the belt of ore from the lower latitudes of the table is swept off into the corresponding section of the receiving trough. What of ore remains on the higher latitudes subsequently meets with a similar arrangement which sweeps it off into its compartment. If the table turns from the left to the right, and we follow the process, beginning at the left edge of the ore-mud compartment, it will be seen that a first sector of the receiving trough gathers the light dross, a succeeding one an intermediate product, a third the most highly purified ore. The "intermediate" is generally run into the ore-mud trough of a second table to be further analysed.

In the "Continuous Wash-Pumps" (Continuirliche Setzpumpe) of the Harz, three funnel-shaped vessels (one of which is shown in fig. 4) are set in a frame beside one another, but at different levels, so that any overflow from No. 1 runs into No. 2 and thence into No. 3. Each funnel communicates below with its own compartment of a common cistern. Into each funnel a riddle with narrow meshes is inserted somewhere near the upper end, while, beside the riddle, there is a pump of short range, which, by means of an excentric, is worked so that the piston alternately goes rapidly down and slowly up. The mode of working is best explained by an example. At Breinigerberg in Rhenish Prussia the apparatus serves to separate a complex ore into the following four parts, which we enumerate in the order of their specific gravities—(1) galena (the heaviest), (2) pyrites, (3) blende, (4) dross. Sieve No. 1 is charged with granules of galena, just large enough not to slip through the meshes, No. 2 similarly with granules of pyrites, No. 3 with those of blende. The crude ore-mud goes into sieve 1; the jerking action of the pump alternately tosses the particles up into the water and allows them to fall; the heaviest naturally come down first, but what is most striking is that nothing will pass through the bed of galena but what is at least as heavy as galena itself. In a similar manner No. 2 and No. 3

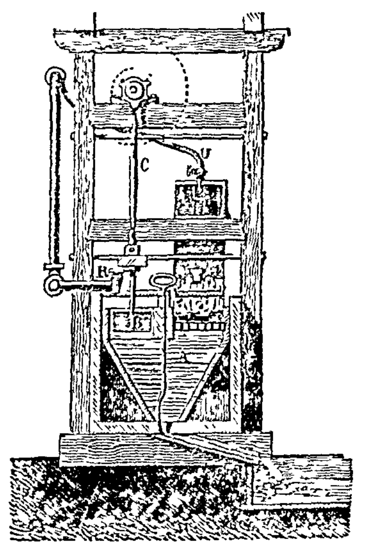

FIG. 4.—Continuous Wash-Pump.

funnels sift out the pyrites and the blende respectively, so that almost nothing but dross runs off ultimately. The apparatus is said to do its work with a wonderful degree of precision, and of course is susceptible of wider application, but it ceases to work when the raw material is a slime so fine that the particles fall too slowly.

Modes of Producing High Temperatures.—Most of what is to be said on this topic has already been anticipated in the articles FUEL, FURNACE, and BELLOWS; but a few notes may be added on specially metallurgic points.

Furnace Materials.—In a metallurgic furnace the working parts at least must be made of special materials capable of withstanding the very high temperatures to which they are exposed and the action of the fluxes which may be used. No practically available material fully meets both requirements, but there is no lack of merely fire-proof substances.

Of native stones, a pure quartzose sandstone, free from marl, may be named as being well adapted for the generality of structures; but such sandstone, or indeed any kind of fire-proof stone, is not always at hand. What is more readily procured, and consequently more widely used, is refractory brick, made from "fire-clay." The characteristic chemical feature of fire-clays is that in them the clay proper (always some kind of hydrated silicate of alumina) is associated with only small proportions of lime, magnesia, ferrous oxide, or other protoxides. If the percentage of these goes beyond certain limits, the bricks, when strongly heated, melt down into a slag. The presence of free silica, on the other hand, adds to their refractoriness. In fact the best fire-bricks in existence are the so-called Dinas bricks, which consist substantially of silica, contaminated only with just enough of bases to cause it to frit together on being baked. Dinas bricks, however, on account of their high price, are reserved for special cases involving exceptionally high temperatures. Amongst ordinary fire-bricks those from Stourbridge enjoy the highest reputation. It follows from what has just been said that, in a metallurgic furnace, lime-mortar cannot be used as a cement, but must be replaced by fire-clay paste.

In the construction of cupels, reverberatory furnaces, &c., only the general groundwork is, as a rule, made of built bricks, and this groundwork is coated over with some kind of special fire-proof and flux-proof material, such as bone-ash, a mixture of baked fire-clay and cokes or graphite, or of quartz and very highly silicated slags, &c. These beddings are put on in a loose powdery form, and then stamped fast. They offer the advantage that, when worn out, they are easily removed and renewed. The powerful draught which a metallurgic fire needs can be produced by a chimney, where the fuel forms a relatively shallow layer spread over a large grating; but, when closely-packed deep masses of fuel or fuel and ore have to be kept ablaze, a blast becomes indispensable.

Chimneys.—The efficiency of a chimney is measured by the velocity V with which the air ascends through it, multiplied by its section; and the former is in roughly approximate accordance with the formula

$$V = k\sqrt{2gh(T - T_0)/T_0},$$

where h stands for the height of the chimney, g for the acceleration of gravity (32·2 feet per second), and T and T_0 for the absolute temperatures (meaning the temperatures counted from −273° C.) of the air within and the air without the chimney respectively, while k is a factor meant to account for the resistances which the air, in its progress through the furnace, &c., has to overcome. In practice T is taken as the mean temperature of the chimney gases, which theoretically is not unobjectionable; but the weakest point in the formula is the smallness and utter inconstancy of the factor k, which, according to Péclet, generally assumes some value of the power $\frac{1}{2}$, $\frac{1}{3}$, &c. Yet the formula is of some use as enabling one to see the way in which V depends on h and $(T - T_0)/T_0$ conjointly,—to see, for instance, how deficient chimney height may be compensated for by an increase of temperature in the chimney gases, and *vice versa*.

Blowing-Machines.—Of the several kinds of blowers described under BELLOWS (*q.v.*), the "fans" are the best means for producing large volumes of wind of relatively small but steady pressure; "bellows" are indicated in the case of work on a relatively small scale requiring moderate wind pressure; while the "cylinder blast" comes in where large masses of high-pressure wind are required. Two highly interesting blowing-machines, however, are omitted in that article, which may be shortly described here.

The "Water Blast" (Wassertrommelgebläse) is interesting historically, having been used metallurgically in Hungary for many centuries. A mass of water, stored up in a reservoir, is made to fall down continuously through a high narrow vertical shaft having air-holes at its upper end. The vertical column of water sucks in air through these holes and carries it down with it into a kind of inverted tub standing in a reservoir kept at a constant level. Air and water there separate, the former flowing away through a pipe into a wind-box, from which it is led to its destination.

The "Cagniardelle" (figs. 5, 6), so called from its inventor Cagniard Latour, also utilizes water to carry air, but in quite another way. By means of a round shaft passing through its axis, a cylindrical drum of sheet-metal is suspended slantingly in a mass of water, so that the lower end is fully immersed, while of the upper end the segment above the upper side of the shaft is uncovered. The space between shaft and drum is converted into a very wide screw-shaped canal by a band of sheet-metal hermetically fixed edgeways to the two. Both the top and the bottom end of the drum are partially closed by flat

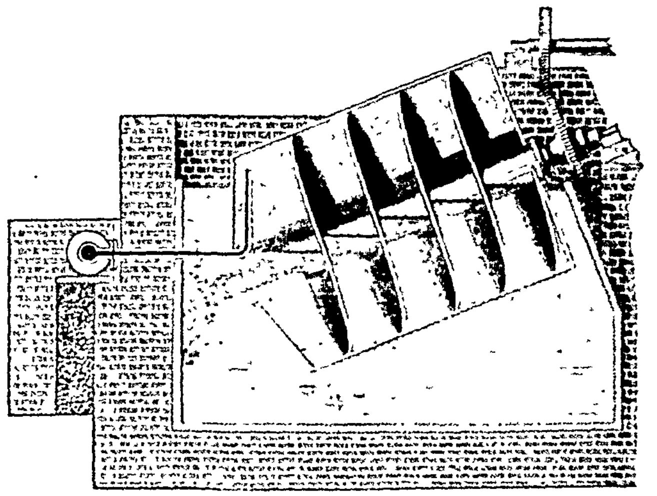

FIG. 5.—Cagniardelle.

bottoms soldered or riveted to the respective edges; the lower one leaves a ring-shaped opening between its edge and the shaft, which serves for the introduction of a fixed air-pipe bent so as to reach up to near the top of the drum's air-space; in the upper bottom three quadrants are closed, *the fourth is open*. Supposing the screw-canal, traced from below, to go from the left to the right, the drum is made to revolve in the same sense, and the effect is that, in each revolution, the screw-canal at its top end swallows a certain volume of air which, by the succeeding entrance of the water—which, of course, moves relatively to the screw—is pushed towards and ultimately into the air-space at the bottom end. The Cagniardelle yields a perfectly continuous blast, and, as it is not encumbered with any dead resistances except the friction of the shaft against its bearings (which can be reduced to very little) and the very slight friction of the water against the screw-canal, it utilizes a very large percentage of the energy spent on it. This percentage, according to experiments by Schwamkrug, amounts to from 75 to 84·5; in the case of the cylinder-blast it is 60 to 65 per cent.; with bellows, about 40 per cent.; with the "Wassertrommelgebläse" 10 to 15 per cent. Hence the "Wassertrommelgebläse" stands last in relative efficiency; but we must not forget that it alone directly utilizes native energy, while, in the cylinder blast, for example, 100 units of work done by the steam-engine involve a vastly greater energy spent on the engine as heat.

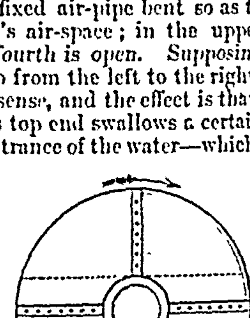

Fig. 6.

To maintain a desired temperature in a given furnace charged in a certain manner, the introduction of a certain volume of air per unit of time is necessary. But this quantity, in a given blowing-machine, is determined by the over-pressure of the wind, as measured by a manometer, the velocity of the wind being approximately proportional to $\sqrt{M/(B+M)}$, where M stands for the height of the mercury-manometer, and B for that of the barometer. Hence the practical metallurgist, in adjusting his blast, has nothing to do but to see that the manometer shows the reading which, by previous trials, has been proved to yield an adequate supply of wind.

Fuel.—In some isolated cases the ore itself, by its combustion, supplies the necessary heat for the operation to be performed upon it. Thus, for instance, the roasting of blackband iron-stone is effected by simply piling up the ore and setting fire to it, so that the ore is at the same time its own furnace and fuel; in the Bessemer process of steel-making, the burning carbon of the pig-iron supplies the heat necessary for its own combustion; and a similar process has been tried experimentally, and not without success, for the working up of certain kinds of pyrites. But, as a rule, the high temperatures required for the working of ores are produced by the combustion of extraneous fuel, such as wood, wood-charcoal, coal, coke. Of these four, wood-charcoal is of the widest applicability, but not much used in Britain on account of its high price. High-class coke or pure anthracite, volume for volume,

gives the highest temperature. Wood or coal is indicated when a voluminous flame is one of the requisites. Obviously fuel of the same kind and quality gives a higher calorific intensity when, before use, it is deprived by drying of its moisture, or when it is used in conjunction with a hot instead of a cold blast. This latter principle, as every one knows, is largely discounted in the manufacture of pig-iron, where nowadays coal, with the help of the hot blast, is made to do what formerly could only be effected with charcoal or coke. For further information see FUEL and IRON.

Chemical Operations.—In regard to processes of amalgamation and to wet-way processes, we have nothing to add to what was given in a previous paragraph;[1] we therefore here confine ourselves, in the main, to pyro-chemical operations.

The method to be adapted for the extraction of a metal from its ore is determined chiefly, though not entirely, by the nature of the non-metallic component with which the metal is combined. The simplest case is that of the reguline ores where there is no non-metallic element. The important cases are those of GOLD, BISMUTH, and MERCURY (*q.v.*).

Oxides, Hydrates, Carbonates, and Silicates.—All iron and tin ores proper fall under this heading, which, besides, comprises certain ores of copper, of lead, and of zinc. In any case the first step consists in subjecting the crude ore to a roasting process, the object of which is to remove the water and carbonic acid, and burn away, to some extent at least, what there may be of sulphur, arsenic, or organic matter. The residue consists of an impure (perhaps a very impure) oxide of the respective metal, which in all cases is reduced by treatment with fuel at a high temperature. Should the metal be present in the silicate form, lime must be added in the smelting to remove the silica and liberate the oxide.

In the case of zinc the temperature required for the reduction lies above the boiling point of the metal; hence the mixture of ore and reducing agent (charcoal is generally used) must be heated in a retort combined with the necessary condensing apparatus. In all the other cases the reduction is effected in the fire itself, a tower-shaped blast furnace being preferably used. The furnace is charged with alternate layers of fuel and ore (or rather ore and flux, see below), and the whole kindled from below. The metallic oxide, partly by the direct action of the carbon with which it is in contact, but principally by that of the carbonic oxide produced in the lower strata from the oxygen of the blast and the hot carbon there, is reduced to the metallic state; the metal fuses and runs down, with the slag, to the bottom of the furnace, whence both are withdrawn by the periodic opening of plug-holes provided for the purpose.

Sulphides.—Iron, copper, lead, zinc, mercury, silver, and antimony very frequently present themselves in this state of combination, as components of a very numerous family of ores which may be divided into two sections: (1) such as substantially consist of simple sulphides, as iron pyrites (FeS_2), galena (PbS), zinc blende (ZnS), cinnabar (HgS); and (2) complex sulphides, such as the various kinds of sulphureous copper ores (all substantially compounds or mixtures of sulphides of copper and iron); bournonite, a complex sulphide of lead, antimony, and copper; rothgiltigerz, sulphide of silver, antimony, and arsenic; fahlerz, sulphides of arsenic and antimony, combined with sulphides of copper, silver, iron, zinc, mercury, silver; and mixtures of these and other sulphides with one another.

In the treatment of a sulphureous ore, the first step as a rule is to subject it to oxidation by roasting it in a reverberatory or other furnace, which, in the first instance, leads to the burning away of at least part of the arsenic and part of the sulphur. The effect on the several individual metallic sulphides (supposing only one of these to be present) is as follows:—

1. Those of silver (Ag_2S) and mercury (HgS) yield sulphurous acid gas and metal; in the case of silver, sulphate is formed as an intermediate product, at low temperatures. Metallic mercury, in the circumstances, goes off as a vapour, which is collected and condensed; silver remains as a regulus, but pure sulphide of silver is hardly ever worked.

2. Sulphides of iron and zinc yield the oxides Fe_2O_3 and ZnO as final products, some basic sulphate being formed at the earlier stages, more especially in the case of zinc. The oxides can be reduced by carbon.

3. The sulphides of lead and copper yield, the former a mixture of oxide and normal sulphate, the latter one of oxide and basic sulphate. Sulphate of lead is stable at a red heat; sulphate of copper breaks up into oxide, sulphurous acid, and oxygen. In practice, neither oxidation process is ever pushed to the end; it is stopped as soon as the mixture of roasting-product and unchanged sulphide contains oxygen and sulphur in the ratio of $O_2:S$. The access of air is then stopped and the whole heated to a higher temperature, when the potential SO_2 actually goes off as sulphurous-acid gas and the whole of the metal is eliminated as such. This method is largely utilized in the smelting of lead (from galena) and of copper from copper pyrites. In the latter case, however, the sulphide Cu_2S has first to be produced from the ore, which is done substantially as follows. The ore is roasted with silica until a certain proportion of the sulphur is burned away as SO_2, while a corresponding proportion of oxygen has gone to the metal part of the ore. Now it so happens that copper has a far greater affinity for sulphur than iron has; hence any locally produced oxide of copper, as long as sufficient sulphide of iron is left, is sure to be reconverted into sulphide, and the final result is that, while a large quantity of oxidized iron passes into the slag, all the copper and part of the iron separate out as a mixed regulus of Cu_2S and FeS ("mat"). This regulus, by being fused up repeatedly with oxidized copper ores or rich copper slags (virtually with CuO and silica), gradually yields up the whole of its iron, so that ultimately a regulus of pure subsulphide of copper, Cu_2S ("fine mat"), is obtained, which is worked up for metal as above explained.

4. Sulphide of antimony, when roasted in air, is converted into a kind of alloy of sulphide and oxide; the same holds for iron, only its oxysulphide is quite readily converted into the pure oxide Fe_2O_3 by further roasting. Oxysulphide of antimony, by suitable processes, can be reduced to metal, but these processes are rarely used, because the same end is far more easily obtained by "precipitation," *i.e.*, withdrawing the sulphur by fusion with metallic iron, forming metallic antimony and sulphide of iron. Both products fuse, but readily part, because fused antimony is far heavier than fused sulphide of iron is. A precisely similar method is used occasionally for the reduction of lead from galena. Sulphide of lead when fused together with metallic iron in the proportion of 2Fe : 1PbS yields a regulus (=1Pb) and a "mat" Fe_2S, which, however, on cooling, decomposes into FeS parts of ordinary sulphide and Fe parts of finely divided iron. What we have just been explaining are only two special cases of a more general metallurgic proposition. According to Fournet, any one of the metals copper, iron, tin, zinc, lead, silver, antimony, arsenic, in general, is capable of desulphurizing or precipitating (at least partially) any of the others that follows it in the series just given, and it does so the more readily and completely the greater the number of intervening terms. Hence, supposing a complete mixture of these metals to be melted down under circumstances admitting of only a partial sulphuration of the whole, the copper has the best chance of passing into the "mat," while the arsenic is the first to be eliminated as such, or, in the presence of oxidants, as oxide.

Arsenides.—Although arsenides are amongst the commonest impurities of ores generally, ores consisting essentially of arsenides are comparatively rare. The most important of them are certain double arsenides of cobalt and nickel, which in practice, however, are always contaminated with the arsenides or other compounds of foreign metals, such as iron, manganese, &c. The general mode of working these ores is as follows. The ore is first roasted by itself, when a part of the arsenic goes off as such and as oxide (both volatile), while a complex of lower arsenides remains. This residue is now subjected to careful oxidizing fusion in the presence of glass or some other fusible solvent for metallic bases. The effect is that the several metals are oxidized away and pass into the slag (as silicates) in the following order,—first the manganese, secondly the iron, thirdly the cobalt, lastly (and very slowly) the nickel; and at any stage the as yet unoxidized residue of arsenide assumes the form of a fused regulus, which sinks down through the slag as a "speis." (This term, as will readily be understood, has the same meaning in reference to arsenides as "mat" has in regard to sulphides.) By stopping the process at the right moment, we can produce a speis which contains only cobalt and nickel, and if at this stage also the flux is renewed we can further produce a speis which contains only nickel and a slag which substantially is one of cobalt only. The composition of the speises generally varies from $AsMe_{3\cdot2}$ to $AsMe_2$, where "Me" means one atomic weight of metal in toto, so that in general $1Me = xFe + yCo + zNi$, where $x+y+z=1$. The siliceous cobalt is utilized as a blue pigment called "smalte"; the nickel-speis is worked up for metal, preferably by wet processes.

Minor Reagents.—Besides the oxidizing and reducing agents naturally present in the fire, and the "fluxes" added for the production of slags, there are various minor reagents; of which the more important may be noticed here. One—namely, metallic iron as a desulphurizer—has already been referred to.

Oxide of lead, PbO (litharge), is largely used as an oxidizing agent. At a red heat, when it melts, it readily attacks all metals, except silver and gold, the general result being the formation of a mixed oxide and of a mixed regulus, a distribution, in other words, of both the lead and the metal acted on between slag and regulus. More important and more largely utilized is its action on metallic sulphides, which, in general, results in the formation of three things besides sulphurous acid gas, viz., a mixed oxide slag including the excess of litharge, a regulus of lead (which may include bismuth and other more readily reducible metals), and, if the litharge is not sufficient for a complete oxidation, a "mat" comprising the more readily sulphurizable metals. Oxide of lead, being a most powerful solvent for metallic oxides generally, is also

[1] Examples are given in GOLD and COPPER. See also SILVER.

largely used for the separation of silver or gold from base metallic oxides.

Metallic lead is to metals generally what oxide of lead is to metallic oxides. It accordingly is available as a solvent for so to say licking up small particles of metal diffused throughout a mass of slag or other dross, and uniting them into one regulus. This naturally leads us to consider the process of "cupellation," which discounts the solvent powers of both metallic lead and its oxide. This process serves for the extraction of gold and silver from their alloys with base metals such as copper, antimony, &c. The first step is to fuse up the alloy with a certain proportion of lead, which is determined by the weight of base metal to be eliminated, and is always sufficient to produce a lead-alloy of low fusing point. This alloy is heated on a shallow dish-shaped bed of bone earth to redness, and at this temperature subjected to the action of air. The base metals (copper, &c.) are oxidized away, the first portions as an infusible scum containing little oxide of lead, the latter in the form of a solution in molten litharge. Lead is, in general, less oxidizable than the other base metals; hence the last instalment of liquid litharge which runs off is pure, and the ultimately remaining regulus consists of silver and gold only. These latter may be separated by nitric acid or boiling oil of vitriol, which converts the silver into soluble salts and leaves the gold.

Oxide of iron, and also binoxide of manganese, are used for the decarburation of pig-iron. The oxygen of the reagent burns the carbon of the pig into carbonic acid, while the metal of the reagent becomes iron and FeO or MnO respectively, the oxides uniting with the silica added as such, or formed by the oxidation of the silicon of the pig, into a fusible slag.

Iron pyrites, FeS_2, is employed for the preliminary concentration of traces of gold diffused throughout slags or base ores. The reagent, through the action of the heat, gives up one-half of its sulphur, which reduces part of the metallic oxides present. The gold and silver unite with what is left of protosulphide of iron (FeS) into a mat, which is then worked up for the noble metals.

Fluxes.—Practically speaking, all ores are contaminated with more or less of gangue, which in general consists of infusible matter, and consequently, if left unheeded in the reduction of the metallic part of the ore, would retain more or less of the metal disseminated through it, or at best foul the furnace. To avoid this, the ore as it goes into the furnace is mixed with "fluxes" so selected as to convert the gangue into a fusible "slag," which readily runs down through the fuel with the regulus and separates from the latter. The quality and proportion of flux should, if possible, be so chosen that the formation of the slag sets in only after the metal has been reduced and molten; or else part of the basic oxide of the metal to be extracted may be dissolved by the slag and its reduction thus be prevented or retarded. Slags are not, as one might be inclined to think, a necessary evil; if an ore were free from gangue we should add gangue and flux from without to produce a slag, because one of its functions is to form a layer on the regulus which protects it against the further action of the blast or furnace gases. Fluxes may be arranged under the three heads of (1) fluor-spar (which is *sui generis*), (2) basic fluxes, and (3) acid fluxes.

Fluor-spar owes its name to the facility with which it fuses up at a red heat with silica, sulphates of lime and barium, and a few other infusible substances into homogeneous masses. It shows little tendency to dissolve basic oxides, such as lime, &c. One part of fluor-spar liquefies about half a part of silica, four parts of sulphate of lime, and one and a half parts of sulphate of baryta. Upon these facts its wide application in metallurgy is founded.

Carbonate of soda (or potash) may be said to be the most powerful of basic fluxes. It dissolves silica and all silicates into fusible glasses. On the other hand, borax may be taken as a type for the acid fluxes. At a red heat, when it forms a viscid fluid, it readily dissolves up all basic oxides into fusible complex borates. Now the gangue of an ore in general consists either of some basic material such as carbonate of lime (or magnesia), ferric oxide, alumina, &c., or of silica (quartz) or some more or less acid silicate, or else of a mixture of the two classes of bodies. So any kind of gangue might be liquefied by means of borax or by means of alkaline carbonate; but neither of the two is used otherwise than for assaying; what the practical metal-smelter does is to add to a basic gangue the proportion of silica, and to an acid ore the proportion of lime, or, indirectly, of ferrous or perhaps manganous oxide, which it may need for the formation of a slag of the proper qualities. The slag must possess the proper degree of saturation. In other words, taking $SiO_2 + nMeO$ (where MeO means an equivalent of base) as a formula for the potential slag, n must have the proper value. If n is too small, *i.e.*, if the slag is too acid, it may dissolve up part of the metal to be brought out as a silicate; if n is too great, *i.e.*, the slag too basic, it may refuse to dissolve, for instance, the ferrous oxide which is meant to go into it, and this oxide will then be reduced, and its metal (iron in our example) contaminate the regulus. In reference to the problem under discussion, it is worth noting that oxides of lead and copper are more readily reduced to metals than oxide of iron Fe_2O_3 is to FeO, the latter more readily to FeO than FeO itself to metal, and FeO more readily to metal than manganous oxide is. Oxide of calcium (lime) is not reducible at all. The order of basicity in the oxides (their readiness to go into the slag) is precisely the reverse.

Most slags being, as we have seen, complex silicates, it is a most important problem of scientific metallurgy to determine the relations in this class of bodies between chemical composition on the one hand and fusibility and solvent power for certain oxides (CaO, FeO, SiO, &c.) on the other. Now the composition of a silicate can be stated in an infinite number of ways; but there must be one mode of formulation which reduces the law to its simplest terms. The mode adapted by metallurgists is something like the following. If we start with the quantity H_2Cl_2 of muriatic acid or the quantity H_2SO_4 of sulphuric acid, it is clear that to convert either into a normal salt we require such a quantity of base as will convert the H_2 of the acid completely into water; but the quantity of base that does so is that containing one atomic weight of oxygen. Hence it is reasonable to define the quantities K_2O of potash,[1] Na_2O of soda,[1] CaO of lime, MgO of magnesia, FeO of ferrous oxide, $\frac{1}{3}Al_2O_3(=alO)$ of alumina, $\frac{1}{3}Fe_2O_3(=feO)$ of ferric oxide, as representing each "one equivalent" of base also in reference to silica, although silica has a characteristically indefinite basicity. Most slags are alloys or compounds of silicates of Al_2O_3 or Fe_2O_3, and of silicates of protoxides (CaO, &c.), hence their general composition is

$$n(RO + xSiO_2) + m[(fe \text{ or } al)O + xSiO_2].$$

This introduction will enable the reader to understand the following mode of classifying and naming composition in silicates.

Name.	Formula.	Oxygen Ratio. Base. : Acid.	x
I. Singulo-silicates	$\frac{1}{2}SiO_2 + 1MO$	1 : 1	$\frac{1}{2}$
II. Bi-silicates	$1SiO_2 + 1MO$	1 : 2	1
III. Tri-silicates	$\frac{3}{2}SiO_2 + 1MO$	1 : 3	$\frac{3}{2}$

The names are the metallurgic ones; scientific chemists designate Class I. as orthosilicates, Class II. as metasilicates, Class III. as sesquisilicates. In the formulæ M stands for K_2, Ca, Fe, &c., or for al$=\frac{2}{3}$Al, fe$=\frac{2}{3}$Fe, &c.; or, shortly, MO for one equivalent of base as above defined. It should be possible to represent each quality of a silicate as a function of x, $\frac{n}{m}$, and of the nature of the individual bases that make up the RO and (fe or al) O respectively. Our actual knowledge falls far short of this possibility. The problem, in fact, is a very tough one, the more so as it is complicated by the existence of aluminates, compounds such as $Al_2O_3.3CaO$, in which the alumina plays the part of acid, and the occasional existence of compounds of fluorides and silicates in certain slags. The following notes on the fusibility of simple silicates are taken from Plattner's researches.

Of the lime silicates, the tri-silicate melts at 2100° C., the bi-silicate at 2150°.

Magnesia silicates are most refractory. The bi-silicate and tri-silicate melt in the oxyhydrogen flame at 2250°.

Of manganous silicates, the easily fusible bi-silicate is yellow or red; the tri-silicate is more refractory.

Of cuprous (Cu_2O) silicates, the bi-silicate is violet, and melts pretty easily; the singulo-silicate is red, dense, and rather refractory.

Cupric silicates, as slags, hardly exist,—the CuO being always reduced to at least Cu_2O.

Lead silicates all melt readily into yellowish transparent glasses. But they have no standing as slags.

As regards the ferrous silicates, the singulo-silicate (orthosilicate) fuses at 1790° (this is about the composition of iron-puddling slag); the bi-silicate is less readily fusible.

Ferric silicates (unmixed) do not exist as slags,—the Fe_2O_3 being reduced in the fire to 1FeO, although Fe_2O_3 occasionally replaces part of the Al_2O_3 in complex silicates.

Alumina silicates are all infusible in even the hottest furnace fires. They begin to soften in the oxyhydrogen flame at about 2400°. But certain aluminates, for instance the salt $3\,CaO.1Al_2O_3$ according to Sefström, melt at furnace heats.

The fusing points of mixtures of two simple silicates cannot be calculated from those of the components. In many cases it is lower than either of the latter two. Thus for instance most magnesia-lime silicates fuse,—the bi-silicate combination (Mg, Ca)$OSiO_2$ most readily.

Alumina silicates become fusible by addition of a sufficient proportion of silicate of lime at about 1918°. The singulo-silicate and bi-silicate combinations melt into grey glasses. Magnesia acts like lime, and so, in a more limited sense, do ferrous and manganous oxides; but their double compounds with Al_2O_3 and silica are more viscid when fused.

Plattner's work is a bold attempt to deal synthetically with the problem here presented, but it does not go the length of even an approximate solution. No one seems to have done much to continue it; hence in the meantime the metallurgist has, for his

[1] Few slags contain more than traces of alkalies.

guidance, to rely on the very numerous analyses which have been made of slags actually produced (by the rule of thumb) in successful metallurgical operations. For some of such slags also Plattner has determined the fusing points. He found for (1) Freiberg lead slag, 9RO, 3alO, $8SiO_2$; oxygen-ratio, 3 : 4; melting-point at 1317° C.; (2) Freiberg crude slag, 15RO, 3alO, $18SiO_2$; oxygen-ratio, 1 : 1; melting-point at 1331° C.; (3) Freiberg black-copper slag, 24FeO, Al_2O_3, $15SiO_2$; oxygen-ratio, 9 : 10; melting-point at 1338° C.; (4) High-furnace slag, 6CaO, 3alO, $9SiO_2$; oxygen-ratio, 1 : 1; melting-point at 1431° C.[1]

Metallurgic Assaying.—To assay an ore originally meant to execute a set of tentative experiments on a small scale in order to find out the proper mode of working it practically. But nowadays the term is always used in the sense of an analysis carried out to determine the money-value of an ore. For this purpose, in many cases it is sufficient to determine the percentages of the metals for which the ore is meant to be worked. But sometimes nothing short of a complete analysis will do. This holds more especially of ores of iron. As this metal is cheap, the value of an ore containing it depends as much on the nature and relative quantities of the impurities as on the percentage of metal. The proved absence of sulphur and phosphorus may be worth more than an additional 5 per cent. of iron, which latter again would perhaps not compensate for the proved presence of a large percentage of uncombined silica.

An assay to be of any value must start with a fair sample of the object of sale. The fulfilment of this condition in all cases is difficult. The general method is, from say a given ship load of ore, to take out (say) half a ton of ore from a large number of different places and to crush this large sample into small fragments of uniform size, which are well shovelled up together. From different parts of this ore-heap a sample of the second order—amounting to, say, 20 ℔—is then drawn, and rendered more homogeneous by finer powdering and mixing. From this sample of the second (or perhaps from one of the third) order quantities of 1 or 2 ℔ are bottled up for assaying. At the same time the moisture of the ore is determined, on a large scale, by some conventional method, such as the drying of 1 or 2 ℔ in an open basin at 100° C., and weighing of the residue as dry ore. This is done at the sampling place by the firms concerned. The assayer further pounds up and mixes his sample, and then proceeds to determine the percentages of moisture and metal in his own way. He has always the choice between two methods, the dry and the wet. For the majority of gold or silver ores, and for cobalt and nickel ores almost as a rule, certain dry-process tests are preferred as the most exact analytically. In almost all other cases it may be said that the wet method is susceptible of the higher degree of precision, yet even in some of these cases the old dry-process tests are preferred to the present day. For instance, all copper ores in the British Isles are sold by the result of the Swansea assay, a kind of imitation of the process of sulphureous copper-ore smelting; and this, singularly, is adhered to even in the case of such cupriferous materials as are worked by the wet way, although the Swansea assay is well known to lose about 1 per cent. of the copper present. A copper-smelter therefore had better buy 5 per cent. than 10 per cent. copper-pyrites cinders, because in the first case he pays only for four-fifths, while in the latter he must pay for nine-tenths of the copper present. To compensate for this anomaly, empirical methods have been contrived for calculating prices. (W. D.)

METALS. The earliest evidence of a knowledge and use of metals is found in the prehistoric implements of the so-called Bronze and Iron ages. In the earliest periods of written history, however, we meet with a number of metals in addition to these two. The Old Testament mentions six metals—gold, silver, copper, iron, tin, and lead. The Greeks, in addition to these and to bronze, came also to know mercury; and the same set of metals, without additions, forms the list of the Arabian chemists of the 8th and of the Western chemists of the 13th century. During the 15th century Basilius Valentinus discovered antimony; he also speaks of zinc and bismuth, but their individuality was established only at a later period. About 1730–40 the Swede Brand discovered arsenic and cobalt (the former is not reckoned a metal by modern chemists), while the Englishman Ward recognized the individuality of platinum. Nickel was discovered in 1774 by Cronstedt, manganese in 1774 by Scheele. The brothers D'Elhujart, in 1783, prepared tungsten; Hjelm, in 1782, isolated molybdenum from molybdic oxide, where its existence had been conjecturally asserted by Bergmann in 1781. Uranium, as a new element, was discovered by Klaproth in 1789; but his metallic "uranium," after having been accepted as a metal by all chemists until 1841, was then recognized as an oxide by Péligot, who subsequently isolated the true metal. Tellurium was discovered by Müller von Reichenbach in 1782 (again by Klaproth in 1798); titanium, by Klaproth in 1795; chromium, by Vauquelin in 1797; tantalum, by Hatchett in 1801, and by Ekeberg in 1802. Palladium, rhodium, iridium, and osmium (which four metals always accompany platinum in its ores) were discovered, the first two by Wollaston in 1803, the other two by a number of chemists; but their peculiarity was established chiefly by Smithson Tennant.

After Davy, in 1807 and 1808, had recognized the alkalies and alkaline earths as metallic oxides, the existence of metals in all basic earths became a foregone conclusion, which was verified sooner or later in all cases. But the discovery of aluminium by Wöhler in 1828, and that of magnesium by Bussy in 1829, claim special mention. Cadmium, a by no means rare heavy metal, was discovered only in 1818, by Stromeyer.

Of the large number of discoveries of rare metals which have been made in more recent times only a few can be mentioned, as marking new departures in research or offering other special points of interest. In 1861 Bunsen and Kirchhoff, by means of the method of spectrum analysis, which they had worked out shortly before, discovered two new alkali-metals which they called cæsium and rubidium. By means of the same method Crookes, in 1861, discovered thallium; Reich and Richter, in 1863, indium; and Lecoq de Boisbaudran, in 1875, gallium. The existence of the last-named metal had been maintained, theoretically, by Mendelejeff, as early as 1871. The existence of vanadium was proved in 1830 by Sefström; but what he, and subsequently Berzelius, looked upon as the element was, in 1867, proved to be really an oxide by Roscoe, who also succeeded in isolating the true metal.

The development of earlier notions on the constitution of metals and their genetic relation to one another forms the most interesting chapter in the history of chemistry (see ALCHEMY). What modern science has to say on the matter is easily stated: all metals properly so called (*i.e.*, all metals not alloys) are elementary substances; hence, chemically speaking, they are not "constituted" at all, and no two can be related to each other genetically in any way whatever. Our scientific instinct shrinks from embracing this proposition as final; but in the meantime it must be accepted as correctly formulating our ignorance on the subject. All metallic elements agree in this that they form each at least one basic oxide, or, what comes to the same thing, one chloride, stable in opposition to liquid water. This at once suggests an obvious definition of metals as a class of substances, but the definition would be highly artificial and objectionable on principle, because when we speak of metals we think, not of their accidental chemical relations, but of a certain sum of mechanical and physical properties which unites them all into one natural family. What these properties are we shall now endeavour to explain.

All metals, when exposed in an inert atmosphere to a sufficient temperature, assume the form of liquids, which all present the following characteristic properties. They are (at least practically) non-transparent; they reflect light in a peculiar manner, producing what is called "metallic lustre." When kept in non-metallic vessels they take the shape of a convex meniscus. These liquids, when exposed to higher temperatures, some sooner others later, pass into vapours. What these vapours are like is not known in many cases, since, as a rule, they can be produced only at

[1] For further information on slags, see Berthier, *Traité des essais par la voie sèche*; Winkler, *Erfahrungssätze über die Bildung der Schlacken*, Freiberg, 1827; Plattner, *Vorlesungen über allgemeine Hüttenkunde*, i. 28 *sq.*; Percy, *Metallurgy*.

very high temperatures, precluding the use of transparent vessels. Silver vapour is blue, potassium vapour is green, many others (mercury vapour, for instance) are colourless. The liquid metals, when cooled down sufficiently, some at lower others at higher temperatures, freeze into compact solids, endowed with the (relative) non-transparency and the lustre of their liquids. These frozen metals in general form compact masses consisting of aggregates of crystals belonging to the regular or rhombic or (more rarely) the quadratic system. But in many cases the crystals are so closely packed as to produce an apparent absence of all structure. Compared with non-metallic solids, they in general are good conductors of heat and of electricity. But their most characteristic, though not perhaps their most general, property is that they combine in themselves the apparently incompatible properties of elasticity and rigidity on the one hand and plasticity on the other. To this remarkable combination of properties more than to anything else the ordinary metals owe their wide application in the mechanical arts. In former times a high specific gravity used to be quoted as one of the characters of the genus; but this no longer holds, since we have come to know of a whole series of metals which float on water. Let us now proceed to see to what degree the mechanical and physical properties of the genus are developed in the several individual metals.

Non-Transparency.—This, in the case of even the solid metals, is perhaps only a very low degree of transparency. In regard to gold this has been proved to be so; gold leaf, or thin films of gold produced chemically on glass plates, transmit light with a green colour. On the other hand, those infinitely thin films of silver which can be produced chemically on glass surfaces are absolutely opaque. Very thin films of liquid mercury, according to Melsens, transmit light with a violet-blue colour; also thin films of copper are said to be translucent. Other metals, so far as we know, have not been more exactly investigated in this direction.

Colour.—Gold is yellow; copper is red; silver, tin, and some others are pure white; the majority exhibit some modification or other of grey.

Reflexion of Light.—Polished metallic surfaces, like those of other solids, divide any incident ray into two parts, of which one is refracted while the other is reflected,—with this difference, however, that the former is completely absorbed, and that the latter, in regard to polarization, is quite differently affected.[1] The degree of absorption is different for different metals. According to Jamin, the remaining intensity, after one and ten successive perpendicular reflexions respectively from the metal-mirrors named, is as follows (original intensity = 1):—

	Silver.		Speculum Metal.		Steel.	
	1 R.	10 R.	1 R.	10 R.	1 R.	10 R.
Red	·929	·478	·692	·035	·609	·007
Yellow	·905	·339	·632	·010	·599	·006
Violet	·867	·242	·599	·006	·599	·006

This shows the great superiority of silver as a reflecting medium, especially in the case of repeated reflexion.

Crystalline Form.—Most (perhaps all) metals are capable of crystallization, and in most cases isolated crystals can be produced by judiciously managed partial freezing. The crystals belong to the following systems:—*regular system*—silver, gold, palladium, mercury, copper, iron, lead; *quadratic system*—tin, potassium; *rhombic system*—antimony, bismuth, tellurium, zinc, magnesium.

Structure.—Perhaps all metals, in the shape which they assume in freezing, are crystalline, only the degree of visibility of the crystalline arrangement is very different in different metals, and even in the same metal varies according to the slowness of solidification and other circumstances.

Of the ordinary metals, antimony, bismuth, and zinc may be mentioned as exhibiting a very distinct crystalline structure: a bar-shaped ingot readily breaks, and the crystal faces are distinctly visible on the fracture. Tin also is crystalline: a thin bar, when bent, "creaks" audibly from the sliding of the crystal faces over one another; but the bar is not easily broken, and exhibits an apparently non-crystalline fracture.—Class I.

Gold, silver, copper, lead, aluminium, cadmium, iron (pure), nickel, and cobalt are practically amorphous, the crystals (where they exist) being so closely packed as to produce a virtually homogeneous mass.—Class II.

The great contrast in apparent structure between cooled ingots of Class I. and of Class II. appears, however, to be owing chiefly to the fact that, while the latter crystallize in the regular system, metals of Class I. form rhombic or quadratic crystals. Regular crystals expand equally in all directions; rhombic and quadratic ones expand differently in different directions. Hence, supposing the crystals immediately after their formation to be in absolute contact with one another all round, then, in the case of Class II., such contact will be maintained on cooling, while in the case of Class I. the contraction along a given straight line will in general have different values in any two neighbouring crystals, and the crystals consequently become, however slightly, detached from one another. The crystalline structure which exists on both sides becomes visible only in the metals of the first class, and only there manifests itself as brittleness.

Closely related to the structure of metals is their degree of "plasticity" (susceptibility of being constrained into new forms without breach of continuity). This term of course includes as special cases the qualities of "malleability" (capability of being flattened out under the hammer) and "ductility" (capability of being drawn into wire); but it is well at once to point out that these two special qualities do not always go parallel to each other, for this reason amongst others that ductility in a higher degree than malleability is determined by the tenacity of a metal. Hence tin and lead, though very malleable, are little ductile. The quality of plasticity is developed to very different degrees in different metals, and even in the same species it depends on temperature, and may be modified by mechanical or physical operations. A bar of zinc, for instance, as obtained by casting, is very brittle; but when heated to 100° or 150° C. it becomes sufficiently plastic to be rolled into the thinnest sheet or to be drawn into wire. Such sheet or wire then remains flexible after cooling, the originally only loosely cohering crystals having got intertwisted and forced into absolute contact with one another,—an explanation supported by the fact that rolled zinc has a somewhat higher specific gravity (7·2) than the original ingot (6·9). The same metal, when heated to 205° C., becomes so brittle that it can be powdered in a mortar. Pure iron, copper, silver, and other metals are easily drawn into wire, or rolled into sheet, or flattened under the hammer. But all these operations render the metals harder, and detract from their plasticity. Their original softness can be restored to them by "annealing," *i.e.*, by heating them to redness and then quenching them in cold water. In the case of iron, however, this applies only if the metal is perfectly pure. If it contains a few parts of carbon per thousand, the annealing process, instead of softening the metal, gives it a "temper," meaning a higher degree of hardness and elasticity (see below).

What we have called plasticity must not be mixed up

[1] This may be the cause of the peculiarity of metallic lustre.

with the notion of softness, which means the degree of facility with which the plasticity of a metal can be discounted. Thus lead is far softer than silver, and yet the latter is by far the more plastic of the two. The now famous experiments of Tresca (*Comptes Rendus*, lix. 754) show that the plasticity of certain metals at least goes considerably farther than had before been supposed. He operated with lead, copper, silver, iron, and some other metals. Round disks made of these substances were placed in a closely fitting cylindrical cavity drilled in a block of steel, the cavity having a circular aperture of two or four centimetres below. By means of an hydraulic press, applied to a superimposed piston, a pressure of 100,000 kilos was made to act upon the disks, when the metal was seen to "flow" out of the hole like a viscid liquid. In spite of the immense rearrangement of parts there was no breach of continuity. What came out below was a compact cylinder with a rounded bottom, consisting of so many layers superimposed upon one another. Parallel experiments with layers of dough or sand plus some connecting material proved that the particles in all cases moved along the same tracks as would be followed by a flowing cylinder of liquid. Of the better known metals potassium and sodium are the softest; they can be kneaded between the fingers like wax. After these follow first thallium and then lead, the latter being the softest of the metals used in the arts. Among these the softness decreases in about the following order:—lead, pure silver, pure gold, tin, copper, aluminium, platinum, pure iron. As liquidity might be looked upon as the *ne plus ultra* of softness, this is the right place for stating that, while most metals, when heated up to their melting points, pass pretty abruptly from the solid to the liquid state, platinum and iron first assume, and throughout a long range of temperatures retain, a condition of viscous semi-solidity which enables two pieces of them to be "welded" together by pressure into one continuous mass. Potassium and sodium might probably be welded if their surfaces could be kept clear of oxide.

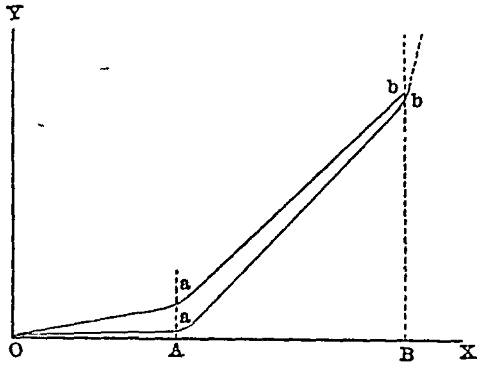
According to Prechtl, the ordinary metals, in regard to the degree of facility or perfection with which they can be hammered flat on the anvil, rolled out into sheet, or drawn into wire, form the following descending series:—

Hammering.	*Rolling into Sheet.*	*Drawing into Wire.*
Lead.	Gold.	Platinum.
Tin.	Silver.	Silver.
Gold.	Copper.	Iron.
Zinc.	Tin.	Copper.
Silver.	Lead	Gold.
Copper.	Zinc.	Zinc.
Platinum.	Platinum.	Tin.
Iron.	Iron.	Lead.

To give an idea of what can be done in this way, it may be stated that gold can be beaten out to leaf of the thickness of $\frac{1}{3800}$ mm.; and that platinum, by judicious work, can be drawn into wire $\frac{1}{200000}$ mm. thick.

By the hardness of a metal we mean the resistance which it offers to the file or to the engraver's tool. Taking it in this sense, it does not necessarily measure, *e.g.*, the resistance of a metal to abrasion by friction. Thus, for instance, 10 per cent. aluminium bronze is scratched by an edge-tool made of ordinary steel as used for knife-blades. And yet it has been found that the sets of needles used for perforating postage stamps last longer if made of aluminium bronze than they do if made of steel.

Elasticity.—All metals are elastic to this extent that a change of form, brought about by stresses not exceeding certain limit values, will disappear on the stress being removed. Strains exceeding the "limit of elasticity" result in permanent deformation or (if sufficiently great) in rupture. Where this limit lies is in no case precisely known. According to Wertheim[1] (who has done more for our knowledge of the subject than any one else) and Hodgkinson, the real law seems to be pretty much as indicated by the two curves on the accompanying diagram, where, in reference to a metallic wire, stretched by an appended weight, the abscissa always means the numerical value P of the weight, the ordinate of the upper curve the total elongation caused by P, the ordinate of the lower curve that part of the elongation which remains when P is removed, so that the piece of the ordinate between the two curves gives the temporary ("elastic") expansion. From P=0 up to a somewhat indefinite point (*a* or A) both curves are nearly straight lines, the lower almost coinciding in its beginning with the axis of abscissæ; from that point onwards these two curves approach each other, and at a short distance from the point of rupture they rapidly converge towards intersection. For any value of P which lies fairly on the safe side of A, we have approximately



$$\lambda = \frac{lP}{q}\epsilon,$$

where λ means the elastic (or substantially the total) expansion, l the length, and q the square section of the wire or cylindrical bar operated upon. The reciprocal of ϵ (viz. $E = 1/\epsilon$) is called the "modulus of elasticity."

Wertheim has determined this constant for a large number of metals and alloys. He used three methods: one was to measure the elongations produced, in a wire of given dimensions, by a succession of charges; the other two consisted in causing a measured bar to give off a musical note by (*a*) longitudinal and (*b*) transversal vibration, and counting the vibrations per second. The following table gives some of his results. Column 2 gives the constant E for millimetre and kilogramme. Hence 1000/E is the elongation in millimetres per metre length per kilo. Column 3 shows the charge causing a permanent elongation of 0·05 mm. per metre,—which, for practical purposes, he takes as giving the limit of elasticity; column 4 gives the breaking strain. Values of E in square brackets [ ] are derived from vibration experiments; the rest from direct measurements of elongations. Numbers in round brackets ( ) do not necessarily refer to the same specimen as the other data.

Name	E.	For Wire of 1 Square mm. Section, Weight (in Kilos) causing	
		Permanent Elongation of $\frac{1}{20000}$.	Breakage.
Lead, drawn	1,803	0·25	2·1
„ annealed	1,727	0·20	1·8
Tin, drawn	[3,923]	0·45	(2·45)
„ annealed	[4,060]	0·20

Palladium, drawn	11,759	18	
„ annealed	9,789	under 5	27
Copper, drawn	12,449	12	40
„ annealed	10,519	under 3	30
Platinum wire, medium thickness, drawn	17,004	(26)	
„ „ annealed	15,518	(14)	
Platinum wire, thick, drawn	15,987		34
„ „ annealed	15,622		23
Iron,[2] drawn	20,869	32	61
„ [2] annealed	20,794	under 5	47
Nickel,[3] drawn			$\frac{3}{2}\times 61$
Cobalt,[3] „			2×61
Aluminium[4]	7,040		
Aluminium bronze[4]	10,700		
Brass[5]	8,543		
German silver[6]	10,788		

The above numbers may be assumed to hold for temperatures from 15° to 20° C. Wertheim executed determinations also at other temperatures; but, as his numbers do not appear to reveal the true

[1] *Annales de Chimie et de Physique* [iii.], vol. xii.

[2] From Du Brery. [3] Approximate, by H. St Clair Deville.

[4] From deflexion of hammered bar of 5 mm. thickness, charged in the middle; determined by W. Dittmar.

[5] Composition, $ZnCu_2$ (Wertheim). [6] Composition, $Zn_4Cu_{13}Ni_3$ (Wertheim).

relations between E and temperature, we quote the results of Kohlrausch and Loomis, who found the following relations between the modulus E_0 for 0° C. and the value E_t for $+t°$ C.:—

$$\text{Iron:}\quad E_t = E_0(1 - {\cdot}000483\,t - {\cdot}00000012\,t^2).$$
$$\text{Copper:}\quad E_t = E_0(1 - {\cdot}000572\,t - {\cdot}00000028\,t^2).$$
$$\text{Brass:}\quad E_t = E_0(1 - {\cdot}000485\,t - {\cdot}00000136\,t^2).$$

Thus, for these three metals at least, the value of E diminishes, when temperature increases, at pretty much the same rate per degree of temperature.

Specific Gravity.—This varies in metals from ·594 (lithium) to 22·48 (osmium), and in one and the same species is a function of temperature and of previous physical and mechanical treatment. It has in general one value for the powdery metal as obtained by reduction of the oxide in hydrogen below the melting point of the metal, another for the metal in the state which it assumes spontaneously on freezing, and this latter value again, in general, is modified by hammering, rolling, or wire-drawing, &c. These mechanical operations do not necessarily add to the density; stamping, it is true, does so necessarily, but rolling or drawing occasionally causes a diminution of the density. Thus, for instance, chemically pure iron in the ingot has the specific gravity 7·844; when it is rolled out into thin sheet, the value falls to 7·6; when drawn into thin wire, to 7·75 (Berzelius). The following table gives the specific gravities of all metals (except a few very rare ones) according to the most trustworthy modern determinations. Where special statements are not made, the numbers may be assumed to hold for the ordinary temperature (15° to 17° or 20° C.), referred to water of the same temperature (specific gravity =1) as a standard, and to hold for the natural frozen metal.

Iridium	22·40	
Osmium	22·477	Deville and Debray, 1876.

Thermic Properties.—*The specific heats of most metals* have been determined very carefully by Regnault. The general result is that, conformably with Dulong and Petit's law, the "atomic heats" all come to very nearly the same value (of about 6·4); *i.e.*, atomic weight by specific heat=6·4. Thus we have for silver by theory 6·4/108=·0593, and by experiment ·0570 for 10° to 100° C.

The expansion by heat varies greatly. The following table gives the linear expansions from 0° to 100° C. according to Fizeau (*Comptes Rendus*, lxviii. 1125), the length at 0° being taken as unity.

Name of Metal.	Expansion 0° to 100°.
Platinum, cast	·000 907
Gold, cast	·001 451
Silver, cast	·001 936
Copper, native, from Lake Superior	·001 708
Copper, artificial	·001 869
Iron, soft, as used for electromagnets	·001 228
,, reduced by hydrogen and compressed	·001 208
Cast steel, English annealed	·001 110
Bismuth, in the direction of the axis	·001 642
,, at right angles to axis	·001 239
,, mean expansion, calculated	·001 374
Tin, of Malacca, compressed powder	·002 269
Lead, cast	·002 948
Zinc, distilled, compressed powder	·002 905
Cadmium, distilled, compressed powder	·003 102
Aluminium, cast	·002 336
Brass (71·5 per cent. copper, 28·5 per cent. zinc)	·001 879
Bronze (86·3 per cent. copper, 9·7 per cent. tin, 4·0 per cent. zinc).	·001 802

The coefficient of expansion is constant for such metals only as crystallize in the regular system; the others expand differently in the directions of the different axes. To eliminate this source of uncertainty these metals were employed as compressed powders. The cubical expansion of mercury from 0° to 100° C. is ·018153 $=\frac{1}{55{\cdot}087}$ (Regnault).

Fusibility and Volatility.—The fusibility in different metals is very different, as shown by the following table, which, besides including all the fusing points (in degrees C.) of metals which have been determined numerically, indicates those of a selection of other metals by the positions assigned to them in the table. Of the temperatures given, those above (say) 500° C. must be looked upon as rough approximations.

Name of Metal.	Fusing Point.	Authority.
Mercury	−38·8	B. Stewart.
Cæsium	+26 to 27	Setterberg.
Gallium	30·1	L. de Boisbaudran.
Rubidium	38·5	Bunsen.
Potassium	62·5	,,
Sodium	95·5	,,
Lithium	180·0	?
Indium	176	Richter (?)
Tin	228	Rudberg.

Yellow Heat	1,100	Pouillet.
Copper	1,200	
Iron, wrought	1,300 to 1,400	
,, chemically pure	higher	
Cobalt	1,400	
Nickel	1,600	
Uranium	?	
Dazzling White Heat	1,500 to 1,600	Pouillet.
Palladium is barely fusible at the highest wind-furnace heat. The following melt only in the oxyhydrogen flame:—		
Platinum	2,000	
Iridium		
Rhodium		
Ruthenium		
Max. Temp. of Oxyhydrogen Flame	2,870	Bunsen.[1]
Osmium does not melt at 2,870°, *i.e.*, is as yet infusible.		

Of the volatility of metals we have little precise knowledge; only the following boiling points are known numerically:—

Name of Metal.	Boiling Point.	Authority.
Mercury	357·3	Regnault.
Cadmium	860	Deville and Troost.
Zinc	1,040	,, ,,
Potassium	below 1,040	Dewar and Dittmar.
Sodium	above 1,040	,, ,,

For practical purposes the volatility of metals may be stated as follows:—

1. Distillable below redness: mercury.
2. Distillable at red heats: *cadmium, alkali metals, zinc, magnesium.*
3. Volatilized more or less readily when heated beyond their fusing points in open crucibles: antimony (very readily), lead, bismuth, tin, silver.

[1] Bunsen, *Jahresb. f. Chem.*, 1867, p. 41; *Phil. Mag.*, xxxiv. 489.

4. Barely so: gold, (copper).
5. Practically non-volatile: (copper), iron, nickel, cobalt, aluminium; also lithium, barium, strontium, and calcium.

In the oxyhydrogen flame silver boils, forming a blue vapour, while platinum volatilizes slowly, and osmium, though infusible, very readily.

Latent Heats of Liquefaction—Of these we know little. The following numbers are due to Person—ice, it may be stated, being 80.

Metal.	Latent Heat.	Metal.	Latent Heat.
Mercury	2·82	Cadmium	13·6
Lead	5·37	Silver	21·1
Bismuth	12·4	Zinc	28·1

Of the latent heats of vaporization only that of mercury has been determined,—by Marignac, who found it to be 103 to 106 units.

Conductivity.—Conductivity, whether thermic or electric, is very differently developed in different metals; and, as an exact knowledge of these conductivities is of great scientific and practical importance, much attention has been given to their numerical determination. The following are the modes in which the two conductivities have been defined as quantities.

1. *Thermic.*—Imagine one side (I) of a metallic plate, D units thick, to be kept at the constant temperature t_1, the other (II) at t_2. After a sufficient time each point between I and II will be at a constant intermediate temperature, and in every unit of time a constant quantity Q of heat will pass from any circumscribed area S on I to the opposite area S on II, according to the equation

$$Q = l\frac{S(t_1-t_2)}{D}.$$

l is called the (internal) conductivity of the metal the plate is made of. It is, strictly speaking, a function of t_1 and t_2; but within a given small interval of temperatures it may be taken as a constant.

2. *Electric.*—When a given constant battery is closed successively by different wires of the same sort, then, according to experience, the strength I of the current (as measured for instance by the heat-equivalent of the electricity flowing through the circuit in unit of time) is in accordance with the equation

$$A/I = 1 + rl/s,$$

where l is the length and s the square section of the wire, while A is a constant which, for our purpose, need not be defined in regard to its physical meaning; r measures the specific resistance of the particular metal. Supposing a certain silver wire on the one hand and a certain copper wire on the other, when substituted for each other, to produce currents of the same strength, we have

$$r_1 l_1/s_1 = r_2 l_2/s_2,$$

whence

$$r_1/r_2 = s_1 l_2/(s_2 l_1) = k$$

where k is the computed value of the ratio on the right-hand side. Hence, taking r_2, the resistance of copper, as unity, we have $r_1 = k$, *i.e.*, k gives us the specific resistance of silver, that of copper being taken = 1. In this relative manner resistances are usually measured, silver generally being taken as the standard of comparison. Supposing the relative resistance of a metal to be R, the reciprocal 1/R is called its "electric conductivity." For the same metal R varies with the temperature, the higher temperature corresponding to the higher resistance. The following table gives the electric conductivities of a number of metals as determined by Matthiesen, and the relative internal thermic conductivities of (nominally) the same metals as determined by Wiedemann and Franz, with rods about 5 mm. thick, of which one end was kept at 100° C., the rest of the rod in a "vacuum" (of 5 mm. tension) at 12° C. Matthiesen's results, except in the two cases noted, are from his memoir in *Pogg. Ann.*, 1858, ciii. 428.

[1] Published in 1860, and declared by Matthiesen to be more exact than the old numbers.

Going by Matthiesen's old numbers, we find them to agree fairly with Wiedemann and Franz's thermic conductivities, which supports an obvious and pretty generally received proposition. Matthiesen's new numbers for gold and copper, however, destroy the harmony.

Magnetic Properties.—Iron, nickel, and cobalt are the only metals which are attracted by the magnet and can become magnets themselves. But in regard to their power of retaining their magnetism none of them comes at all up to the compound metal steel. See MAGNETISM.

Chemical Changes.

The chemical changes which metals are liable to may be classified according to the loss of metallicity involved in them. We will adopt this principle and begin with the action of metals on metals, which, as experience shows, always leads to the formation of truly metallic compounds.

Any two or more metals when mixed together in the liquid state unite chemically, or at least molecularly, in this sense that, although the mixture, on standing (hot), may separate into layers, each layer is a homogeneous solution or "alloy" of, in general, all the components in one another. With binary combinations the following two cases may present themselves:—(1) the two metals mix permanently in any proportion; or (2) either of the two metals refuses to take up more than a certain limit-proportion of the other; hence a random mixture of the two metals will, in general, part into two layers,—one a solution of A in B, the other a solution of B in A. The first case presents itself very frequently; it holds, for instance, for gold and silver, gold and copper, copper and silver, lead and tin, and any alloy of these two and bismuth. Many other cases might be quoted. A good example of the second case is lead and zinc, either of which dissolves only a very small percentage of the other. In the preparation of an alloy we need not start with the components in the liquid state; the several metals need only be heated together in the same crucible when, in general, the liquid of the more readily fusible part dissolves the more refractory components at temperatures far below their fusing points. Molten lead, for instance, as many a tyro in chemical analysis has come to learn to his cost, readily runs through a platinum crucible at little more than its own fusing point.

A homogeneous liquid alloy, when solidified suddenly, say by pouring it drop by drop into cold water, necessarily yields an equally homogeneous solid. But it may not be so when it is allowed to freeze gradually. If, in this case, we allow the process to go a certain way, and then pour off the still liquid portion, the frozen part generally presents itself in the shape of more or less distinct crystals; whether this happens or not, the rule is that its composition differs from that of the mother liquor, and consequently from that of the original alloy. This phenomenon of "liquation," as it is called, is occasionally utilized in metallurgy for the approximate separation of metals from one another;[2] but in the manipulation of alloys made to be used as such it may prove very inconvenient. It does so, for instance, in the case of the copper-silver alloy which our coins are made of; in a large ingot of such sterling silver the core may contain as much as 0·3 per-cent. of silver more than the outer shell.

The existence of crystallized alloys, as the phenomenon of liquation generally, strongly suggests the idea that alloys generally are mixtures, not of their elementary components, but of chemical compounds of these elements with one another, associated possibly with uncombined remnants of these. This notion is strongly supported by the fact that the formation of many alloys involves an obvious evolution of heat and a decided modification in what one would presume to be the properties of the corresponding

[2] A good illustration is afforded by the process of Pattinson as used for concentrating the silver in argentiferous lead. See LEAD.

mixture. The case of sodium amalgam may be quoted as a forcible illustration. What goes by this name in laboratories is an alloy of two to three parts of sodium with one hundred parts of mercury, which is easily produced by forcing the two components into contact with each other by means of a mortar and pestle, when they unite, with deflagration, into an alloy which after cooling assumes the form of a grey, hard, brittle solid, although mercury is a liquid, and sodium, though a solid, is softer than wax. Similar evidence of chemical action we have in the cases of brass (copper and zinc), bronze (copper and tin), aluminium bronze (copper and aluminium), and in many others that might be quoted. There are indeed a good many alloys the formation of which is not accompanied by any obvious evolution of heat or any very marked change in the mean properties of the components. But in the absence of all precise thermic researches on the subject we are not in a position to assert the absence of chemical action in any case. Indeed our knowledge of the proximate composition of alloys is in the highest degree indefinite—we do not even know of a single composite metal which has been really proved to be an unitary compound, and hence the important problem of the relation in alloys between properties and composition must be attacked on a purely empirical basis. What has been done in this direction is shortly summarized in the following paragraphs.

Colour.—Most metals are white or grey; so are the alloys of these metals with one another. Gold alloys generally exhibit something like the shade of yellow which one would expect from their composition; its amalgams, however, are all white, not yellow. Copper shows little tendency to impart its characteristic red colour to its alloys with white or grey metals. Thus, for instance, the silver alloy up to about 30 per cent. of copper exhibits an almost pure white colour. The alloys of copper with zinc (brass) or tin (bronze) are reddish-yellow when the copper predominates largely. As the proportion of white metal increases, the colour passes successively into dark yellow, pale yellow, and ultimately into white. Aluminium bronze, containing from 5 to 10 per cent. of aluminium, is golden-yellow.

Plasticity.—This quality is most highly developed in certain pure metals, notably in gold, platinum, silver, and copper. Of platinum alloys little is known. The other three, on uniting with one another, substantially retain their plasticities, but the addition of any metal outside the group leads to deterioration. Thus, for instance, according to Karsten, copper, by being alloyed with as little as 0·6 per cent. of zinc, loses its capability of being forged at a red heat; it cracks under the hammer. Antimony or arsenic to the extent of 0·15 per cent. renders it unfit for being rolled into thin sheet or drawn out into fine wire, and makes it brittle in the heat; 0·1 per cent. of lead prohibits its conversion into leaf.

Hardness, Elasticity, Tensile Strength.—In reference to these qualities, we shall confine ourselves to some very striking changes for the better which the metals (1) gold, (2) silver, (3) copper suffer when alloyed with moderate proportions (10 per cent. or so) of (1) copper, (2) copper, (3) tin, zinc, or aluminium respectively. Any of these five combinations leads to a considerable increase in the three qualities named, although these are by no means highly developed in the added metals; most strikingly it does so in the case of aluminium bronze (copper and aluminium), which is so hard as to be very difficult to file, and is said to be equal in tensile strength to wrought iron. To illustrate this we give in the following table, after Matthiesen, the breaking strains of double wires, No. 23 gauge, in lb avoirdupois, for certain alloys on the one hand and their components on the other.

Separate Metals.		*Alloys.*	
Copper	25–30	Gun metal, 12 per cent. of tin	80–90
Tin	less than 7		
Copper	25–30	Standard (22 carat) gold	70–75
Gold	20–25		
Silver	40–45	Alloy, $\frac{2}{3}$ of silver, $\frac{1}{3}$ of platinum	75–80
Platinum	45–50		

Specific Gravity.—This subject has been extensively investigated by Matthiesen, Calvert and Johnson, Kuppfer, and others. In discussing the results it is convenient to compare the values (S) found with the values (S_0) calculated on the assumption that the volume of the alloy is equal to the sum of the volumes of the components. Let p_1, p_2, p_3...stand for the relative weights of the components, P for their joint weight, S_1, S_2, S_3...for their specific gravities, and we have

$$\frac{P}{S_0}=\frac{p_1}{S_1}+\frac{p_2}{S_2}+\dots$$

where the expression on the right hand obviously means the conjoint volume V_0 of the components; but the actual volume of the alloy formed by their union is, in general, $V=V_0(1+e)$, where e means the expansion (or, when negative, the contraction) of unit-volume of mixture. Hence the real value

$$S=S_0/(1+e)\,,$$

whence

$$e=(S_0-S)/S.$$

Matthiesen's investigation (*Pogg. Annalen* for 1860, vol. cx. p. 21) extends over a large number of binary alloys derived from the metals named in the following table. He naturally began by procuring pure specimens of these metals and determining their specific gravities. The results (each the mean of a number of determinations) were as follows:—

Name.	Specific Gravity S at t° C.	t	Adopted Atomic Weight.
Antimony	6·713	14·3°	122·3
Tin	7·294	12·8	118
Cadmium	8·655	10·5	112
Bismuth	9·823	12·3	208
Silver	10·468	13·2	108
Lead	11·376	13·5	207·4
Mercury	13·573	14·5	200
Gold	19·265	12·8	197

In these, as in all the subsequent determinations for the alloys, the weighings were reduced to the vacuum, and the values for S referred to water at 4° C. as unity. From eight metals twenty-eight different kinds of binary alloys can be produced; of these twenty-eight combinations eighteen were selected; in each case the two components were fused together in a variety of properly chosen atomic proportions, and the specific gravities of these alloys were determined. The net results are summarized in the following table, which, for each combination A, B, in the first two columns gives the composition in multiplies of the "atomic-weights" given in the table just quoted, while column 3 gives the values of e as calculated by the writer from Matthiesen's numbers for S_0 and S. Hence, for example, in the accompanying entries the first line shows that the union into an alloy of twice 118 parts of tin and once 197 parts of gold involves an expansion from 1 volume into 1·004; the second that the union of once 118 parts of tin with four times 197 parts of gold involves a contraction from 1 volume into 1 − ·028.

To make these numbers trustworthy it would be necessary to determine their probable errors; and this Matthiesen has not done. It would appear that any value of e from 0 to (say) $\pm$ ·002 counts for nothing, and anything up to ·004 certainly must be taken as not proving much either way. If this is correct, then

(1) No contraction or expansion is proved in the cases Sb, Bi; Cd, Bi; Cd, Pb; Au, Ag;

(2) A contraction (from 0·5 to 4·7 per cent.) is proved for Sn, Ag; Bi, Ag; Bi, Au; Pb, Au; Pb, Bi; Hg, Sn; Hg, Pb; Sn, Bi (?); Au, Ag (?);

(3) An expansion (from ·5 to 0·8 per cent.) is proved for Sb, Sn; Sb, Pb; Sn, Cd (?); Sn, Pb (?); certain cases of Sn, Au and Pb, Ag;

(4) In the two series Sn, Au and Pb, Ag, there are cases both of expansion and of contraction.

Thermic and Electric Properties.—The specific heat of an alloy, so far as we know, is always in approximate accordance with Dulong and Petit's law. Thus the specific heat of Cu_5Al_1 is

$$\frac{(5+1)\times 6{\cdot}4}{5\times 63{\cdot}5+1\times 27},$$

with about the same degree of correctness as the "constant" 6·4 can claim for itself.

Expansion.—Matthiesen, from numerous determinations made with alloys and their components, concludes that the expansion of an alloy (from 0° to 100° C.) is nearly equal to the sum of the expansions of its components. Supposing, for instance, one volume of gold to expand (from 0° to t) by α, and one volume of silver by β; then an alloy of four volumes of gold and three volumes of silver expands by $(4\alpha+3\beta)/7$ per unit.

Fusibility.—In the case of an alloy the melting-point and the freezing-point are, in general, separated by a greater or less interval of temperature, and the latter in itself may have two values as shown by Rudberg, who found that when a fused alloy of tin and lead is allowed to freeze the thermometer becomes stationary at two successive points, as shown in the following table, where x means the number of atomic weights of tin united with y of lead in the given case, and the temperatures are in centigrade degrees.

x	0	1	1	3	4	12	∞
y	∞	3	1	1	1	1	0
First point	(325°)	280°	240°	187°	187°	210°	(228°)
Second point	(325°)	187°	187°	187°	187°	187°	(228°)

We see that the first point varies with, while the second, within the range of the experiments, proved independent of, the proportion in which the two metals are united.

The melting-point of many alloys lies below that of even the most fusible component, as illustrated in the following tables, where the numbers mean parts by weight.

Tin and Lead (Rudberg).

Per cent. of Tin.	Per cent. of Lead.	Melting-point.
100	0	228°
0	100	325
74	26	194
63	37	186
53	47	196
36	64	241
16	84	289

Name of Alloy.	Tin.	Lead.	Bismuth.	Cadmium.	Melting-point.
Newton's	3	2	5	0	100°
Rose's	3	8	8	0	95
Erman's	1	1	2	0	93·7
Wood's	2	4	7	1	70
(Cadmium)	0	0	0	1	(320)

All these alloys melt in boiling water.

The electric conductivity of alloys *qua* alloys has been investigated by Matthiesen. He confined himself to binary alloys derived from a certain set of elementary metals. The main results of his researches are given in ELECTRICITY, vol. viii. p. 51. For the practical electrician it is important to observe how very much the conductivity of copper is impaired by very minute admixtures even of metals that are good conductors, and also by non-metallic contamination, especially with oxygen (present as Cu_2O).

Metallic Substances Produced by the Union of Metals with Small Proportions of Non-Metallic Elements.

Hydrogen, as was shown by Graham, is capable of uniting with (always very large proportions of) certain metals, notably with palladium, into metal-like compounds. But those hydrogen alloys, being devoid of metallurgic interest, fall better under the heading PALLADIUM.

Oxygen.—Mercury and copper (perhaps also other metals) are capable of dissolving their own oxides with formation of alloys. Mercury, by doing so, becomes viscid and unfit for its ordinary applications. Copper, when pure to start with, suffers considerable deterioration in plasticity. But the presence of moderate proportions of cuprous oxide has been found to correct the evil influence of small contaminations by arsenic, antimony, lead, and other foreign metals. Most commercial coppers owe their good qualities to this compensating influence.

Arsenic combines readily with all metals into true arsenides, which latter, in general, are soluble in the metal itself. The presence in a metal of even small proportions of arsenide generally leads to considerable deterioration in mechanical qualities.

Phosphorus.—The remark just made might be said to hold for phosphorus were it not for the existence of what is called "phosphorus-bronze," an alloy of copper with phosphorus (*i.e.*, its own phosphide), which possesses valuable properties. According to Abel, the most favourable effect is produced by from 1 to $1\frac{1}{2}$ per cent. of phosphorus. Such an alloy can be cast like ordinary bronze, but excels the latter in hardness, elasticity, toughness, and tensile strength. See PHOSPHORUS.

Carbon.—Most metals when in a molten state are capable of dissolving at least small proportions of carbon, which, in general, leads to a deterioration in metallicity, except in the case of iron, which by the addition of small percentages of carbon gains in elasticity and tensile strength with little loss of plasticity (see IRON).

Silicon, so far as we know, behaves to metals pretty much like carbon, but our knowledge of facts is limited. What is known as "cast iron" is essentially an alloy of iron proper with 2 to 6 per cent. of carbon and more or less of silicon (see IRON). Alloys of copper and silicon were prepared by Deville in 1863. The alloy with 12 per cent. of silicon is white, hard, and brittle. When diluted down to 4·8 per cent., it assumes the colour and fusibility of bronze, but, unlike it, is tenacious and ductile like iron.

Action of the More Ordinary Chemical Agents on Simple Metals.

To avoid repetition, let us state beforehand that the metals to be referred to are always understood to be given in the compact (frozen) condition, and that, wherever a series of metals are enumerated as being similarly attacked, the degree of readiness in the action is (so far as our knowledge goes) indicated by the order in which the several members are named,—the more readily changed metal always standing first.

Water, at ordinary or slightly elevated temperatures, is decomposed more or less readily, with evolution of hydrogen gas and formation of a basic hydrate, by (1) potassium (formation of KHO), sodium (NaHO), lithium (LiOH), barium, strontium, calcium (BaO_2H_2, &c.); (2) magnesium, zinc, manganese (MgO_2H_2, &c.).

In the case of group 1 the action is more or less violent, and the hydroxides formed are soluble in water and very

strongly basylous; metals of group 2 are only slowly attacked, with formation of relatively feebly basylous and practically insoluble hydrates. Disregarding the rarer elements (as we propose to do in this section), the metals not named so far may be said to be proof against the action of pure water in the absence of free oxygen (air).

By the conjoint action of water and air, thallium, lead, bismuth are oxidized, with formation of more or less sparingly soluble hydrates ($ThHO$, PbO_2H_2, BiO_3H_3), which, in the presence of carbonic acid, pass into still less soluble basic carbonates.

Iron, as everybody knows, when exposed to moisture and air, "rusts," that is, undergoes gradual conversion into a brown ferric hydrate, $Fe_2O_3xH_2O$; but this process never takes place in the absence of air, and it is questionable whether it ever sets in in the absence of carbonic acid. What is known is that iron never rusts in solutions of caustic alkalies or lime (which reagents preclude the presence of free carbonic acid), while it does so readily in ordinary moist air containing CO_2. When once started the process proceeds with increasing rapidity, the ferric hydrate produced acting as a carrier of oxygen; it gives up part of its oxygen to the adjoining metal, being itself reduced to (perhaps) Fe_3O_4, which latter again absorbs oxygen from the air to become ferric hydrate and so on (Kuhlmann).

Copper, in the present connexion, is intermediate between iron and the following group of metals.

Mercury, if pure, and all the "noble" metals (silver, gold, platinum, and platinum-metals), are absolutely proof against water even in the presence of oxygen and carbonic acid.

The metals grouped together above under 1 and 2 act on steam pretty much as they do on liquid water. Of the rest, the following are readily oxidized by steam at a red heat, with formation of hydrogen gas,—zinc, iron, cadmium, cobalt, nickel, tin. Bismuth is similarly attacked, but slowly, at a white heat. Aluminium is barely affected even at a white heat, if it is pure; the ordinary impure metal is liable to be very readily oxidized.

Aqueous Sulphuric or Hydrochloric Acid, of course, readily dissolves groups 1 and 2, with evolution of hydrogen and formation of chlorides or sulphates. The same holds for the following group (A):—[manganese, zinc, magnesium] iron, aluminium, cobalt, nickel, cadmium. Tin dissolves readily in strong hot hydrochloric acid as $SnCl_2$; aqueous vitriol does not act on it appreciably in the cold; at 150° it attacks it more or less quickly, according to the strength of the acid, with evolution of sulphuretted hydrogen or, when the acid is stronger, of sulphurous acid gas and deposition of sulphur (Calvert and Johnson). A group (B), comprising copper, are, substantially, attacked only in the presence of oxygen or air. Lead, in sufficiently dilute acid, or in stronger acid if not too hot, remains unchanged. A group (C) may be formed of mercury, silver, gold, and platinum, which are not touched by either aqueous acid in any circumstances.

Hot (concentrated) oil of vitriol does not attack gold, platinum, and platinum-metals generally; all other metals (including even silver) are converted into sulphates, with evolution of sulphurous acid. In the case of iron, ferric sulphate, $Fe_2(SO_4)_3$, is produced; tin yields a somewhat indefinite sulphate of its binoxide SnO_2.

Nitric Acid (Aqueous).—Gold, platinum, iridium, and rhodium only are proof against the action of this powerful oxidizer. Tin and antimony (also arsenic) are converted by it (ultimately) into hydrates of their highest oxides SnO_2, Sb_2O_5 (As_2O_5),—the oxides of tin and antimony being insoluble in water and in the acid itself. All other metals, including palladium, are dissolved as nitrates, the oxidizing part of the reagent being generally reduced to nitric oxide, NO, or sometimes to N_2O_3 or N_2O_4. Iron, zinc, cadmium, also tin under certain conditions, reduce the dilute acid, partially at least, to nitrous oxide, N_2O, or nitrate of ammonia, $NH_4.NO_3 = N_2O + 2H_2O$.

Aqua Regia, a mixture of nitric and hydrochloric acids, converts all metals (even gold, the "king of metals," whence the name) into chlorides, except only rhodium, iridium, and ruthenium, which, when pure, are not attacked.

Caustic Alkalies.—Of metals not decomposing liquid pure water, only a few dissolve in aqueous caustic potash or soda, with evolution of hydrogen. The most important of these are aluminium and zinc, which are converted into aluminate, $Al_2O_33(K_2$ or $Na_2)O$, and zincate, $ZnO.RHO$, where $R = K$ or Na respectively. But of the rest the majority, when treated with boiling sufficiently strong alkali, are attacked at least superficially; of ordinary metals only gold, platinum, and silver are perfectly proof against the reagents under consideration, and these accordingly are used preferably for the construction of vessels intended for analytical operations involving the use of aqueous caustic alkalies. For preparative purposes iron is universally employed and works well; but it is not available analytically, because a superficial oxidation of the empty part of the vessel (by the water and air) cannot be prevented. According to the writer's experience basins made of pure malleable nickel are free from this drawback; they work as well as platinum, and rather better than silver ones do. There is hardly a single metal which holds out against the alkalies themselves when in the state of fiery fusion; even platinum is most violently attacked. In chemical laboratories fusions with caustic alkalies are always effected in vessels made of gold or silver, these metals holding out fairly well even in the presence of air. Gold is the better of the two. Iron, which stands so well against aqueous alkalies, is most violently attacked by the fused reagents. Yet tons of caustic soda are fused daily in chemical works in iron pots without thereby suffering contamination, which seems to show that (clean) iron, like gold and silver, is attacked only by the conjoint action of fused alkali and air, the influence of the latter being of course minimized in large-scale operations.

Oxygen or Air.—The noble metals (from silver upwards) do not combine directly with oxygen given as oxygen gas (O_2), although, like silver, they may absorb this gas largely when in the fused condition, and may not be proof against ozone, O_3. Mercury, within a certain range of temperatures situated close to its boiling point, combines slowly with oxygen into the red oxide, which, however, breaks up again at higher temperatures. All other metals, when heated in oxygen or air, are converted, more or less readily, into stable oxides. Potassium, for example, yields peroxide, K_2O_2 or K_2O_4; sodium gives Na_2O_2; the barium-group metals, as well as magnesium, cadmium, zinc, lead, copper, are converted into their monoxides MeO. Bismuth and antimony give (the latter very readily) sesquioxide (Bi_2O_3 and Sb_2O_3, the latter being capable of passing into Sb_2O_4). Aluminium, when pure and kept out of contact with siliceous matter, is only oxidized at a white heat, and then very slowly, into alumina, Al_2O_3. Tin, at high temperatures, passes slowly into binoxide, SnO_2.

Sulphur.—Amongst the better known metals, gold and aluminium are the only ones which, when heated with sulphur or in sulphur vapour, remain unchanged. All the rest, under these circumstances, are converted into sulphides. The metals of the alkalies and alkaline earths, also magnesium, burn in sulphur-vapour as they do in oxygen. Of the heavy meals, copper is the one which exhibits by far the greatest avidity for sulphur, its subsulphide Cu_2S being the stablest of all heavy metallic sulphides in opposition to dry reactions. See METALLURGY.

Chlorine.—All metals, when treated with chlorine gas at the proper temperatures, pass into chlorides. In some cases the chlorine is taken up in two instalments, a lower chloride being produced first, to pass ultimately into a higher chloride. Iron, for instance, is converted first into $FeCl_2$, ultimately into Fe_2Cl_6, which practically means a mixture of the two chlorides, or pure Fe_2Cl_6 as a final product. Of the several products, the chlorides of gold and platinum ($AuCl_3$ and $PtCl_4$) are the only ones which when heated beyond their temperature of formation dissociate into metal and chlorine. The ultimate chlorination product of copper, $CuCl_2$, when heated to redness, decomposes into the lower chloride, Cu_2Cl_2, and chlorine. All the rest, when heated by themselves, volatilize, some at lower, others at higher temperatures.

Of the several individual chlorides, the following are liquids or solids, volatile enough to be distilled from out of glass vessels:—$AsCl_3$, $SbCl_3$, $SnCl_4$, $BiCl_3$, $HgCl_2$, the chlorides of arsenic, antimony, tin, bismuth, mercury respectively. The following are readily volatilized in a current of chlorine, at a red heat:—Al_2Cl_6, Cr_2Cl_6, Fe_2Cl_6, the chlorides of aluminium, chromium, iron. The following, though volatile at higher temperatures, are not volatilized at dull redness:—KCl, $NaCl$, $LiCl$, $NiCl_2$, $CoCl_2$, $MnCl_2$, $ZnCl_2$, $MgCl_2$, $PbCl_2$, $AgCl$, the chlorides of potassium, sodium, lithium, nickel, cobalt, manganese, zinc, magnesium, lead, silver. Somewhat less volatile than the last-named group are the chlorides (MCl_2) of barium, strontium, and calcium.

Metallic chlorides, as a class, are readily soluble in water. The following are the most important exceptions:—chloride of silver, $AgCl$, and subchloride of mercury, Hg_2Cl_2, are absolutely insoluble; chloride of lead, $PbCl_2$, and subchloride of copper, Cu_2Cl_2, are very sparingly soluble in water. The chlorides $AsCl_3$, $SbCl_3$, $BiCl_3$, are at once decomposed by (liquid) water, with formation of oxide (As_2O_3) or oxychlorides ($SbClO$, $BiClO$) and hydrochloric acid. The chlorides $MgCl_2$, Al_2Cl_6, Cr_2Cl_6, Fe_2Cl_6 suffer a similar decomposition when evaporated with water in the heat. The same holds in a limited sense for $ZnCl_2$, $CoCl_2$, $NiCl_2$, and even $CaCl_2$. All chlorides, except those of silver and mercury (and, of course, those of gold and platinum), are oxidized by steam at high temperatures, with elimination of hydrochloric acid.

The above statements concerning the volatilities and solubilities of metallic chlorides form the basis of a number of important analytical methods for the separation of the respective metals.

For the characters of metals as chemical elements the reader is referred to the article CHEMISTRY and to the special articles on the different metals. (W. D.)

METAL-WORK. Among the many stages in the development of primeval man, none can have been of greater moment in his struggle for existence than the discovery of the metals, and the means of working them. The names generally given to the three prehistoric periods of man's life on the earth—the Stone, the Bronze, and the Iron age—imply the vast importance of the progressive steps from the flint knife to the bronze celt, and lastly to the keen-edged elastic iron weapon or tool. The length of time during which each of these ages lasted must of course have been different in every country and race in the world. The Digger Indians of South California have even now not progressed beyond the Stone Age; while some of the tribes of Central Africa are acquainted with the use of copper and bronze, though they are unable to smelt or work iron.

The metals chiefly used have been gold, silver, copper and tin (the last two generally mixed, forming an alloy called bronze), iron, and lead. The peculiarities of these various metals have naturally marked out each of them for special uses and methods of treatment. The durability and the extraordinary ductility and pliancy of gold, its power of being subdivided, drawn out, or flattened into wire or leaf of almost infinite fineness, have led to its being used for works where great minuteness and delicacy of execution were required; while its beauty and rarity have, for the most part, limited its use to objects of adornment and luxury, as distinct from those of utility. In a lesser degree most of the qualities of gold are shared by silver, and consequently the treatment of these two metals has always been very similar, though the greater abundance of the latter metal has allowed it to be used on a larger scale and for a greater variety of purposes.

Bronze is an alloy of copper and tin in varying proportions, the proportion of tin being from 8 to 20 per cent. The great fluidity of bronze when melted, the slightness of its contraction on solidifying, together with its density and hardness, make it especially suitable for casting, and allow of its taking the impress of the mould with extreme sharpness and delicacy. In the form of plate it can be tempered and annealed till its elasticity and toughness are much increased, and it can then be formed into almost any shape under the hammer and punch. By other methods of treatment, known to the ancient Egyptians, Greeks, and others, but now forgotten, it could be hardened and formed into knife and razor edges of the utmost keenness. In many specimens of ancient bronze small quantities of silver, lead, and zinc have been found, but their presence is probably accidental.

In modern times, after the discovery of zinc, an alloy of copper and zinc called brass has been much used, chiefly for the sake of its cheapness as compared with bronze. In beauty, durability, and delicacy of surface it is very inferior to bronze, and, though of some commercial importance, has been of but little use in the production of works of art.

To some extent copper was used in an almost pure state during mediæval times, especially from the 12th to the 15th century, mainly for objects of ecclesiastical use, such as pyxes, monstrances, reliquaries, and croziers, partly on account of its softness under the tool, and also because it was slightly easier to apply enamel and gilding to pure copper than to bronze (see fig. 1). In the mediæval period it was used to some extent in the shape of thin sheeting for roofs, as at St Mark's, Venice; while during the 16th and 17th centuries it was largely employed for ornamental domestic vessels of various sorts.

Iron.[1]—The abundance in which iron is found in so many places, its great strength, its remarkable ductility and malleability in a red-hot state, and the ease with which two heated surfaces of iron can be welded together under the hammer combine to make it specially suitable for works on a large scale where strength with lightness are required—things such as screens, window-grills, ornamental hinges, and the like.

In its hot plastic state iron can be formed and modelled under the hammer to almost any degree of refinement, while its great strength allows it to be beaten out into leaves and ornaments of almost paper-like thinness and delicacy. With repeated hammering, drawing out, and annealing, it gains much in strength and toughness, and the addition of a very minute quantity of carbon converts

[1] Some recent analyses of the iron of prehistoric weapons have brought to light the interesting fact that many of these earliest specimens of iron manufacture contain a considerable percentage of nickel. This special alloy does not occur in any known iron ores, but is invariably found in meteoric iron. It thus appears that iron was manufactured from meteorolites which had fallen to the earth in an almost pure metallic state, possibly long before prehistoric man had learnt how to dig for and smelt iron in any of the forms of ore which are found on this planet.

it into steel, less tough, but of the keenest hardness. The large employment of cast iron is comparatively modern, in England at least only dating from the 16th century; it is not, however, incapable of artistic treatment if due regard be paid to the necessities of casting, and if no attempt is made to imitate the fine-drawn lightness to which wrought iron so readily lends itself. At the best, however, it is not generally suited for the finest work, as the great contraction of iron in passing from the fluid to the solid state renders the cast somewhat blunt and spiritless.

Among the Assyrians, Egyptians, and Greeks the use of iron, either cast or wrought, was very limited, bronze being the favourite metal for almost all purposes. The difficulty of smelting the ore was probably one reason for this, as well as the now forgotten skill which enabled bronze to be tempered to a steel-like edge. It had, however, its value, of which a proof occurs in Homer (*Il.* xxiii.), where a mass of iron is mentioned as being one of the prizes at the funeral games of Patroclus.

Methods of Manipulation in Metal-Work.—Gold, silver, and bronze may be treated in various ways, the chief of which are (1) casting in a mould, and (2) treatment by hammering and punching (French, *repoussé*).

The first of these, casting, is chiefly adapted for bronze, or in the case of the more precious metals only if they are used on a very small scale. The reason of this is that a repoussé relief is of much thinner substance than if the same design were cast, even by the most skilful metal-worker, and so a large surface may be produced with a very small expenditure of valuable metal.

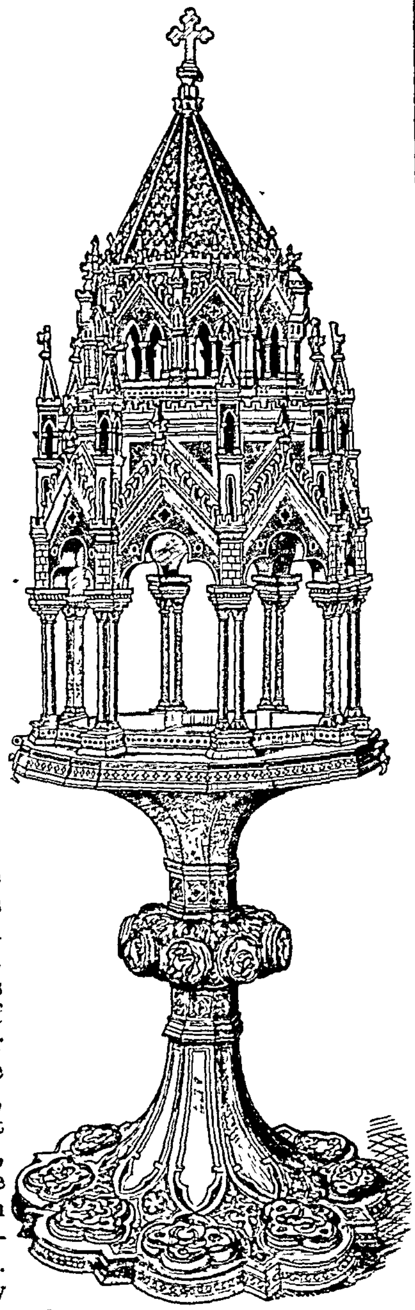

Fig. 1.—Monstrance of Copper Gilt; Italian work of the 15th century.

Casting is probably the most primitive method of metal-work. This has passed through three stages, the first being represented by solid castings, such as are most celts and other implements of the prehistoric time; the mould was formed of clay, sand, or stone, and the fluid metal was poured in till the hollow was full. The next stage was, in the case of bronze, to introduce an iron core, probably to save needless expenditure of the more valuable metal. The British Museum possesses an interesting Etruscan or Archaic Italian example of this primitive device. It is a bronze statuette from Sessa on the Volturno, about 2 feet high, of a female standing, robed in a close-fitting chiton. The presence of the iron core has been made visible by the splitting of the figure, owing to the unequal contraction of the two metals. The forearms, which are extended, have been cast separately and soldered or brazed on to the elbows.

The third and last stage in the progress of the art of casting was the employment of a core, generally of clay, round which the metal was cast in a mere skin, only thick enough for strength, without waste of metal. The Greeks and Romans attained to the greatest possible skill in this process. Their exact method is not certainly known, but it appears probable that they were acquainted with the process now called *à cire perdue*—the same as that employed by the great Italian artists in bronze, and still unimproved upon even at the present day. Cellini, the great Florentine artist of the 16th century, has described it fully in his *Trattato della Scultura.* If a statue was to be cast, the figure was first roughly modelled in clay—only rather smaller in all its dimensions than the future bronze; all over this a skin of wax was laid, and worked by the sculptor with modelling tools to the required form and finish. A mixture of pounded brick, clay, and ashes was then ground finely in water to the consistence of cream, and successive coats of this mixture were then applied with a brush, till a second skin was formed all over the wax, fitting closely into every line and depression of the modelling. Soft clay was then carefully laid on to strengthen the mould, in considerable thickness, till the whole statue appeared like a shapeless mass of clay, round which iron hoops were bound to hold it all together. The whole was then thoroughly dried, and placed in a hot oven, which baked the clay, both of the core and the outside mould, and melted the wax, which was allowed to run out from small holes made for the purpose. Thus a hollow was left, corresponding to the skin of wax between the core and the mould, the relative positions of which were preserved by various small rods of bronze, which had previously been driven through from the outer mould to the rough core. The mould was now ready, and melted bronze was poured in till the whole space between the core and the outer mould was full. After slowly cooling, the outer mould was broken away from outside the statue, and the inner core as much as possible broken up and raked out through a hole in the foot or some other part of the statue. The projecting rods of bronze were then cut away, and the whole finished by rubbing down and polishing over any roughnesses or defective places. The most skilful sculptors, however, had but little of this after-touching to do, the final modelling and even polish which they had put upon the wax being faithfully reproduced in the bronze casting.

The further enrichment of the object by enamels and inlay of other metals was practised at a very early period by Assyrian, Egyptian, and Greek metal-workers, as well as by the artists of Persia and mediæval Europe.

The second chief process, that of hammered work (Greek, *sphyrelata*; French, *repoussé*), was probably adopted for bronze-work on a large scale, before the art of forming large castings was discovered. In the most primitive method thin plates of bronze were hammered over a wooden core, rudely cut into the required shape, the core serving the double purpose of giving shape to and strengthening the thin metal.

A further development in the art of hammered work consisted in laying the metal plate on a soft and elastic bed of cement made of pitch and pounded brick. The design was then beaten into relief from the back with hammers and punches, the pitch bed yielding to the protuberances which were thus formed, and serving to pro-

vent the punch from breaking the metal into holes. The pitch was then melted away from the front of the embossed relief, and applied in a similar way to the back, so that the modelling could be completed on the face of the relief, the final touches being given by the graver. This process was chiefly applied by mediæval artists to the precious metals, but by the Assyrians, Greeks, and other early nations it was largely used for bronze.

The great gates of Shalmaneser II., 859–824 B.C., from Balawat, now in the British Museum, are a remarkable example of this sort of work on a large scale, though the treatment of the reliefs is minute and delicate. The "Siris bronzes," in the same museum, are a most astonishing example of the skill attained by Greek artists in this repoussé work (see Brönsted's *Bronzes of Siris*, 1836). They are a pair of shoulder-pieces from a suit of bronze armour, and each has in very high relief a combat between a Greek warrior and an Amazon. No work of art in metal has probably ever surpassed these little figures for beauty, vigour, and expression, while the skill with which the artist has beaten these high reliefs out of a flat plate of metal appears almost miraculous. The heads of the figures are nearly detached from the ground, their substance is little thicker than paper, and yet in no place has the metal been broken through by the punch. They are probably of the school of Praxiteles, and date from the 4th century B.C. (see fig. 2).

FIG. 2.—One of the Siris Bronzes.

Copper and tin have been but little used separately. Copper in its pure state may be worked by the same methods as bronze, but it is inferior to it in hardness, strength, and beauty of surface. Tin is too weak and brittle a metal to be employed alone for any but small objects. Some considerable number of tin drinking-cups and bowls of the Celtic period have been found in Cornwall in the neighbourhood of the celebrated tin and copper mines, which appear to have been worked from a very early period. The existence of these mines was known to the Phœnicians, who carried on a considerable trade in metals with the south-west corner of England and the Scilly Isles —probably the Cassiterides of Pliny and other classical writers.

The use of lead has been more extended. In sheets it forms the best of all coverings for roofs and even spires. In the Roman and mediæval periods it was largely used for coffins, which were often richly ornamented with cast work in relief. Though fusible at a very low temperature, and very soft, it has great power of resisting decay from damp or exposure. Its most important use in an artistic form has been in the shape of baptismal fonts, chiefly between the 11th and the 14th centuries. The superior beauty of colour and durability of old specimens of lead is owing to the natural presence of a small proportion of silver. Modern smelters carefully extract this silver from the lead ore, thereby greatly impairing the durability and beauty of the metal.

As in almost all the arts, the ancient Egyptians excelled in their metal-work, especially in the use of bronze and the precious metals. These were worked by casting and hammering, and ornamented by inlay, gilding, and enamels with the greatest possible skill.

From Egypt perhaps was derived the early skill of the Hebrews. Further instruction in the art of metal-working came probably to the Jews from the neighbouring country of Tyre. The description of the great gold lions of Solomon's throne, and the laver of cast bronze supported on figures of oxen, shows that the artificers of that time had overcome the difficulties of metal-working and founding on a large scale. The Assyrians were perhaps the most remarkable of all ancient nations for the colossal size and splendour of their works in metal; whole circuit walls of great cities, such as Ecbatana, are said to have been covered with metal plates, gilt or silvered.

Herodotus, Athenæus, and other Greek and Roman writers have recorded the enormous number of colossal statues and other works of art for which Babylon and Nineveh were so famed. The numerous objects of bronze and other metals brought to light by the excavations of the last forty years in the Tigris and Euphrates valleys, though mostly on a small scale, bear witness to the great skill and artistic power of the people who produced them; while the recent discovery of some bronze statuettes, shown by inscriptions on them to be not later than 2200 B.C., proves how early was the development of this branch of art among the people of Assyria.

The Metal-Work of Greece.—The poems of Homer are full of descriptions of elaborate works in bronze, iron, gold, and silver, which, even when full allowance is made for poetic fancy, show clearly enough a very advanced amount of skill in the working and ornamenting of these metals among the Greeks of his time. His description of the shield of Achilles, made of bronze, enriched with bands of figure reliefs in gold, silver, and tin, could hardly have been written by a man who had not some personal acquaintance with works in metal of a very elaborate kind. Again, the accuracy of his descriptions of brazen houses—such as that of Alcinous, *Od.* vii. 81—is borne witness to by Pausanias's mention of the bronze temple of Athena Χαλκίοικος in Sparta, and the bronze chamber dedicated to Myron in 648 B.C., as well as by the discovery of the stains and bronze nails, which show that the whole interior of the so-called treasury of Atreus at Mycenæ was once

covered with a lining of bronze plates. Of the two chief methods of working bronze, gold, and silver, it is probable that the hammer process was first practised, at least for statues, among the Greeks, who themselves attributed the invention of the art of hollow casting to Theodorus and Rhœcus, both Samian sculptors, about the middle of the 6th century B.C. Pausanias specially mentions that one of the oldest statues he had ever seen was a large figure of Zeus in Sparta, made of hammered bronze plates riveted together. With increased skill in large castings, and the discovery of the use of cores, by which the fluid bronze was poured into a mere skin-like cavity, hammered or repoussé work (Greek, *sphyrelata*) was only used for small objects where lightness was desirable, or for the precious metals in order to avoid large expenditure of metal. The colossal statues of ivory and gold by Phidias were the most notable examples of this use of gold, especially his statue of Athena in the Parthenon, and the one of Zeus at Olympia. The nude parts, such as face and hands, were of ivory, while the armour and drapery were of beaten gold. The comparatively small weight of gold used by Phidias is very remarkable when the great size of the statues is considered.

A graphic representation of the workshop of a Greek sculptor in bronze is given on a fictile vase now in the Berlin Museum (see Gerhard's *Trinkschalen*, plates xii., xiii.). One man is raking out the fire in a high furnace, while another behind is blowing the bellows. Two others are smoothing the surface of a statue with scraping tools, formed like a strigil. A fourth is beating the arm of an unfinished figure, the head of which lies at the workman's feet. Perhaps the most important of early Greek works in cast bronze, both from its size and great historical interest, is the bronze pillar (now in the Hippodrome at Constantinople) which was erected to commemorate the victory of the allied Greek states over the Persians at Platæa in 479 B.C. (see Newton's *Travels in the Levant*). It is in the form of three serpents twisted together, and before the heads were broken off was at least 20 feet high. It is cast hollow, all in one piece, and has the names of the allied states engraved on the lower part of the coils. Its size and the beauty of its surface show great technical skill in the founder's art. On it once stood the gold tripod dedicated to Apollo as a tenth of the spoils. It is described both by Herodotus and Pausanias.

Marble was comparatively but little used by the earlier Greek sculptors, and even Myron, a rather older man than Phidias, seems to have executed nearly all his most important statues in metal.

Additional richness was given to Greek bronze-work by gold or silver inlay on lips, eyes, and borders of the dress; one remarkable statuette in the British Museum has eyes inlaid with diamonds, and fret-work inlay in silver on the border of the chiton.

The mirrors of the Greeks are among the most important specimens of their artistic metal-work. These are bronze disks, one side polished to serve as a reflector, and the back ornamented with engraved outline drawings, often of great beauty (see Gerhard, *Etruskische Spiegel*, 1843–67).

The Greek workman, in fact, was incapable of making an ugly thing. Whatever the metal or whatever the object formed, whether armour, personal ornaments, or domestic vessels, the form was always specially adapted to its use, the ornament natural and graceful, so that the commonest water-jar was a delight alike to him who made it and those who used it.

In metal-work, as in other arts, the Romans were pupils and imitators of the Greeks. Owing to the growth of that spirit of luxury which in time caused the extinction of the Roman empire, a considerable demand arose for magnificent articles of gold and silver plate. The finest specimens of these that still exist are the very beautiful set of silver plate found buried near Hildesheim in 1869, now in the Berlin Museum. They consist of drinking vessels, bowls, vases, ladles, and other objects of silver, parcel-gilt, and exquisitely decorated with figures in relief, both cast and repoussé. There are electrotypes of these in the South Kensington Museum.

When the seat of the empire was changed from Rome to Byzantium, the latter city became the chief centre for the production of artistic metal-work. From Byzantium the special skill in this art was transmitted in the 9th and 10th centuries to the Rhenish provinces of Germany and to Italy, and thence to the whole of Western Europe; in this way the 18th-century smith who wrought the Hampton Court iron gates was the heir to the mechanical skill of the ancient metal-workers of Phœnicia and Greece.

In that period of extreme degradation into which all the higher arts fell after the destruction of the Roman empire, though true feeling for beauty and knowledge of the subtleties of the human form remained for centuries almost dormant, yet at Byzantium at least there still survived great technical skill and power in the production of all sorts of metal-work. In the age of Justinian (first half of the 6th century) the great church of St Sophia at Constantinople was adorned with an almost incredible amount of wealth and splendour in the form of screens, altars, candlesticks, and other ecclesiastical furniture made of massive gold and silver.

Metal-Work in Italy.—It was therefore to Byzantium that Italy turned for metal-workers, and especially for goldsmiths, when, in the 6th to the 8th centuries, the basilica of St Peter's in Rome was enriched with masses of gold and silver for decorations and fittings, the gifts of many donors from Belisarius to Leo III., the mere catalogue of which reads like a tale from the *Arabian Nights.* The gorgeous Pala d'Oro, still in St Mark's at Venice, a gold retable covered with delicate reliefs and enriched with enamels and jewels, was the work of Byzantine artists during the 11th century. This work was in progress for more than a hundred years, and was set in its place in 1106 A.D., though still unfinished (see Bellomo, *Pala d'Oro di S. Marco*, 1847).

It was, however, especially for the production of bronze doors for churches, ornamented with panels of cast work in high relief, that Italy obtained the services of Byzantine workmen (see Garrucci, *Arte Cristiana*, 1872–82). One artist named Staurachios produced many works of this class, some of which still exist, such as the bronze doors of the cathedral at Amalfi, dated 1066 A.D. Probably by the same artist, though his name was spelled differently, were the bronze doors of San Paolo fuori le Mura, Rome, careful drawings of which exist, though the originals were destroyed in the fire of 1824. Other important examples exist at Ravello (1197), Salerno (1099), Amalfi (1062), Atrani (1087); and doors at Monreale in Sicily and at Trani, signed by an artist named Barisanos (end of the 12th century); the reliefs on these last are remarkable for expression and dignity, in spite of their early rudeness of modelling and ignorance of the human figure.

Most of these works in bronze were enriched with fine lines inlaid in silver, and in some cases with a kind of niello or enamel. The technical skill of these Byzantine metal-workers was soon acquired by native Italian artists, who produced many important works in bronze similar in style and execution to those of the Byzantine Greeks. Such, for example, are the bronze doors of San Zenone at Verona (unlike the others, of repoussé not cast work); those of the Duomo of Pisa, cast in 1180 by Bonannus, and of the

Duomo of Troia, the last made in the beginning of the 12th century by Oderisius of Benevento. Another artist named Roger of Amalfi worked in the same way; and in the year 1219 the brothers Hubertus and Petrus of Piacenza cast the bronze door for one of the side chapels in San Giovanni in Laterano. One of the most important early specimens of metal-work is the gold and silver altar of Sant' Ambrogio in Milan. In character of work and design it resembles the Venice Pala d'Oro, but is still earlier in date, being a gift to the church from Archbishop Angilbert II. in 835 A.D. (see Du Sommerard, and D'Agincourt, *Moyen Âge*). It is signed WOLVINIVS MAGISTER PHABER; nothing is known of the artist, but he probably belonged to the semi-Byzantine school of the Rhine provinces; according to Dr Rock he was an Anglo-Saxon goldsmith. It is a very sumptuous work, the front of the altar being entirely of gold, with repoussé reliefs and cloisonnée enamels; the back and ends are of silver, with gold ornaments. On the front are figures of Christ and the twelves apostles; the ends and back have reliefs illustrating the life of St Ambrose.

The most important existing work of art in metal of the 13th century is the great candelabrum now in Milan cathedral. It is of gilt bronze, more than 14 feet high; it has seven branches for candles, and its upright stem is supported on four winged dragons. For delicate and spirited execution, together with refined gracefulness of design, it is unsurpassed by any similar work of art. Every one of the numerous little figures with which it is adorned is worthy of study for the beauty and expression of the face, and the dignified arrangement of the drapery (see fig. 3).

FIG. 3.—Boss from the Milanese Candelabrum.

The semi-conventional open scroll-work of branches and fruit which wind around and frame each figure or group is devised with the most perfect taste and richness of fancy, while each minute part of this great piece of metal-work is finished with all the care that could have been bestowed on the smallest article of gold jewellery. Though something in the grotesque dragons of the base recalls the Byzantine school, yet the beauty of the figures and the keen feeling for graceful curves and folds in the drapery point to a native Italian as being the artist who produced this wonderful work of art. There is a cast in the South Kensington Museum.

During the 13th and 14th centuries in Italy the wide-spread influence of Niccolo Pisano and his school encouraged the sculptor to use marble rather than bronze for his work. At this period wrought iron came into general use in the form of screens for chapels and tombs, and grills for windows. These are mostly of great beauty, and show remarkable skill in the use of the hammer, as well as power in adapting the design to the requirements of the material. Among the finest examples of this sort of work are the screens round the tombs of the Scala family at Verona, 1350–75,—a sort of net-work of light cusped quatrefoils, each filled up with a small ladder (scala) in allusion to the name of the family. The most elaborate specimen of this wrought work is the screen to the Rinuccini chapel in Santa Croce, Florence, of 1371, in which moulded pillars and window-like tracery have been wrought and modelled by the hammer with extraordinary skill (see Wyatt, *Metal-Work of Middle Ages*). Of about the same date are the almost equally magnificent screens in Sta Trinita, Florence, and at Siena across the chapel in the Palazzo Pubblico. The main part of most of these screens is filled in with quatre-foils, and at the top is an open frieze formed of plate iron pierced, repoussé, and enriched with engraving.

In the 14th century great quantities of objects for ecclesiastical use were produced in Italy, some on a large scale, and mostly the works of the best artists of the time.

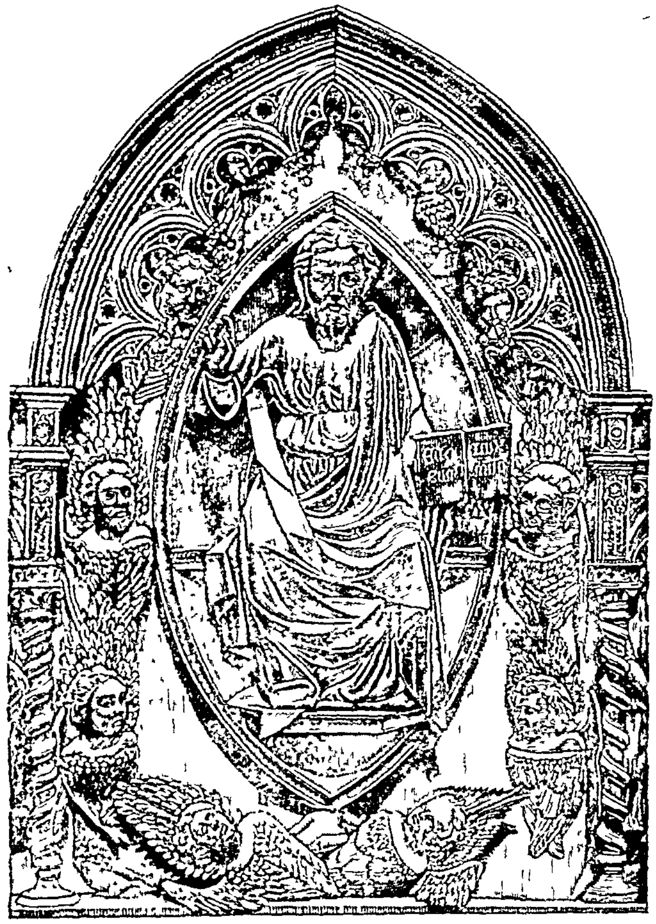

FIG. 4.—Silver Repoussé Reliefs from the Pistoia Retable.

The silver altar of the Florence baptistery is one of the chief of these; it was begun in the first half of the 14th century, and not completed till after 1477 (see *Gaz. des Beaux Arts*, Jan. 1883). A whole series of the greatest artists in metal laboured on it in succession, among whom were Orcagna, Ghiberti, Verrocchio, Ant. Pollajuolo, and many others. It has elaborate reliefs in repoussé work, cast canopies, and minute statuettes, with the further enrichment of translucent coloured enamels. The silver altar and retable of Pistoia cathedral (see fig. 4), and the great shrine at Orvieto, are works of the same class, and of equal importance.

Whole volumes might be devoted to the magnificent works in bronze produced by the Florentine artists of this century, works such as the baptistery gates by Ghiberti, and the statues of Verrocchio, Donatello, and many others, but these come rather under the head of sculpture.

Some very magnificent bronze screens were produced at this time, especially that in Prato cathedral by Simone, brother of Donatello, in 1444–61, and the screen and bronze ornaments of the tomb of Piero and Giovanni dei Medici in San Lorenzo, Florence, by Verrocchio, in 1472.

At the latter part of the 15th century and the beginning of the 16th the Pollajuoli, Ricci, and other artists devoted much labour and artistic skill to the production of candlesticks and smaller objects of bronze, such as door-knockers, many of which are works of the greatest beauty. The candlesticks in the Certosa near Pavia, and in the cathedrals of Venice and Padua, are the finest examples of these.

Niccolò Grossi, who worked in wrought iron under the patronage of Lorenzo dei Medici, produced some wonderful specimens of metal-work, such as the candlesticks, lanterns, and rings fixed at intervals round the outside of the great palaces (see fig. 5). The Strozzi palace in Florence and the Palazzo del Magnifico at Siena have fine specimens of these,—the former of wrought iron, the latter in cast bronze.

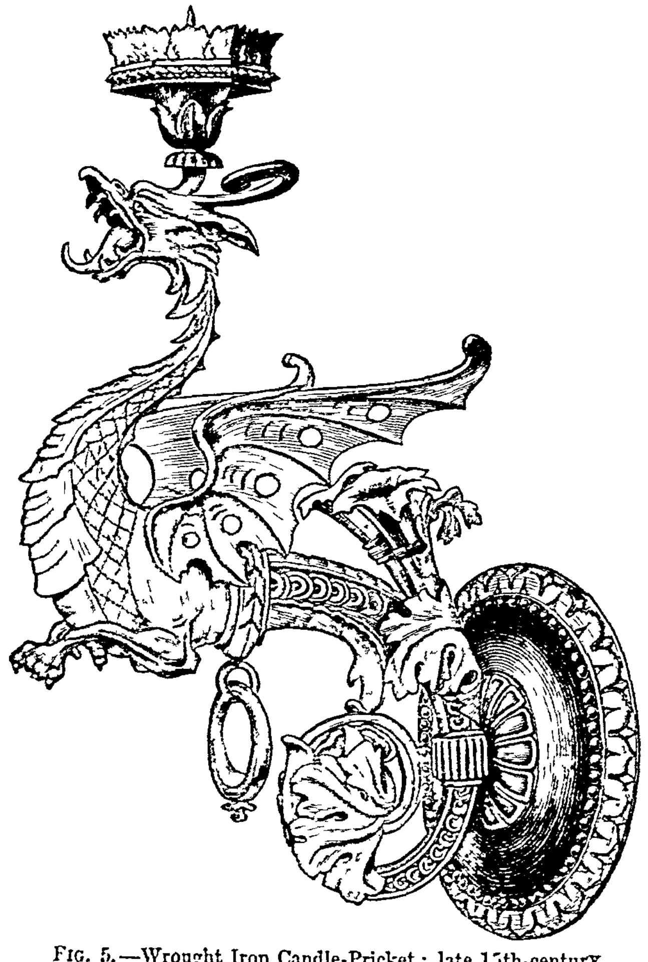

Fig. 5.—Wrought Iron Candle-Pricket; late 15th-century. Florentine work.

At Venice fine work in metal, such as salvers and vases, was being produced, of almost Oriental design, and in some cases the work of resident Arab artificers. In the 16th century Benvenuto Cellini was supreme for skill in the production of enamelled jewellery, plate, and even larger works of sculpture (see Plon's *Ben. Cellini*, 1882), and John of Bologna in the latter part of the same century inherited to some extent the skill and artistic power of the great 15th-century artists. Since that time Italy, like other countries, has produced little metal-work of real value.

Spain.—From a very early period the metal-workers of Spain have been distinguished for their skill, especially in the use of the precious metals. A very remarkable set of specimens of goldsmith's work of the 7th century are the eleven votive crowns, two crosses, and other objects found in 1858 at Guarrazar, and now preserved at Madrid and in Paris in the Cluny Museum (see Du Sommerard, *Musée de Cluny*, 1852). Magnificent works in silver, such as shrines, altar crosses, and church vessels of all kinds, were produced in Spain from the 14th to the 16th century,—especially a number of sumptuous tabernacles (*custodia*) for the host, magnificent examples of which still exist in the cathedrals of Toledo and Seville. The bronze and wrought iron screens—*rejas*, mostly of the 15th and 16th centuries—to be found in almost every important church in Spain are very fine examples of metal-work. They generally have moulded rails or ballusters, and rich friezes of pierced and repoussé work, the whole being often thickly plated with silver. The common use of metal for pulpits is a peculiarity of Spain; they are sometimes of bronze, as the pairs in Burgos and Toledo cathedrals, or in wrought iron, like those at Zamora and in the church of San Gil, Burgos. The great candelabrum or *tenebrarium* in Seville cathedral is the finest specimen of 16th-century metal-work in Spain; it was mainly the work of Bart. Morel in 1562. It is of cast bronze enriched with delicate scroll-work foliage, and with numbers of well-modelled statuettes, the general effect being very rich and graceful. Especially in the art of metal-work Spain was much influenced in the 15th and 16th centuries by both Italy and Germany, so that numberless Spanish objects produced at that time owe little or nothing to native designers. At an earlier period Arab and Moorish influence is no less apparent.

England.—In Saxon times the English metal-workers, especially of the precious metals, possessed great skill, and appear to have produced shrines, altar-frontals, retables, and other ecclesiastical furniture of considerable size and magnificence.

Dunstan, archbishop of Canterbury (925–988), like Bernward, bishop of Hildesheim a few years later, and St Eloi of France three centuries earlier, was himself a skilful worker in all kinds of metal. The description of the gold and silver retable given to the high altar of Ely by Abbot Theodwin in the 11th century, shows it to have been a large and elaborate piece of work decorated with many reliefs and figures in the round. In 1241 Henry III. gave the order for the great gold shrine to contain the bones of Edward the Confessor (see W. Burges in *Gleanings from Westminster*). It was the work of members of the Otho family, among whom the goldsmith's and coiner's crafts appear to have been long hereditary. Countless other important works in the precious metals adorned every abbey and cathedral church in the kingdom.

In the 13th century the English workers in wrought iron were especially skilful. The grill over the tomb of Queen Eleanor at Westminster, by Thomas de Leghton, made about 1294, is a remarkable example of skill in welding and modelling with the hammer (see fig. 6).

The rich and graceful iron hinges, made often for small and out-of-the-way country churches, are a large and important class in the list of English wrought iron-work. Those on the refectory door of Merton College, Oxford, are a beautiful and well-preserved example dating from the 14th century.

More mechanical in execution, though still very rich in effect, is that sort of iron tracery work produced by cutting out patterns in plate, and superimposing one plate over the other, so as to give richness of effect by the shadows produced by these varying planes. The screen by Henry V.'s tomb at Westminster is a good early specimen of this kind of work.

The screen to Bishop West's chapel at Ely, and that round Edward IV.'s tomb at Windsor, both made towards the end of the 15th century, are the most magnificent

English examples of wrought iron, in which every art and feat of skill known to the smith has been brought into play to give variety and richness to the work.

Much wrought-iron work of great beauty was produced at the beginning of the 18th century, especially under the superintendence of Sir Christopher Wren (see Ebbetts, *Iron Work of 17th and 18th Centuries*, 1880). Large flowing leaves of acanthus and other plants were beaten out with wonderful spirit and beauty of curve. The gates from Hampton Court are the finest examples of this class of work (see fig. 7).

From an early period bronze and latten (a variety of brass) were much used in England for the smaller objects both of ecclesiastical and domestic use, but except for tombs and lecterns were but little used on a large scale till the 16th century. The full-length recumbent effigies of Henry III. and Queen Eleanor at Westminster, cast in bronze by the "cire perdue" process, and thickly gilt, are equal, if not superior, in artistic beauty to any sculptor's work of the same period (end of the 13th century) that was produced in Italy or elsewhere. These effigies are the work

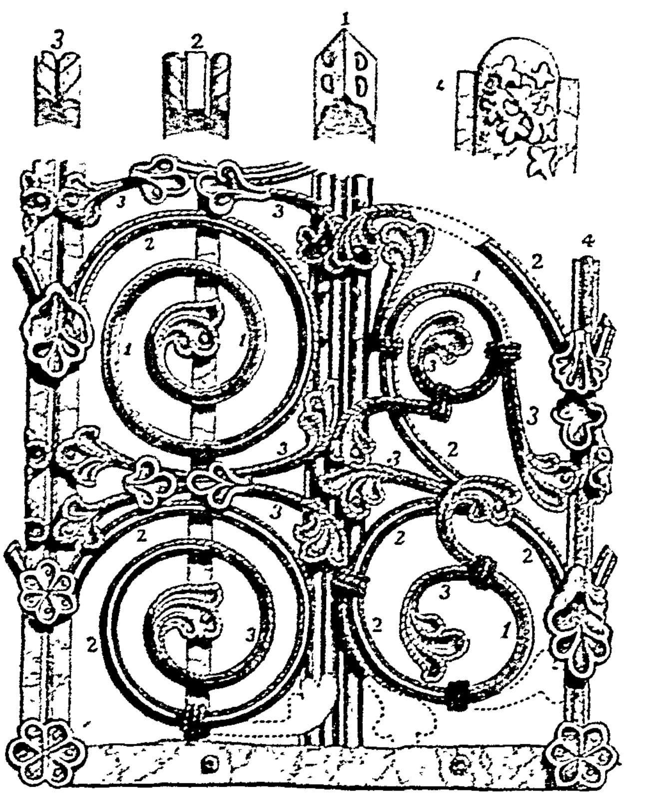

Fig. 6.—Part of the "Eleanor Grill."

of an Englishman named William Torel (see *Westminster Gleanings*). The gates to Henry VII.'s chapel, and the screen round his tomb at Westminster (see fig. 8), are very elaborate and beautiful examples of "latten" work, showing the greatest technical skill in the founder's art. In latten also were produced the numerous monumental brasses of which about two thousand still exist in England. Though a few were made in the 13th century, yet it was not till the 14th that they came into general use. They are made of cast plates of brass, with the design worked upon them with the chisel and graver. All those, however, to be seen in English churches are not of native work—great quantities of them being Flemish imports (see Cotman, Waller, and Boutell on Monumental Brasses).

In addition to its chief use as a roof covering, lead was sometimes used in England for making fonts, generally tub-shaped, with figures cast in relief. Many examples exist: *e.g.*, at Tidenham, Gloucestershire; Warborough and Dorchester, Oxon; Chirton, Wilts; and other places.

Germany.—Unlike England, Germany in the 10th and 11th centuries produced large and elaborate works in cast bronze, especially doors for churches, much resembling the contemporary doors made in Italy under Byzantine influence. Bernward, bishop of Hildesheim, 992–1022, was especially skilled in this work, and was much influenced in design by a visit to Rome in the suite of Otho III. The bronze column with winding reliefs now at Hildesheim was the result of his study of Trajan's column, and the bronze door which he made for his own cathedral shows classical influence, especially in the composition of the drapery of the figures in the panels.

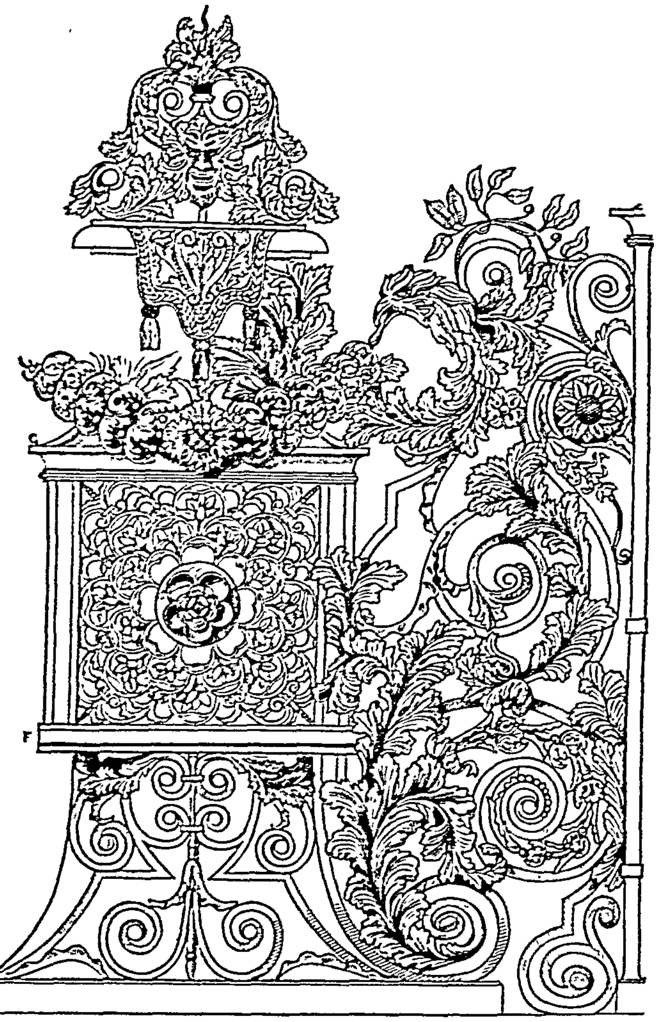

Fig. 7.—Part of one of the Hampton Court Gates.

The bronze doors of Augsburg (1047–72) are similar in style. The bronze tomb of Rudolph of Swabia in Mersburg cathedral (1080) is another fine work of the same school. The production of works in gold and silver was also carried on vigorously in Germany. The shrine of the three kings at Cologne is the finest surviving example.

At a later time Augsburg and Nuremberg were the chief centres for the production of artistic works in the various metals. Herman Vischer, in the 15th century, and his son and grandsons were very remarkable as bronze founders. The font at Wittenberg, decorated with reliefs of the apostles, was the work of the elder Vischer, while Peter and his son produced, among other important works, the shrine of St Sebald at Nuremberg, a work of great finish and of astonishing richness of fancy in its design (see Doebner, *Christliches Kunstblatt*, 1866, Nos. 10–12). The tomb of Maximilian I., and the statues round it, at Innsbruck, begun in 1521, are perhaps the most meritorious German work of this class in the 16th century, and show considerable Italian influence.

In wrought iron the German smiths, especially during the 15th century, greatly excelled. Almost peculiar to Germany is the use of wrought iron for grave-crosses and sepulchral monuments, of which the Nuremberg and other cemeteries contain fine examples. Many elaborate well-canopies were made in wrought iron, and gave full play to the fancy and invention of the smith. The celebrated 15th-century example over the well at Antwerp, attributed to Quintin Massys, is the finest of these.

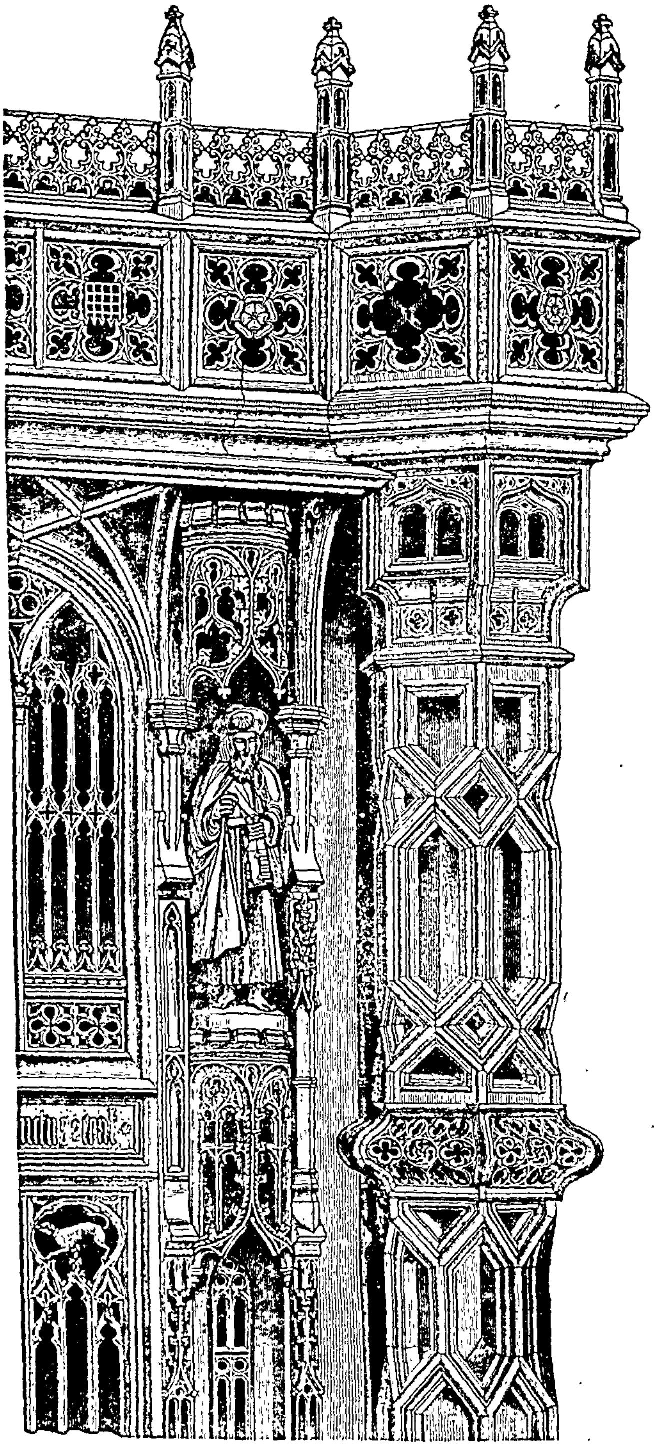

FIG. 8.—Part of Henry VII.'s Bronze Screen.

France.—From the time of the Romans the city of Limoges has been celebrated for all sorts of metal-work, and especially for brass enriched with enamel. In the 13th and 14th centuries many life-size sepulchral effigies were made of beaten copper or bronze, and ornamented by various-coloured "champlevé" enamels. The beauty of these effigies led to their being imported into England; most are now destroyed, but a fine specimen still exists at Westminster on the tomb of William de Valence (1296). In ornamental iron-work for doors the French smiths were pre-eminent for the richness of design and skilful treatment of their metal. No examples probably surpass those on the west doors of Notre Dame in Paris—now unhappily much falsified by restoration. The crockets and finials on the flèches of Amiens and Rheims are beautiful specimens of a highly ornamental treatment of cast lead, for which France was especially celebrated. In most respects, however, the development of the various kinds of metal-working went through much the same stages as in England.

Persia and Damascus.—The metal-workers of the East, especially in brass and steel, were renowned for their skill even in the time of Theophilus, the monkish writer on the subject in the 13th century. But it was during the reign of Shah Abbas I. (d. 1628) that the greatest amount of skill both in design and execution was reached by the Persian workmen. Delicate pierced vessels of gilt brass, enriched by tooling and inlay of gold and silver, were among the chief specialties of the Persians (see fig. 9).

FIG. 9.—Brass Vase, pierced and gilt; 17th century Persian work.

A process called by Europeans "damascening" (from Damascus, the chief seat of the export) was used to produce very delicate and rich surface ornament. A pattern was incised with a graver in iron or steel, and then gold wire was beaten into the sunk lines, the whole surface being then smoothed and polished. In the time of Cellini this process was copied in Italy, and largely used, especially for the decoration of weapons and armour. The repoussé process both for brass and silver was much used by Oriental workers, and even now fine works of this class are produced in the East, old designs still being adhered to.

Recent Metal-Work.—In modern Europe generally the arts of metal-working both as regards design and technical skill are not in a flourishing condition. The great bronze lions of the Nelson monument in London are a sad example of the present low state of the founder's art. Coarse sand-casting in England now takes the place of the delicate "cire perdue" process.

Some attempts have lately been made in Germany to revive the art of good wrought-iron work. The Prussian gates, bought at a high price for the South Kensington Museum, are large and pretentious, but unfortunately are only of value as a warning to show what wrought iron ought not to be. Some English recent specimens of hammered work are more hopeful, and show that one or two smiths are working in the right direction.

METAMORPHOSIS. This term has been employed in several distinct senses in biology. During the early part of the century it was constantly used to include the current morphological conceptions, as, for instance, of the parts of a flower as modified or "metamorphosed" leaves, or of the segments of a skull as modified vertebræ. It is still frequently employed to denote that progressive change from the general to the special undergone by all developing tissues and organs (see BIOLOGY, EMBRYOLOGY), but in this sense is conveniently superseded by the term "differentiation." In the process of animal development, two types are broadly distinguishable,—a fœtal type, in which development takes place wholly or in greater part either within the egg or within the body of the parent, and a larval type, in which the young are born in a condition more or less differing from that of the adult, while the adult stage again is reached in one of two ways, either by a process of gradual change, or by a succession of more or less rapid and striking transformations, to which the term metamorphosis is now usually restricted. Metamorphosis is generally regarded as having been brought about by the action of natural selection, partly in curtailing and reducing the phases of development (an obvious advantage in economy of both structural and functional change), and partly also in favouring the acquirement of such secondary characters as are advantageous in the struggle for existence. Freshwater and terrestrial animals develop without metamorphosis much more frequently than marine members of the same group, a circumstance which has been variously explained. For details of metamorphoses see the articles on the various groups of animals; see also Balfour's *Comparative Embryology*, 1880–81.

METAPHYSIC

THE term metaphysic, originally intended to mark the place of a particular treatise in the collection of Aristotle's works, has, mainly owing to a misunderstanding, survived several other titles,—such as "First Philosophy," "Ontology," and "Theology," which Aristotle himself used or suggested. Neo-Platonic mystics interpreted it as signifying that which is not merely "after" but "beyond" physics, and found in it a fit designation for a science which, as they held, could not be attained except by one who had turned his back upon the natural world. And writers of a different tendency in a later time gladly accepted it as a convenient nickname for theories which they regarded as having no basis in experience, in the same spirit in which the great German minister Stein used the analogous title of "metapolitics" for airy and unpractical schemes of social reform. A brief indication of the contents of Aristotle's treatise may enable us to give a general definition of the science which was first distinctly constituted by it, and to determine in what sense the subjects which that science has to consider are beyond nature and experience.

For Aristotle, metaphysic is the science which has to do with Being as such, Being in general, as distinguished from the special sciences which deal with special forms of being. There are certain questions which, in Aristotle's view, we have a right to ask in regard to everything that presents itself as real. We may ask what is its ideal nature or definition, and what are the conditions of its realization; we may ask by what or whom it was produced, and for what end; we may ask, in other words, for the formal and the material, for the efficient and the final causes of everything that is. These different questions point to different elements in our notion of Being, elements which may be considered in their general relations apart from any particular case of their union. These, therefore, the first philosophy must investigate. But, further, this science of being cannot be entirely separated from the science of knowing, but must determine at least its most general principles. For the science that deals with what is most universal in being is, for that very reason, dealing with the objects which are most nearly akin to the intelligence. These, indeed, are not the objects which are first presented to our minds; we begin with the particular, not the universal, with a πρῶτον ἡμῖν which is not πρῶτον φύσει; but science reaches its true form only when the order of thought is made one with the order of nature, and the particular is known through the universal. Yet this conversion or revolution of the intellectual point of view is not to be regarded as an absolute change from error to truth; for Aristotle holds that *nihil est in intellectu quod non prius in sensu*, in the meaning that in sense perception there is already the working of that discriminative intelli-

gence[1] which, beginning in sense perception, with the distinction of particular from particular, can rest only when it has apprehended things in their universal forms or definitions. Looking at knowledge *formally*, the highest law of thought, the law of contradiction (or, as we might call it, to indicate Aristotle's meaning more exactly, the law of definition or distinction), is already implied in the first act of perception by which one thing is distinguished from another. Looking at it *materially*, the reason of man is to be conceived as potentially all that is knowable; *i.e.*, objects are so related to it that for it to know them in their essential definitions is only to know itself. The aim of science, in this view, is to break through the husk of matter, and to apprehend things in their forms, in which they are one with the mind that knows them. Hence also it follows that in rising to the most universal science, the science of Being in general, the mind is not leaving the region of immediate experience, in which it is at home, for a far-off region of abstractions. Rather it is returning to itself, apprehending that which is most closely related to itself, and which therefore, though it is late in being made the direct object of investigation, is yet presupposed in all that is, and is known.[2]

Metaphysic, then, is the science which deals with the principles which are presupposed in all being and knowing, though they are brought to light only by philosophy. Another trait completes the Aristotelian account of it. It is theology, or the science of God. Now God is νόησις νοήσεως, pure self-consciousness, the absolute thought which is one with its object, and He is therefore the first cause of all existence. For, while the world of nature is a world of motion and change, in which form is realized in matter, this process of the finite can be explained only by referring it back to an unmoved mover, in whom there is no distinction of matter and form, and who is, therefore, in Aristotle's view, to be conceived as pure form, the purely ideal or theoretic activity of a consciousness whose object is itself. Such a conception, however, while it secures the independence and absoluteness of the unmoved mover, by removing him from all relation to what is other than himself, seems to make his connexion with the world inexplicable. We can on this theory refer the world to God, but not God to the world. Hence Aristotle seems sometimes to say that God is the first mover only as He is the last end after which all creation strives, and this leads him to attribute to nature a desire or will which is directed towards the good as its object or end.

Aristotle then brings together in his metaphysic three elements which are often separated from each other, and the connexion of which is far from being at once obvious. It is to him the science of the first principles of being. It is also the science of the first principles of knowing. Lastly, it is the science of God, as the beginning and end of all things, the absolute unity of being and thought, in which all the differences of finite thought and existence are either excluded or overcome.

To some this description of the contents of Aristotle's treatise, and especially the last part of it, may seem to be a confirmation of all the worst charges brought against metaphysic. For at both extremes this supposed science seems to deal with that which is beyond experience, and which therefore cannot be verified by it. It takes us back to a beginning which is prior to the existence as well as to the consciousness of finite objects in time and space, and on to an end to which no scientific prophecy based upon our consciousness of such objects can reach. In the former aspect of it, it has to do with notions so abstract and general that it seems as if they could not be fixed or tested by reference to any experience, but must necessarily be the playthings of dialectical sophistry. In the latter aspect of it, it entangles us in questions as to the final cause and ultimate meaning of things, questions involving so comprehensive a view of the infinite universe in which we are insignificant parts that it seems as if any attempt to answer them must be for us vain and presumptuous. On both sides, therefore, metaphysic appears to be an attempt to occupy regions which are beyond the habitable space of the intelligible world—to deal with ideas which are either so vague and abstract that they cannot be fastened to any definite meaning, or so complex and far-reaching that they can never by any possibility be verified. For beings like men, fixed within these narrow limits of space and time, the true course, it would seem, is to "cultivate their gardens," asking neither whence they come nor whither they go, or asking it only within the possible limits of history and scientific prophecy. To go back to the beginning or on to the end is beyond them, even in a temporal, still more in a metaphysical, sense. That which is πρῶτον φύσει escapes us even more absolutely than the prehistorical and pregeological records of man and his world. That which is ὕστατον φύσει escapes us even more absolutely than the far-off future type of civilization, which social science vainly endeavours to anticipate. Our state is best pictured by that early Anglican philosopher who compared it to a bird flying through a lighted room "between the night and the night." The true aim of philosophy is, therefore, it would seem, to direct our thoughts to the careful examination and utilization of the narrow space allotted to us by an inscrutable power, and with scientific self-restraint to refrain from all speculation either on first or on final causes.

The main questions as to the possibility and the nature of metaphysic, according to Aristotle's conception of it, may be summed up under two heads. We may ask whether we can in any sense reach that which is beyond experience, and, if so, whether this "beyond" is a first or a last principle, a pre-condition or a final cause of nature and experience, or both. The former question branches out into two, according as we look at metaphysic from the objective or the subjective side, or, to express the matter more accurately, according as we consider it in relation to those natural objects which are *merely* objects of knowledge, or in relation to those spiritual objects which are also subjects of knowledge. We shall therefore consider metaphysic, first, in relation to science in general, and, secondly, in relation to the special science of psychology. The latter question also has two aspects; for, while the idea of a first cause or principle points to the connexion between metaphysic and logic, the idea of a last principle or final cause connects metaphysic with theology. We shall therefore consider in the third place the relation of metaphysic to logic, and in the fourth place its relation to religion and the philosophy of religion.

1. *The Relation of Metaphysic to Science.*—The beginnings of science and metaphysic are identical, though there is a sense in which it may be admitted that the metaphysical comes before the scientific or positive era. The first efforts of philosophy grasp at once at the prize of absolute knowledge. No sooner did the Greeks become dissatisfied with the pictorial synthesis of mythology by which their thoughts were first lifted above the confusion of particular things, than they asked for one universal principle which should explain all things. The Ionic school sought to find some one phenomenon of nature which might be used as the key to all other phenomena. The Eleatics, seeing the

[1] Δύναμις κριτική, *Anal. Post.*, ii. 99*b*.

[2] What is said here as to the intelligence is partly taken from the *De Anima*. The necessary qualifications of the above general statement of Aristotle's views will be given subsequently.

futility of making one finite thing the explanation of all other finite things, tried to find that explanation in the very notion of unity or being itself. We need not underestimate the speculative value of such bold attempts to sum up all the variety of the world in one idea, but it is obvious that they rather give a name to the problem than solve it, or that they put the very consciousness of the problem in place of the solution of it. Science is possible only if we can rise from the particular to the universal, from a subjective view of things as they immediately present themselves to us in perception to an objective determination of them through laws and principles which have no special relation to any particular set of events or to any one individual subject. But this is only one aspect of the matter. To advance from a conception of the world *in ordine ad individuum* to one *in ordine ad universum*, and so to discount and eliminate what is merely subjective and accidental in our first consciousness of the world, is the beginning of knowledge. But little is gained unless the universal, which we reach through the negation of the particulars, is more than their mere negation; unless it is a law or principle by means of which we can explain the particulars. Now the defect of early philosophy was that its universal was "the one beyond the many," not the "one in the many,"—in other words, that it was not a law or principle by which the particulars subsumed under it could be explained, but simply the abstraction of an element common to them. But the process of knowledge is a process that involves both analysis and synthesis, negation and reaffirmation of the particulars with which we start. If we exaggerate the former aspect of it, we enter upon the *via negativa* of the mystics, the way of pure abstraction and negation, which would open the mind to the ideal reality of things simply by shutting it to all the perceptions of sensible phenomena. And, if we follow out this method to its legitimate result, we must treat the highest abstraction, the abstraction of Being, as if it were the sum of all reality, and the Neo-Platonic ecstasy in which all distinction, even the distinction of subject and object, is lost as the only attitude of mind in which truth can be apprehended.

In the philosophy of the Socratic school we find the first attempt at a *systematic* as opposed to an *abstract* theory—the first attempt to bring together the one and the many, and so to determine the former that it should throw light upon the latter. Yet even in Plato the tendency to oppose the universal to the particular is stronger than the tendency to relate them to each other, and in some of his dialogues, as, *e.g.*, in the *Phædo*, we find a near approach to that identification of the process of knowledge with abstraction which is the characteristic of mysticism. Aristotle, therefore, had some ground for taking the Platonic principle that "the real is the universal" in a sense which excludes the reality of the individual. Yet, though he detected Plato's error in opposing the universal to the particular, and though, at the same time, he did not entirely lose sight of the truth which Plato had exaggerated, that the particular is intelligible only *through* the universal, Aristotle was not able to escape the influence of that dualism which had marred the philosophy of his predecessor. Hence the effect of his protest against a philosophy of abstraction was partly neutralized by his separation between the divine Being as pure form and nature as the unity of form and matter, and again by his separation of the pure reason which apprehends the forms of things from the perceptions of sense which deal with forms realized in matter. And after Aristotle's time the tendency of philosophy was more and more to withdraw from contact with experience. The Neo-Platonic philosophy, and the Christian theology which was so strongly influenced by it, contained, indeed, an idea of the reconciliation of God and nature, and hence of form and matter, which must ultimately be fatal to dualism, and therefore to the method of mere abstraction. But the explicit meaning of the philosophy of the Middle Ages was still dualistic, and the mode in which the Aristotelian formulæ were wrought into the substance of Christian doctrine by the scholastics tended more and more to conceal that idea of the unity of opposites which was involved in Christianity. Hence mediæval realism presented, in its most one-sided form, the doctrine that "the real is the universal," meaning by the universal nothing more than the abstract. And, as a natural consequence, the modern insurrection of the scientific spirit against scholasticism took its start from an equally bald and one-sided assertion of the opposite principle, that "the real is the individual," meaning by that the individual of immediate perception. If Platonism had dwelt too exclusively on one aspect of the process of knowledge, viz., that it seeks to rise above the particular, the sensible, the subjective, to the universal, the intelligible, the objective, as if in the latter alone were reality to be found, modern men of science learnt from their first nominalistic teachers to regard the universal as nothing more than an abbreviated expression for the particulars, and science itself as a mere generalization of the facts of sensible perception. But this view of scientific knowledge, as a mere reaffirmation of what is immediately given in sense, is as imperfect as the opposite theory, which reduces it to the mere negation of what is so given. An ideal world utterly and entirely divorced from the phenomenal, and an ideal world which is simply a repetition of the phenomenal, are equally meaningless. The processes of science have both a negative and a positive side; they involve a negation of the particular as it is immediately presented in sense, but only with a view to its being reaffirmed with a new determination through the universal. The fact as it is first presented to us is not the fact as it is; for, though it is from the fact as given that we rise to the knowledge of the law, it is the law that first enables us to understand what the fact really means. Our first consciousness of things is thus, not an immovable foundation upon which science may build, but rather a hypothetical and self-contradictory starting-point of investigation, which becomes changed and transformed as we advance.

The nominalism of scientific men in modern times is due to two special causes, one of which has already been mentioned. It is partly due to the traditions of a time when mediæval realism was the great enemy of science. The Baconian protest against the "anticipation of nature" was a relative truth when it was urged against a class of writers who supposed that true theories could be attained without regard to facts; the Baconian assertion of the necessity of attending to *axiomata media* was the necessary correction of the tendencies of mystics, who supposed that philosophy could attain its end by grasping at once at absolute unity, and contented themselves, therefore, with a unity which did nothing to explain the differences. But, when the former was turned into the dogmatic assertion that the mind is, or ought to be, passive in the process of knowledge, as having in itself no principle for the explanation of things, and when the latter was turned into the dogmatic assertion that science can only proceed from part to part and never from the whole to the parts, these relative truths became a source of error. And this error was confirmed and increased by the mistaken views of those who first tried to correct it. For these, admitting that scientific truth is entirely derived from external experience, only ventured to assert the existence of *a priori* knowledge alongside of, and in addition to, that which is *a posteriori*. In other words, they sought in inner experience a basis for

those beliefs which outward experience seemed unable to support. But this basis was soon found to be treacherous. Introspection, observation of the inner life as opposed to and distinguished from the outer life, could be only an observation of the facts of the individual consciousness as such; and to base religion and morality on such a foundation was to treat God and right as subjective phenomena, which do not necessarily correspond to any objective reality. Nor was this conclusion really evaded by the assertion of the self-evidencing necessity of such ideas and beliefs, or of the principles upon which they are founded. For this necessity, as a subjective phenomenon, might be accounted for otherwise than by the supposition of their objective validity. Such scepticism, further, was favoured by the progress of science, which, as it advanced from physics to biology and sociology, became more and more inconsistent with the idea of an absolute breach between inner and outer experience, and narrowed the sphere which had been hitherto reserved for the former. Man, it was urged, is but a part in a greater whole, not exempted from the law of action and reaction which connects all parts of that whole with each other. His individual life contains only a few links in a chain of causation that goes back to a beginning and onward to an end of which he knows nothing. And, as Spinoza says, *vis qua unaquæque res in existendo perseverat a causis externis infinite superatur.* Hence to treat ideas which are only states of the individual consciousness as the explanation of the world, instead of treating them as phenomena to be explained by its relation to that world, seemed to be an absurdity. The particular beliefs and tendencies of the mind were to be regarded, not as ultimate facts in reference to which everything is to be interpreted, but rather as facts which are themselves to be referred to more general causes and laws. It thus appeared that the attempt to divide truth into an *a posteriori* and an *a priori* part, the latter of which should find its evidence in an inner experience as the former in an outer experience, is an illusive process. If the *a priori* is reduced to the level of the *a posteriori*, it becomes impossible to base on the *a priori* any beliefs that go beyond the range of subjective experience. If the self and the not-self are taken simply as different finite things, which we can observe in turn, their relations must be brought under the general laws of the connexion of finite things with each other; and the phenomena of mind must be treated, like the phenomena of matter, as facts to be accounted for according to these laws.

But this of itself indicates a way of escape both from the introspective theory and from the empiricism to which it is opposed. For it suggests the question—What is the source of those very laws which guide the procedure of science in accounting for facts, psychological facts among others? When a scientific psychologist of the modern school attempts to show how by habituation of the individual and the race the necessity of thought expressed in the law of causation was produced in the minds of the present generation of men, it is obvious that his whole investigation and argument presuppose the law whose genesis he is accounting for. A glaring instance of such circular reasoning is found in the writings of the most prominent representative of the school in the present day. Mr Spencer begins by laying down as a first postulate of science that necessity of thought must be taken as a criterion of truth. It is by the continual aid of this postulate that he constructs his system of nature, and finally his psychological theory of the development of consciousness in man. Yet the main object of this psychological theory seems to be to account for the very necessities with which the author starts. Obviously such a philosophy contains elements of which the author is imperfectly conscious; for it involves that mind is not only the last product but the first presupposition of nature, or, in other words, that in mind nature returns upon its first principle. But to admit this is at once to lift the conscious being as such above the position which he would hold as merely a finite part of a finite world. It is to assert that nature has an essential relation to a consciousness which is developed in man, and that in the growth of this consciousness we have, not an evolution which is the result of the action of nature as a system of external causes *upon him*, but an evolution in which nature is really "coming to itself," *i.e.*, coming to self-consciousness, *in him.*

Now it was Kant who first—though with a certain limitation of aim—brought this idea of the relativity of thought and being to the consciousness of the modern world. In the *Critique of Pure Reason*, thought, indeed, is not set up as an absolute *prius*, in relation to which all existence must be conceived, but it is set up as the *prius* of experience, and so of all existences which are objects of our knowledge. Experience is for Kant essentially relative to the conscious self; it exists through the necessary subsumption of the forms and matter of sense under the categories, as, on the other hand, the consciousness of self is recognized as essentially dependent on this process. On this view, the *a priori* and *a posteriori* factors of experience do not really exist apart as two separate portions of knowledge. If they are severed, each loses all its meaning. Perceptions in themselves are void; categories in themselves are empty. We do not look outwards for one kind of truth and inwards for another, nor do we even, by an external process, bring facts given as contingent under principles recognized as necessary; but the *a priori* is the condition under which alone the *a posteriori* exists for us. Even if it is allowed that the facts of inner and outer experience contain a contingent element or matter, given under the conditions of time and space, yet neither time nor space nor the facts of experience conditioned by them exist for us except as elements of an experience which is organized according to the categories.

This is the essential truth which Kant had to express. It is marred in his statement of it by the persistent influence of the abstract division between contingent matter given from without and necessary principles supplied from within, a division essentially inconsistent with the attempt to show that the contingent matter is necessarily subsumed under these principles, and indeed exists for us only as it is so subsumed. But Kant himself puts into our hands the means of correcting his own inadequacy, when he reduces the inaccessible thing in itself, which he at first speaks of as affecting our sensibility and so giving rise to the contingent matter of experience, to a noumenon (νοούμενον) which is projected by reason itself. The *Dialectic* exhibits the idea of thought as not only constituting finite experience but also reaching beyond it, though as yet only in a negative way. The mind is, on this view, so far unlimited that it knows its own limits; it is conscious of the defects of its experience, of the contingency of its sensible matter, and the emptiness and finitude of its categories; and by reason of this consciousness it is always seeking in experience an ideal which it is impossible to realize there. Thought measures experience by its own nature, and finds it wanting. It demands a kind of unity or identity in its objects which it is unable to find in the actual objects of experience. It is this demand of reason which lifts man above a mere animal existence, and forces him by aid of the categories to determine the matter of sense as a world of objects; yet, as this finite world of experience can never satisfy the demand

of reason, the consciousness of it is immediately combined with the consciousness of its limited and phenomenal character. The student of the *Critique of Pure Reason* cannot but recognize the strange balance between the real and the phenomenal in which it ends, allowing to man the consciousness of each so far as to enable him to see the defects of the other,—so that by aid of the pure identity of reason he can criticize and condemn the "blindness" or unresolved difference of experience, and by means of the concreteness and complexity of experience he can condemn the "empty" identity of reason.

In order, however, to understand the full bearing of Kant's criticism of knowledge, and at the same time to find the meeting-point of the opposite currents of thought which alternately prevail in it, it will be necessary to consider the subject a little more closely. The lesson of the *Critique* may be gathered up into two points. In the first place, it is a refutation of the ordinary view of experience as something immediately given for thought and not constituted by it. In the second place, it is a demonstration of the merely phenomenal character of the objects of experience, *i.e.*, the demonstration that the objects of experience, even as determined by science, are not things in themselves. Both these results require to be kept clearly in view if we would understand the movement of thought excited by Kant. On the one hand Kant had to teach that what is ordinarily regarded as real, the world of experience, is transcendently ideal, *i.e.*, is determined as real by *a priori* forms of thought. On the other hand he had to teach that the world so determined is empirically and not transcendentally real, *i.e.*, its reality is merely phenomenal. With the former lesson he met the man of science, and compelled him to renounce his materialistic explanation of the world as a thing which exists in independence of the mind that knows it. The world we know is a world which exists only as it exists *for us*, for the thinking subject; hence the thinking subject, the ego, cannot be taken as an object like other objects, an object the phenomena of which are to be explained like other phenomena by their place in the connexion of experience. Having, however, thus repelled scientific materialism by the proof that the reality of experience is ideal, Kant refuses to proceed to the complete identification of reality with ideality, and meets the claims of the metaphysician with the assertion that the reality of experience is merely phenomenal. Hence he rejects any idealism that would involve the negation of things in themselves beyond phenomena, or the identification of the objects of experience with these things. The reality we know is a reality which exists only for us as conscious subjects, but this, though it is the only reality we can know, is not the absolute reality.

It is, however, to be observed that the nature of this opposition between phenomena and things in themselves seems to change as we advance from the *Analytic*, where the existence of such things is presupposed, to the *Dialectic*, where the grounds of that presupposition are examined. At first the opposition seems to be between what is present in consciousness and what is absolutely beyond consciousness. The matter of experience is regarded as given externally in the affections of the sensible subject,—affections caused by an unknown thing in itself, of which, however, they can tell us nothing. On the other hand the form of experience, the categories and principles of judgment which turn these affections into objects of knowledge, are not pure expressions of the real nature, the pure identity, of the subject in itself, but only products of the identity of the self in relation to the sensibility and its forms of time and space. Hence, on both sides we must regard experience as merely phenomenal, alike in relation to the noumenal object and in relation to the noumenal subject, which lurk behind the veil and send forth into experience on the one side affections which become objects through their determination by the unity of thought, and on the other side an identity of thought which becomes self-conscious in relation to the objects so determined by itself.

Kant, however, having thus answered the question of the possibility of experience by reference to two things in themselves which are out of experience, is obliged to ask himself how the *consciousness* of these two things in themselves, and the criticism of experience in relation to them, is possible. And here, obviously, the opposition can no longer be conceived as an opposition between that which is and that which is not in consciousness. For the things in themselves must be present to consciousness in some fashion in order that they may be contrasted with the phenomena. If, therefore, phenomena are now regarded as unreal, it must be because we have an *idea of reality* to which the reality of experience does not fully correspond. In the *Analytic* Kant had been speaking as if the real consisted in something which is not present to the conscious subject at all, though we, by analysis of his experience, can refer to it as the cause of that which is so present. Now in the *Dialectic* he has to account for the fact that the conscious subject himself is able to transcend his experience, and to contrast the objects of it as phenomenal with things in themselves.

Now it is obvious that such an opposition is possible only so far as the thought, which constitutes experience, is at the same time conscious of itself in opposition to the experience it constitutes. The reason why experience is condemned as phenomenal is, therefore, not because it is that which exists for thought as opposed to that which does not exist for thought, but because it imperfectly corresponds to the determination of thought in itself. In other words, it is condemned as unreal, not because it is ideal, but because it is *imperfectly* ideal. And the absolute reality is represented, not as that which exists without relation to thought, but as that which is identical with the thought for which it is. In the *Dialectic*, therefore, the noumenon is substituted for the thing in itself, and the noumenon is, as Kant tells us, the object as it exists for an intuitive or perceptive understanding, *i.e.*, an understanding which does not synthetically combine the given matter of sense into objects by means of categories, but whose thought is one with the existence of the objects it knows. It is the idea of such a pure identity of knowing and being, as suggested by thought itself, which leads us to regard our actual empirical knowledge as imperfect, and its objects as not, in an absolute sense, *real* objects. The noumena are not, therefore, the unknown causes by whose action and reaction conscious experience is produced; they represent a unity of thought with itself to which it finds experience inadequate. This higher unity of thought with itself is what Kant calls reason, and he identifies it with the faculty of syllogizing. Further, he finds in the three forms of syllogism a guiding thread which brings him to the recognition of three forms in which the pure unity of reason presents itself to us in opposition to the merely *synthetic* unity of experience, a psychological, a cosmological, and a theological form. In each of these cases the empirical process of knowledge is accompanied, guided, and stimulated by an idea which nevertheless it is unable to realize or verify. In psychology we have ever present to us an idea of the identity of the self, which is never realized in our actual self-consciousness, because the self of which we are conscious is manifold in its states and because it stands in relation to an external world. The idea of simple identity is, therefore, something we may set

before us as the goal of an ideal psychology, to which we may approximate in so far as we can trace unity of faculty through all the differences of mental phenomena, but to which we can never attain owing to the nature of the matter with which we deal. Again, in our scientific attempts to explain our external experience, the unity of reason takes the form of an idea of the world as a completed infinite whole, which contains all the objects known to us and all other possible objects; but this cannot be realized in an experience which is conditioned by space and time, and is, therefore, ever incomplete. The idea of totality is, therefore, an *ideal*, which guides and stimulates our scientific progress, without which such a thing as science could not exist, but which at the same time can never be realized by science. Lastly, the unity of reason takes a third form in which identity and totality are combined,—as the idea of a unity in which all differences, even the difference of subject and object, are transcended,—the idea of a unity of all things with each other and with the mind that knows them. This idea also is one which science can neither surrender nor realize. It cannot surrender it without giving up that striving after unity without which science would not exist; and it cannot realize it, for the difference between the world, as it is presented to us in actual experience, and the subjective determination of our thinking consciousness cannot be overcome. We can, indeed, use the idea that the world is an organic whole, determined in relation to an end which consciousness sets for itself, as an *heuristic* principle to guide us in following the connexion of things with each other; but, as we cannot by means of any such idea anticipate what the facts of external experience will be, so we cannot prove that for a mind other than ours the unity of things which we represent in this way might not take a quite different aspect. Indeed we have reason to think it would; for, while we always think of a designing mind as using materials which have an existence and nature independent of the purposes to which they are put, the absolute mind must be conceived as creating the materials themselves by the same act whereby they are determined to an end. We must conceive it, in short, as an intuitive understanding for which end and means, objective and subjective, are one, or, in other words, as an intelligence whose consciousness of itself is or contains the existence of all that is object for it.

This new view of the things in themselves as *noumena* or ideals of reason involves a new attitude of thought towards them different from that dogmatic attitude which is provisionally adopted in the *Analytic*. Accordingly, we now find Kant speaking of them, not as things which exist independently of their being conceived, but as "problematical conceptions" of which we cannot even determine whether they correspond to any objects at all. They are "limitative" notions which have a negative value, in so far as they keep open a vacant space beyond experience, but do not enable us to fill that space with any positive realities. They are like dark lanterns which cast light upon the empirical world, and show what are its boundaries, but leave their own nature in obscurity. All that we can say of the noumenal self or subject is that it corresponds to the unity implied in all knowledge, but whether there is such a self, independent of the process of empirical synthesis and the self-consciousness which accompanies that process, we cannot tell. All that we can say of the noumenal reality of the objective world is that it corresponds to the idea of the objects of experience as a completed whole in themselves apart from the process whereby we know them, but whether there is any such real world independent of the process of experience it is impossible to say. Lastly, all that we can say of God is that He corresponds to the idea of the unity of all things with the mind that knows them,—an ideal which is involved in all knowledge,—but whether the realization of this idea in an intuitive understanding is even possible we have no means of determining, however we may suspect that understanding and sensibility are "branches springing from the same unknown root." The *Criticism of Pure Reason* ends, therefore, in a kind of seesaw between two forms of consciousness—a thinking consciousness, which transcends experience and sets before us an idea of absolute reality, but which cannot attain to any knowledge or even certitude of any object corresponding to this idea, and an empirical consciousness, which gives us true knowledge of its objects, but whose objects are determined as merely phenomenal and not absolutely real.

The equipoise thus maintained between the empirical and the intelligible world is, however, in the *Critique of Practical Reason*, overbalanced in favour of the latter. What the theoretical reason could not do "in that it was weak through the flesh," through its dependence on the very empirical consciousness which it sought to transcend, is possible to the practical reason, because it is primarily determined by itself. In our moral consciousness we find ourselves under a law which calls upon us to *act* as beings who are absolutely self-determined or free, and which, therefore, assures us that our intelligible self is our real self, and conclusively determines our empirical self in contrast with it as phenomenal. Thus the moral law gives reality to the intelligible world; or, as Kant expresses it, "the idea of an intelligible world is a point of view beyond the phenomenal which the reason sees itself compelled to take up, in order to think of itself as practical." In other words, the moral law presupposes freedom or determination in the rational being as such, and makes him regard himself, not merely as a link in the chain of conditioned existences in time and space, but as the original source of his own life. The blank space beyond the phenomenal thus begins to be filled up by the idea of a free causality which again postulates a world adequate and conformable to itself. And the man who, as an empiric individuality, is obliged to regard himself merely as an individual being determined by other individual beings and things is authorized as a moral being to treat this apparent necessity as having its reality in freedom, and to look upon himself as the denizen of a spiritual world where nothing is determined for him from without which is not simply the expression of his own self-determination from within. "Thus we have found, what Aristotle could not find, a fixed point on which reason can set its lever, not in any present or future world, but in its own inner idea of freedom,—a point fixed for it by the immovable moral law, as a secure basis from which it can move the human will, even against the opposition of all the powers of nature."[1] Starting from this idea of freedom, therefore, Kant proceeds to reconstruct for *faith* the unseen wor[ld] which in the *Critique of Pure Reason* he had denied as object of *knowledge*. Nor is he content to leave t[he] two worlds in sharp antithesis to each other, but even [in] the *Critique of Practical Reason*, and still more in t[he] *Critique of Judgment*, he brings them into relation to ea[ch] other, and so gives to theoretical reason a kind [of] authority to use for the explanation of the phenome[nal] world those ideas which of itself it might be inclined [to] regard as illusive.

In all this, however, it is difficult to avoid seeing [a] partial retractation of Kant's first views as to the irreconcila[ble] opposition of the phenomenal and the noumenal. For, [in] the first place, the moral imperative is addressed to a s[...]

[1] Kant, i. 638 (Rosenkranz's edition).

which is at one and the same time regarded in both characters, and which is called upon to subsume under the moral law acts which otherwise derive their character and meaning from the relations of the phenomenal world. That the particular nature of men as phenomenal individuals can be the means of realizing the universal law of reason is implied in all Kant's statements of the latter, and particularly in his conception of men as constituting together a "kingdom of ends"; for it is difficult to conceive this kingdom otherwise than as an organic unity of society, in which each individual, by reason of his special tendencies and capacities, has a definite office to fulfil in realizing the universal principle that binds all the members of the kingdom to each other. The *summum bonum*, again, is said to consist in the union of happiness with goodness, *i.e.*, of the empirical conditions of man's individual life as a sensible subject with the pure self-determination of the intelligible self; and God is postulated as a *Deus ex machina* to bind together these two unrelated elements,—a conception which shows the difficulty into which Kant has brought himself by defining them as unrelated. Still more obvious is the effort of Kant to get beyond the dualism of his first view of things in the *Critique of Judgment*. For in that work he maintains that the consciousness of the beautiful and the sublime is or involves a harmony of the understanding or the reason with sense; and, what is still more important, he points out that the idea of organic unity, without which we cannot explain the phenomena of life, contains in it a possibility of the reconciliation of freedom and necessity, of the intelligible and the phenomenal. This idea, he argues, we are authorized by our moral consciousness to apply to the whole course of the things in the phenomenal world, and so to regard it as a process to realize the moral ideal. No doubt he again partially retracts this view when he declares that we must treat the idea of final causality as merely a *subjective* principle of judgment, which, even in the case of living beings, is to be regarded only as necessary for us as finite intelligences. But such saving clauses, in which Kant recurs to the dualism with which he started, cannot hide from us how near he has come to the renunciation of it.

When we regard Kant in this way as asserting from one point of view an absolute limit which from another point of view he permits us to transcend, it becomes obvious that his philosophy is in an unstable equilibrium, which cannot but be disturbed by any one who attempts to develop or even to restate his ideas. Hence we need not wonder that those who take in earnest his denunciations of any attempt to transcend experience generally,—like Professor Huxley,—reject as worthless all Kant's later work; and that, on the other side, those who take in earnest his ideas of freedom, of organic unity, of an intuitive understanding, and of a *summum bonum* in which freedom and necessity meet together, are compelled to break through the arbitrary line which he drew between knowledge and belief. In favour of the former course it is easy in many places to appeal to the letter of Kant. In favour of the latter it need only be pointed out that, in Kant's view, all experience rests upon, or is in its development guided by, those ideas which yet he will not permit us to treat as sources of knowledge. Hence the principles of the *Critique* cannot legitimately be used against metaphysic, except by those who are prepared to admit the ideas of reason, up to the point to which he admits them, as ideas that limit and direct our experience,—while rejecting all use of them to cast light upon that which is beyond experience. In other words, they must maintain the possibility of a purely negative knowledge, of the knowledge of a limit by one who yet cannot go beyond it. They must show how we can have an ideal of knowledge which enables us to criticize experience without enabling us to transform it; they must show how ideas of the supersensible can so far be present to our thought as to make visible the boundaries of the prison of sense in which we are confined, without in any way enabling us to escape from it.

Is this possible? We may gather up the Kantian antithesis in the assertion that experience is the imperfect realization of an ideal of knowledge, derived from reason, with materials, derived from sense and understanding, the nature of which is such that they can never be brought into correspondence with the ideal. But this ideal, in all its three forms, as we have seen, is simply the idea of a pure unity or identity in which all differences are lost or dissolved—whether they be the differences of the inner or of the outer life, or finally the difference of inner and outer, subjective and objective, from each other. Kant's view therefore is, in effect, this, that thought carries with it the consciousness of an identity or unity, to which our actual experience in none of its forms fully corresponds. On the other hand, Kant does not hesitate equally to condemn the identity of thought as "empty" and subjective, because it does not contain in itself nor can evolve from itself the complex matter of experience. But this alternate condemnation of experience as unreal from the point of view of the ideas, and of the ideas as unreal from the point of view of experience, seems to show that *both* are unreal, as being abstract elements, which have no value save in their relation to each other, and which lose all their meaning when separated from the unity to which they belong. According to this view, ideas and experience, noumena and phenomena, if they are opposed, are also necessarily related to each other. If our empirical consciousness of the world of objects in space and time, as determined by the categories, does not correspond to the unity or identity of thought which is our ideal of knowledge, yet that idea of unity or identity is set up by thought in *relation* to experience, and cannot, therefore, be essentially irreconcilable with it. The two terms may be opposed, but their opposition cannot be absolute, seeing that they are in essential relation to each other. It is a great logical error not to discern that a negative relation is still a relation, *i.e.*, that it has a positive unity beyond it. This positive unity may not, indeed, be consciously present to us in our immediate apprehension of the relation in question, but it is necessarily implied in it. Now it is just because, in his separation of noumena and phenomena, Kant omits to note their essential relativity that he is forced to regard the former as a set of abstract identities of which nothing can be known, and the latter as the imperfect products of a synthesis which can never be completed or brought to a true unity. Yet the value of his whole treatment of the ideas of reason in relation to our intellectual and moral experience arises from the fact that in practice he does not hold to this abstract separation of the two elements. Ideas absolutely incommensurable with experience could neither stimulate nor guide our empirical synthesis; they could not even be brought into any connexion with it. When, therefore, Kant brings them into this connexion, he necessarily alters their meaning. Hence the pure abstract identity which excludes all difference is changed, in its application, into the idea of an organic unity, of which the highest type is found in self-consciousness, with its transparent difference of the subjective and objective self. It would be absurd and meaningless to say that science seeks to reduce experience to an abstract identity, in which there is no difference, unless for this were tacitly substituted what is really an entirely different proposition, that science seeks to find in the infinitely diversified world of space and time that unity in difference of which self-consciousness has in itself the pattern. It is in reference to the former kind

of identity—the abstract oneness of formal logic—that Kant proves that it is impossible for experience to be made adequate to ideas. But it is only of the latter kind of identity—the oneness of self-consciousness—that it can be said that it furnishes a guiding principle to scientific investigation or an ideal of knowledge. The same confusion is still more evident in Kant's account of our moral experience, in dealing with which he directly attempts to get synthetic propositions out of the pure identity of reason, in other words, to draw definite moral laws out of the logical principle of non-contradiction. Whatever success he attains is gained by substituting for the formal principle of *self-consistency* the positive idea of *consistency with the self*, and again by conceiving this self as a concrete individual, the member of a society, and so standing in essential relation to other selves. The pure abstraction from all the external results of action and from all motives of desire, which at the beginning of the *Metaphysic of Ethics* Kant declares to be essential to morality, is modified and indeed transformed, as we go on, by the admissions that other rational beings are *not* external to us in any sense that excludes their good from being an end of our endeavour, and that the desires are *not* irrational and immoral except in so far as they are directed to the pleasures of the sensuous individual (which in a conscious being they never entirely are). Both in the speculative and in the practical sphere, therefore, the absolute opposition of the ideal or noumenal to the empirical disappears, as soon as Kant attempts to apply it. For in both the abstract identity of formal logic, which is really the meaning of the noumenon as absolutely opposed to and incommensurable with experience, gives way to the unity of self-consciousness,—a unity which is so far from being *absolutely* opposed to the difference of the empirical consciousness that it necessarily implies it. For self-consciousness presupposes the consciousness of objects; though it is opposed to that consciousness, it is essentially correlated with it, and therefore its opposition cannot be regarded as absolute, or incapable of being transcended.

These considerations may throw some light on the relation of the *Analytic* and *Dialectic* of Kant, and on the nature of the opposition of noumenon and phenomenon as it is presented in the latter. In the deduction of the categories, Kant pointed out the essential relation of the objective world of experience to what he called the "transcendental unity of apperception"; *i.e.*, he pointed out that the unity of consciousness is implied in all its objects. This unity, he further showed, must be conceived as "capable of self-consciousness"; but it actually becomes conscious of self only in relation, though also in opposition, to the other objects determined by it. Now it is this consciousness of itself in opposition to other objects which is the source of Kant's "ideas of reason," of the dissatisfaction of the mind with its empirical knowledge, even in its scientific form, and of the demand for a higher kind of knowledge to which experience is not adequate. That a standard is set up for experience by which it is condemned is simply a result of the further development of that unity which is implied in experience—a result of the progress of thought from consciousness to self-consciousness, and of the contrast between the former and the latter. The problem with which Kant's *Dialectic* attempts to deal, and which it treats as insoluble, is, therefore, simply the problem of *raising consciousness to the form of self-consciousness*; in other words, of attaining to a knowledge of the world of experience as not merely a "synthetic," and therefore imperfect, unity of things external to each other, but as an organic unity of transparent differences, a self-differentiating, self-integrating unity, such as seems to be presented to us in pure self-consciousness. Nor can this problem be regarded as insoluble; for the unity of self-consciousness is identical with the unity of consciousness; it is only that unity become self-conscious. Hence the point of view at which consciousness and self-consciousness seem to be absolutely opposed to each other,—the highest point of view which Kant *distinctly* reaches,—can be regarded only as a stage of transition from the point at which their relative difference and opposition is not yet developed to the point at which they are seen to be the factors or elements of a still higher unity.

The later philosophy of Germany, from Kant to Hegel, is little more than the development of the idea just stated in its twofold aspect. In the first place, it is an attempt to show what is involved in the idea of thought or self-consciousness as in itself an organic whole, a many-in-one, a unity which expresses itself in difference, yet so that the difference remains transparent, and therefore is immediately recognized as expression of the unity. In the second place, it is an attempt to bridge over the difference between thought or self-consciousness and the external world of experience, and to show that this opposition also is subordinated to a higher unity. Or, to put it more directly, the idealistic philosophy of Germany seeks, on the one hand, to develop a logic or metaphysic which bases itself, not, like formal logic, on the idea of bare identity, but on the idea of self-consciousness; and, on the other hand, to show, in a philosophy of nature and spirit, how, by means of this logic, the opposition of thought to its object, or of the *a priori* to the *a posteriori* in knowledge, may be transcended. In the third and fourth sections of this article something more will be said of the manner in which this task was fulfilled. Here only a few words are necessary to sum up the results reached, and to give more distinctness to the new ideal of knowledge which those results suggest. We have seen that Kant's critical attitude involved two things,—on the one hand, the assertion that the existence we know is necessarily existence for thought, and, on the other hand, the denial that that which exists for our thought is absolute reality, a denial which again involves the presence to our thought of an ideal of knowledge, by which our actual knowledge is condemned. This ideal, however, was falsely conceived by Kant as an identity without any difference, and, in this sense, he does not hesitate to apply it even to self-consciousness itself. For, in a remarkable passage,[1] he attempts to prove that the consciousness of self is not a knowledge of the self, by a simple reference to the duality of the self knowing and the self known, arguing that the ego "stands in its own way," just because it exists only *for itself*, *i.e.*, because in knowing itself it presupposes itself. Kant evidently thinks that to know the real self it would be necessary to apprehend it in simple identity as purely an object without reference to a subject, or purely a subject without reference to an object. Yet to this it seems sufficient to answer that such an object or subject would lose its character as object or subject and become equivalent to mere being in general, and that, as such being is a mere abstraction, to know it cannot be the ideal of knowledge. If therefore there be a unity or identity of thought which is not realized in experience, and in reference to which we can regard experience as an imperfect form of knowledge, it cannot be found in this abstract identity of being. In truth, as we have seen, it is found in that very idea of self-consciousness which Kant is criticizing. Just because we are self-conscious, and therefore oppose the unity of the conscious self to the manifoldness of the world in space and time, do we seek *in* the world of space and time for a transparent unity which we cannot at first find there. But, when this is seen, we find in Kant himself the partial solution of the difficulty.

[1] *Kritik*, p. 279 (Rosenkranz's edition), *cf.* Hegel, v. p. 258.

Self-consciousness presupposes consciousness; for, while the apprehension of objects in consciousness is possible only in relation to the unity of the self, yet it is only in relation to and distinction from these objects that we are conscious of that unity. Hence the two opposites, self and not-self, are bound together, and presuppose a unity which reveals itself in their opposition, and which, when made explicit, must reconcile them. If, therefore, self-consciousness, in its first opposition to consciousness, gives rise to an ideal of knowledge to which our empirical knowledge of objects is inadequate, this arises from the fact that not only empirical knowledge but also the ideal to which it is opposed is imperfect, or that they both point to a unity which is manifested in their difference, and which is capable of containing and resolving it. In other words, the opposition of science to its ideal, which Kant has stated in his *Antinomies*, is not an absolute opposition, but one the origin and end of which can be seen.

This opposition reaches its highest point in the contrast between the transparent unity of self-consciousness, in which the difference of knower and known is evanescent, and the essential manifoldness and self-externality of the world in space, in which the differences seem to be insoluble. We must, indeed, think of self-consciousness as having life in itself and therefore as differentiating itself from itself; but this differentiation is held within the limit of its unity, it is a separation of movements which are separated only as they are united. On the other hand, the world in space presents itself as the sphere of external determination, in which things are primarily disunited and act only as they are acted on from without, and in which this external influence never goes so far as to destroy their reciprocal externality. In this sense it is that the opposition of mind and matter was taken by Descartes, and it is a survival of the same mode of thought that leads many even now to draw absolute lines of division between *a priori* and *a posteriori*, between ideas and facts, between spiritual and natural. Kant and Fichte give a new aspect to the difficulty by showing that the difficulty is one of reconciling consciousness and self-consciousness, and that in consciousness there is already present the unity which is manifested in self-consciousness, as, on the other hand, it is only through consciousness and in opposition to it that self-consciousness is possible. And Fichte made a further step when he attempted to show that the categories and the forms of perception, time and space, which Kant had taken as inexplicable facts, are implied in this contrast of consciousness and self-consciousness. The error that clings to Fichte's speculations is, however, that he treats consciousness merely as a necessary illusion which exists simply with a view to self-consciousness, and hence is led to regard self-consciousness itself—because it is essentially related to this necessary illusion—as a schema or image of an unknowable absolute. In fact, in the end Fichte falls back upon the abstract identity in which Kant had found his noumenon, and so ends his philosophy with mysticism. Even Schelling, though he saw that the absolute unity must be one that transcends the difference of self and not-self, did not finally escape the tendency to merge all difference in absolute oneness. On the other hand, it was the endeavour of Hegel to proceed in the opposite way,—not to lose self-consciousness or subjectivity in a mere unity of substance, but rather to show that the absolute substance can be truly defined only as a self-conscious subject. And just because he did this he was prepared to take a further step, and to regard the external world, not as Fichte regarded it, as merely the opposite of spirit, nor as Schelling regarded it, as merely the repetition and co-equal of spirit, but rather as its necessary manifestation or as that in and through which alone it can realize itself. His doctrine therefore might be summed up in two propositions,—first, that the absolute substance is spiritual or self-conscious, and, secondly, that the absolute subject or spirit can be conceived as realizing itself only through that very world of externality which at first appears as its opposite. In both respects Hegel's philosophy reverses the *via negativa* of mysticism, and teaches that it is only through the exhaustion of difference that the unity of science, of which the mind contains in itself the certitude, is to be realized. For mind or spirit, viewed in itself, is conceived as a self-differentiating unity, a unity which exists only through opposition of itself to itself. And it is but a necessary result of such a conception that spirit can fully realize its unity only through a world which in the first instance must present itself as the extreme opposite of spirit. Hence the process of thought in itself, which is exhibited in the logic, ends in the opposition to thought of a world which is its negative counterpart. And the "absolute spirit" of Hegel is thus, not pure self-consciousness, but that more concrete unity of self-consciousness with itself which it attains through and by means of this world.

The effect of this view upon the relation of metaphysic to science, which we are at present considering, is noticeable. It does not, as is often supposed, supersede science by an *a priori* construction of the universe, nor does it leave the results of science unchanged and simply provide for it a deeper foundation. The latter was the point at which Kant and Fichte stopped; for, while they showed the relativity of experience to the principle of self-consciousness, they conceived that the function of metaphysic is completed in showing the phenomenal character of the objects of science, and in reserving a free space beyond the phenomenal world for "God, freedom, and immortality." Schelling, on the other hand, as he did not adopt this merely negative view of the relation of spirit to nature or of *a priori* to empirical truth, was obliged to reinterpret the latter by the former. As, however, he did not recognize any distinctions which were not merely quantitative, he was led to apply the same easy key to every lock, and to think that he had explained all the different forms of existence, organic and inorganic, when he had merely pointed out a certain analogy between them. The metaphysic of Hegel, whatever may be said of the actual philosophy of nature produced by its author, contains no necessity for any such arbitrary procedure. In his *Logic*, indeed, he attempts to give us *in abstracto* the movement of thought in itself, from its simplest determination of being as qualitative or quantitative, through the reflective categories of substance and cause, up to its full consciousness of itself in its organic unity.[1] And in so doing he of course gives us an account of the various categories which science uses in the interpretation of nature. He further attempts to show that the highest categories of science are in themselves imperfect and self-contradictory,—in other words, that they mark a stage of thought which falls short of that unity of being and knowing after which science is striving, and which is the presupposition as well as the goal of all intelligence. But, while he does this, he clearly acknowledges two things,—on the one hand that nature is essentially different from pure self-consciousness, and that therefore logic can never by direct evolution of its categories anticipate the investigations of science, and, in the second place, that the final interpretation of nature through the highest categories presupposes its interpretation by the lower categories, and cannot be directly achieved without it. In other words,

1 This subject—the progress of thought from lower to higher categories and methods—will be more fully discussed in the third section.

science must first determine the laws of nature according to the principles of causality and reciprocity, ere philosophy can be in a position to discover the ultimate meaning of nature by the aid of higher principles. "The philosophy of nature," says Hegel, "takes up the material which physical science by direct dealing with experience has prepared for it at the point to which science has brought it, and again transforms this formed material without going back to experience to verify it. Science must, therefore, work into the hands of philosophy, in order that philosophy in its turn may translate the lower universality of the understanding realized by science into the higher universality of reason, and may show how in the light of this higher universality the intelligible world takes the aspect of a whole which has its necessity in itself. The philosophic way of looking at things is not a capricious attempt, once in a way for a change, to walk upon one's head after one has got tired of walking upon one's feet, or to transform one's work-a-day face by painting it over; but, just because the scientific manner of knowing does not satisfy the whole demand of intelligence, philosophy must supplement it by another manner of knowing."[1]

The result then may be briefly expressed thus. Kant and his successors showed the relativity of the object of knowledge to the knowing mind. He thus pointed out that the ordinary consciousness, and even science, are abstract and imperfect modes of knowing, in so far as in their determination of objects they take no account of a factor which is always present, to wit, the knowing subject. For *their* purposes, indeed, this abstraction is justifiable and necessary, for by it they are enabled within their prescribed limits to give a more complete view of these objects in their relation to each other than if the attempt had been made to regard them also in relation to the knowing subject. At the same time the scientific result so arrived at is imperfect and incomplete, and it has to be reconsidered in the light of a philosophy which retracts this provisional abstraction. For it must be remembered that the fact that science looks at things only in their relation to each other, and not to the knowing mind, narrows the points of view or categories under which it is able to regard them, or, in other words, limits the questions which the mind is able to put to nature. Just because science does not treat its objects as essentially related to the mind, it is unable to rise to what Hegel calls the point of view of reason, or of the "notion"; *i.e.*, it is obliged to treat objects and their relations merely under a set of categories, the highest of which are those of causality and reciprocity, and it is incapable of attaining to the conception of their organic unity. In other words, it is able to reach only a synthetic unity of given differences, and it cannot discover a principle of unity out of which the differences spring and to which they return. Now philosophy goes beyond science just because, along with the idea of the relativity of things to the mind, it brings in the conception of such a unity. Its highest aim is, therefore, not merely, as Kant still held, to secure a place for the supersensible beyond the region of experience, but to reinterpret experience, in the light of a unity which is presupposed in it, but which cannot be made conscious or explicit until the relation of experience to the thinking self is seen,—the unity of all things with each other and with the mind that knows them.

2. *Relation of Metaphysic to Psychology.*—It has already been shown that the doctrine that the thinking subject is presupposed in all objects of knowledge—or, in other words, that existence means existence for a conscious self—is not to be taken in a psychological sense. The idea that all science is based on psychology, and that, therefore, metaphysic and psychology are identical, cannot be retained by any one who has entered into the full meaning of the Kantian criticism. It is, however, so natural a misinterpretation of it, and it is so much favoured by the letter of the very book in which it was first decisively refuted, that it will be useful to point out more directly the fallacy involved in it, especially as this will place us in a better position to determine the true relation of the two parts of philosophy thus confounded.

The misunderstanding first took a definite form in the introduction to Locke's *Essay*, in which he proposes to provide against any undue application of the intellectual powers of man to problems which are too high for them, by first examining and measuring the powers themselves. Stated in this way, it is obvious that the proposal involves an absurdity; for we have nothing to measure with, except the very powers that are to be measured. To see round our knowledge and find its boundary, we must stand outside of it, and where is such a standing ground to be found? We cannot by knowing prescribe limits to knowledge, or, if we seem to be able to do so, it can only be because we compare our actual knowledge with some idea of knowledge which we presuppose. In this way the ancient sceptics—and modern writers like Sir W. Hamilton and Mr Spencer who have followed them—turned the duality involved in the idea of knowledge against its unity, and argued that, because we cannot know the object except as different from and related to the subject, we cannot know it as it is in itself. Obviously in this argument it is involved that in true or absolute knowledge the object must not be distinguished at all from the subject,—to which the easy answer is that *without* such distinction knowledge would be impossible. The sceptic argument, therefore, lands us in the unhappy case pictured in the German proverb: "If water chokes us, what shall we drink?" The object cannot be known if it *is* distinguished from the subject, and it cannot be known if it is *not* distinguished from the subject. Obviously the one objection is as good as the other, and both combined only show that the idea of knowledge involves distinction as well as unity, and unity as well as distinction. The sceptic insists on one of these characteristics to the exclusion of the other, and condemns our actual knowledge because it contains both. In Kant there is undoubtedly some trace of the same fallacy, in so far as the idea by contrast with which he condemns the objects of experience as phenomenal is the idea of an abstract identity without any difference; but we have seen that with him this abstract identity is on the point of passing into an altogether different idea—the idea of self-consciousness as the type of knowledge.

It appears, then, that the idea of measuring our powers before we employ them rests on a paralogism; for what is really meant is that we abstract one of the elements of the idea of knowledge, and then condemn knowledge for having other elements in it. It is possible to criticize and condemn special conceptions as not conforming to our idea of knowledge; but it is not possible to criticize the idea of knowledge itself; all we can do is to explain it. It is possible to see the limited and hypothetical character of certain of our ideas or explanations of things, because we are conscious that in developing them we have left out of account certain elements necessary to the whole truth; but this criticism itself implies, as the standard to which we appeal, a consciousness of truth and reality, a consciousness which we cannot further criticize. Here, therefore, we come upon what must seem to all who think it admissible to question the very possibility of knowledge an inevitable reasoning in a circle. We can answer objections only by means of the very idea which they dispute. But the

[1] Hegel, vii. p. 18.

answer is nevertheless a good one; for the objector also stands within the very circle which he seeks to break, and has no means of breaking it except itself. As soon as he speaks, he can be refuted by his own words; for his doubts also presuppose that unity of the intelligence and the intelligible world which he pretends to deny.

The error, however, cannot be fully corrected until we consider what gives it plausibility. The confusion of the metaphysical with the psychological problem is due to the fact that the being who is the subject of knowledge, for whom all exists that does exist, appears to be one, and only one, of the many objects of knowledge. When we say that existence means only an existence for a thinking self, we seem to be identifying the whole world with the feelings and ideas of men, *i.e.*, with certain phenomena that belong to the life of a class of beings which only forms a part of that world,—phenomena, moreover, that are not exactly the same in any two of that class of beings. If we are to escape this difficulty it is obvious that we must be able to separate the conscious self or subject, as it is implied in all knowledge, from the nature of man as a being who "though formally self-conscious" is yet "part of this partial world," *i.e.*, one of the objects which we know along with and in distinction from other objects, and in whom "the self-consciousness which is in itself complete, and which in its completeness includes the world as its object," is only progressively realized.[1] Metaphysic has to deal with conditions of the knowable, and hence with self-consciousness as that unity which is implied in all that is and is known. Psychology has to inquire how this self-consciousness is realized or developed in man, in whom the consciousness of self grows with the consciousness of a world in space and time, of which he individually is only a part, and to parts of which only he stands in immediate relation. In considering the former question we are considering the sphere within which all knowledge and all objects of knowledge are contained. In considering the latter we are selecting one particular object or class of objects within this sphere,—although no doubt it must make a great difference in our treatment of this object that we have to consider it as existing not only for us but for itself. If nature "becomes self-conscious in man," it is impossible to treat man *merely* as one among the other objects of nature. But it is not less true that he *is* one of those objects, and, in this point of view, the department of science and philosophy that deals with his life is as distinct from metaphysic—which deals with the conditions of all knowing and being—as is astronomy or physics. In both cases we have before us objects which we may consider in themselves apart from their relations to the conscious subject, and in both cases we must take cognizance of these relations if we would have a complete and final view of those objects. It is possible to have a purely objective anthropology or psychology—which abstracts from the relation of man to the mind that knows him—just as it is possible to have a purely objective science of nature. Such a natural science of man, however, will necessarily abstract at the same time from the fact that in man is manifested that universal principle in relation to which all things are and are known. In other words, it will omit that distinctive characteristic of man's being in virtue of which he is a subject of knowledge and a moral agent. Hence the abstraction in this case is more likely to lead to positive error, more likely to produce not only an imperfect but a distorted view of the object. Inorganic nature, if we take it *in itself*, is not untruly viewed, under the categories of causality and reciprocity, as a collection of objects externally determined by each other; the error lies only in taking it as if it could exist in itself. Even organic beings do not suffer much injustice in being brought under such categories; for, though, as living and still more as sensitive beings, they involve in themselves and in their relation to the world a kind of unity of differences to which the categories of external relation imperfectly correspond, yet they are not such unities *for themselves*, but only *for us*. In other words, the principle through which they are and are known is still external to them. Hence also they are determined by outward influences, though these influences act rather as stimuli to what we may call the self-determined movement of their own life than as mechanical or chemical forces which change it. But in man, in so far as he is self-conscious,—and it is self-consciousness that makes him man,—the unity through which all things are and are known is manifested; and therefore he is emancipated, or at least is continually emancipating himself, from the law of external influence. Nature and necessity exist for him as that from which his life starts, in relation to which he becomes conscious of himself, against which he has to assert himself, and in the complete overcoming of which lies the end of all his endeavour. Nature is the negative rather than the positive starting-point of his existence, the presupposition against which he reacts rather than that on which he proceeds; and, therefore, to treat him simply as a natural being is even more inaccurate and misleading than to forget or deny his relation to nature altogether. A true psychology must, however, avoid both errors: it must conceive man as at once spiritual and natural; it must find a reconciliation of freedom and necessity. It must face all the difficulties involved in the conception of the absolute principle of self-consciousness,—through which all things are and are known,—as manifesting itself in the life of a being like man, who "comes to himself" only by a long process of development out of the unconsciousness of a merely animal existence.

This problem first presented itself in a distinct form in the discussions of the Socratic school as to the nature of knowledge, discussions which turn mainly upon the relation of the conscious to the unconscious element in thought. Socrates, by his method more than by any direct statement, drew attention to the fact that all particular judgments in morals involve or presuppose a universal principle. At the same time he pointed out that, so far from this universal principle being known to those who are continually making such judgments, they are not even conscious of its existence. They constantly use general terms whose meaning they have never even thought of defining. The beginning of a rational life for them must therefore lie in their becoming conscious of their ignorance, *i.e.*, conscious that they have been all along judging, and therefore acting, on untested and even unknown assumptions. They must bring the unconscious universal to the light of day and define it, for until that is done it is impossible to live a moral, that is, a rational life. "Virtue is knowledge," *i.e.*, it is acting, not according to opinions, or particular judgments,—whose universal is unknown, and which therefore may be regarded as expressing merely the impulses or habits of the individual,—but in view of a universal principle determined by reason.

The onesidedness of this view—which absolutely condemns as vice all virtue that is not based on conscious principle—was partly corrected by another part of the doctrine of Socrates, who taught that knowledge is something that must be evolved from within the mind, and not merely communicated to it from without. For this implies that the moral principle may be present in men's minds, and may rule their thoughts and actions, long before they become directly conscious of it. They *are* rational although they have never thought about reason, and they

[1] Hume, vol. i. p. 131 (Green's edition).

do not wait for scientific ethics to judge and act morally, any more than they wait for logic to reason correctly. It is this line of thought which is universalized and mythically expressed by Plato in his doctrine of "reminiscence." According to this myth, we were conscious of ideas or universals in our pre-natal state; we forgot them in the shock of birth into this mortal life; but in feeling or sharing the rapture of the poet or the lover we recall them as identified or confused with individual objects which "are like them, or partake in them." The same explanation is given of the practical skill of the general and the statesman, and even of the "right opinion" which guides the ordinary good man. Such opinion is neither knowledge nor ignorance: not knowledge, for general principles or ideas are not in it present to the mind *as* ideas, and therefore the particular cannot be distinctly subsumed under them; yet not ignorance, for the ideas are after all present, though wrapped up in the particulars or confused with them. Nay, in the *Theætetus*, Plato endeavours to show that the pure particular without the universal, sensations without ideas, cannot enter into our consciousness at all, and that therefore the lowest point to which a conscious being can descend is "opinion," in which particular and universal, sensible and intelligible, are mingled together. In other words, no conscious being can apprehend the particular except through the universal, though that universal may be present only *in* consciousness and not *to* it. The task of philosophy is therefore only to make men "recollect themselves," *i.e.*, to make *self-conscious* that universality of thought in which all rational beings "partake," or which, in the language of later philosophy, constitutes reason. The imperfection of Plato's view lay, however, in this, that, while he clearly recognized that the condition of all consciousness of the particular is the universal, he did not see with equal clearness that the universal has a meaning only in relation to the particular. And this tendency to separate universal from particular is naturally accompanied by a tendency to set the subjective against the objective, and to regard the world, not as the manifestation of reason, but as a dualistic world, in which reason is chained to a lower principle—a world which can at best only give a hint or suggestion to the mind to enable it to recollect itself and recover for itself its own treasures. Thus the false method of introspection, the "high *priori* road" of mysticism, was at least opened up by Plato, if he did not altogether forsake the narrower and harder way to the spiritual world through nature and experience.

The great step in advance taken by Aristotle was due to his seeing the danger of this tendency. Those, however, who have maintained that Aristotle is the great *a posteriori* philosopher,—as Plato is the great *a priori* philosopher,—have entirely mistaken the bearing of Aristotle's criticism of the Platonic theory. As strongly as Plato does Aristotle maintain that reason is δυνάμει πάντα τὰ νοητά, and that, therefore, the apprehension of truth *by* the mind is not a mere external communication of it *to* the mind, but rather is the mind coming to a consciousness of itself. As firmly as Plato does he declare that truth in its highest form is self-evidencing, *i.e.*, that the principles of science, the laws of nature, when once they have been discovered, are seen to be true by their own light. His statements to this effect have been neglected or explained away, because they were supposed to be inconsistent with his still more frequently reiterated assertions that it is only from experience and by induction that the truth of things can be discovered. Writers of a later day,—who came to Aristotle with an idea of a fixed opposition between *a priori* and *a posteriori*, and who held that the only possible alternatives were *either* to divide knowledge between the two *or* to explain away one of them,—could not comprehend that Aristotle might be in earnest *both* in asserting that knowledge is derived from experience *and* in asserting that it is an apprehension by reason of that which is identical with itself and needs no extraneous evidence. But Aristotle started with no such fixed opposition. On the contrary, any one who reads the last chapter of the *Posterior Analytics* will see that he had no difficulty in maintaining that knowledge begins in the apprehension of τὸ καθ' ἕκαστον in sense perception, and that it proceeds from many perceptions to experience, and from many experiences to science; while at the same time he declared that the principles of science have their evidence in themselves. And the meaning of this declaration is shown in the *De Anima*, where we find him speaking of knowledge as the realization in the "passive reason" of man of an "active reason" which is eternal and unchangeable, and which in the consciousness of itself includes the knowledge of all things. Of this realization, indeed, there is in man only the potentiality or capacity, but just because this is a pure or universal capacity, because, as Aristotle puts it, it has no quality or determination of its own to stand between it and its objects, it is a capacity in which the absolute reason can realize itself, a capacity of knowing all things. Here we have Plato's myth of reminiscence freed from the metaphor of memory, and reduced to scientific terms; for that myth simply meant that the evolution of knowledge is the development of the mind to the consciousness of itself, and of all that is potentially in it. Only, by the combination of this doctrine with the idea of the necessity of induction, Aristotle at the same time guards against the purely subjective interpretation to which in Plato it was liable. For the process by which the mind "comes to itself" is conceived as a process by which at the same time it rises from the particular to the universal, from the γνώριμα ἡμῖν to the γνώριμα ἁπλῶς, from the bare apprehension of the facts of experience to the knowledge of them through their principles or laws.

Yet Aristotle was as little able as Plato to work out fully a theory of the relation between the universal and the individual reason; and the cause of this failure was in both cases substantially the same. In Plato's philosophy, the ideal tended to divorce itself from the phenomenal world in such wise that the latter was regarded only as suggesting or partaking in the former, but not as entirely explicable by it. It was not merely that, to the mind of the individual in its progress, the veil was only gradually lifted from the rationality of the world, but that in the world there was an irrational element from which the mind could save itself only by flight into the region of abstraction. And, though Aristotle by his doctrine of the essential relation of ideas to experience, or of the development of the mind to the acquisition of knowledge of the world, seemed to be on the way to correct this error, yet he too shrinks from regarding the phenomenal world as in itself intelligible. To him also an irrational matter mingles with things, and is in them a source of contingency and imperfection. Chance is not merely the reflexion upon the world of our imperfect knowledge, but a fact of experience, and there is therefore a region in which our best science cannot rise above generality to universality. In this way there remains for Aristotle an absolute *a posteriori*, a reality which cannot be understood, and which we can scarcely conceive as existing at all for the divine intelligence. At this point the Aristotelian philosophy appears to stand between two alternatives, either that, in the sense of pantheism, the finite world and its contingency is an illusion, or that it is contingent only for the growing intelligence of man, which fully understands neither itself nor the world which is its object. Aristotle, however, does not choose either horn of

the dilemma, and leaves us therefore with an unresolved dualism between thought and its object; and this again necessarily involves a dualism between the active reason, which, as he asserts, realizes itself in man, and the passive reason which constitutes his nature as a finite being.

In the Middle Ages the Platonic and Aristotelian idea that the apprehension of objective truth is one with the evolution of the mind to self-consciousness seemed to be entirely lost. Knowledge of the finite world was regarded as indifferent, and knowledge of the infinite was conceived to be something given on authority, and in reference to which the mind was confined to an attitude of passive reception or implicit faith. No greater slavery of the spirit can be conceived than that in which even the truths of religion and morality—the truths that regard the inmost life of the spirit itself—were taken as a lesson to be learned by rote from the lips of a teacher. Yet the consciousness that such truth, if it was to be received by the mind, still more if it was to transform the mind, could not be entirely foreign to it, found a voice in the scholastic philosophy. And the compromise or truce between faith and reason expressed in the saying of Anselm *credo ut intelligam*,—according to which reason was to confine itself to the analysis and demonstration of the data received in implicit faith from the church,—prepared the way for the recognition that the two are not essentially at variance. The mind that proceeds from *veneratio* to *delectatio*, from awe and submission to the doctrine to enjoyment and appreciation of it, must already in its awe and submission have the beginnings of an intelligent appreciation. Anselm's saying might be understood simply as meaning that we must have spiritual experience ere we can understand the things of the spirit. And in this sense it was adopted by the Reformers to express an idea almost the opposite of that with which the scholastics had associated it,—the idea that the direct apprehension of spiritual truth as entering into the inner life of the subject, as identified with his very consciousness of self, is the basis of all knowledge of it. In the Protestant church of the period after the Reformation, we find a growing tendency to insist on the subjectivity of religion, in the same exclusive and one-sided way in which the mediæval church had insisted on its objectivity. In some extreme representatives of Protestantism this went so far as to lead to a disregard, almost to a rejection, of all objective doctrine, and a reduction of theology to an account of the religious consciousness. On the other hand, while religion was thus made subjective, science claimed to be purely objective, and the followers of Bacon seemed to adopt towards nature the same attitude of passive receptivity which the mediæval Christian was taught to hold towards the church. While man was to learn everything from himself in religion, he was to learn nothing from himself in science. His aim must be to exclude subjective *idola*, in other words, to accept the facts as they were given, and keep himself out of the way. The inevitable result of this difference of view as to the nature of knowledge in these two different regions was, however, on the one hand a withdrawal of religion from all connexion with finite interests, and, especially from the attempt to connect religious principles with the knowledge of the finite world, and, on the other hand, an increasing tendency in those who represented finite science to regard religion as something merely subjective and even individual, as a feeling which could not be translated into thought or made the basis of any knowledge of the objective world.

The opposite principles of certitude which were thus set up for religious truth and truth of science need only to be brought together and contrasted to betray that they rest upon opposite abstractions, neither of which expresses the complete nature of truth or knowledge. On the one hand the truths of religion were maintained just because they were not, or were not merely, objective, but were capable of being tested by inner experience, and identified with the self-consciousness of the individual. On the other hand the truths of science were maintained because they were not, or were not merely, subjective, but were capable of being verified in objective experience. It was rightly seen on the one side that mere subjective feelings or opinions have no validity for any one but the subject of them, and on the other side that what is merely objective or externally given can have permanent value and interest for the intelligence only as it ceases to be mere isolated and unrelated fact—nay, that, even when science has discovered law and order in nature, it still wants the highest value and interest so long as that law and order are not seen as standing in essential relation to the intelligence itself. The idea of truth or knowledge as that which is at once objective and subjective, as the unity of things with the mind that knows them, enables us to understand the condemnation which the religious mind passed upon a merely external dogma, and even its lack of interest in a science which presented itself as an account of merely objective or external facts. And it enables us also to understand the way in which scientific men insisted upon objective fact as the basis of all knowledge, and the disrespect which they felt for a religion which seemed to admit that it had no such support. What is wanted to clear up the confusion on both sides is the growth of the perception among scientific men that the objectivity which they are seeking cannot be mere objectivity (which would be unmeaning), but an objectivity that stands in essential relation to the intelligence, and, on the other hand, the growth of the perception among religious men that the subjectivity of religion only means that God, who is the objective principle by whom things are, and are known, is spiritual, and can therefore be revealed to the spirit. When these two corrections have been made, it must become obvious that the religious consciousness is not the consciousness of another object than that which is present in finite experience and science, but simply a higher way of knowing the same object. And in this it is also involved that the two ideas of *a priori* and *a posteriori*, of that which is evolved from within and that which is given from without, are not essentially opposed to each other, but that the *a posteriori* is simply the first form of a consciousness which in its ultimate development must become *a priori*.

In that philosophy of compromise which was initiated by Descartes, one part of knowledge was regarded as innate, or developed from within, and another part as empirical, or imparted from without. In the second period of the history of modern philosophy this compromise was broken, and the names of Locke and Leibnitz—though with some hesitation on both sides—represent respectively the theories that all knowledge is *a posteriori* and that all knowledge is *a priori*. The compromise seemed to be renewed with Kant, but the form in which it was renewed pointed, as has been already shown, to something more than a compromise, for his doctrine was that the *a posteriori* element, the facts, exist for us only under *a priori* conditions, or, in other words, that what is usually called *a posteriori* is in part *a priori*. The criticism of this view need not be repeated. It is sufficient here to say that if, as Kant shows, the elements are inseparable or organically united, it is impossible to allege that so much belongs to the one and so much to the other. Furthermore, the consciousness of an essential difference in the elements of knowledge is possible only so far as that difference is transcended by the unity of knowledge. We can distinguish the *a priori* from the *a posteriori* only on condition that we can transcend

the distinction, and this means that the distinction itself is not absolute, but that there is a point of view from which the *a posteriori* may be regarded as *a priori*, and that which is given from without to the spirit may be referred to its own self-determined development.

Now it is just here that we come upon the turning-point of the philosophical controversy, in the form which it has taken in modern times. The problem may be expressed thus—In what sense can we apply the idea of development to the human spirit? Are we to treat that development as merely a determination from without, or as an evolution from within, or as partly the one and partly the other? In a sense all writers of the present day would admit that this last is the case. For, on the one hand, even the Darwinian theory accounts for development by aid of what we may call the *a priori* tendency of the individual to maintain itself in the struggle for existence, though it supposes that the condition or medium in which the individual is placed determines the direction in which that development proceeds. And, on the other hand, no one now would adopt the Leibnitzian theory that the individual is a monad, whose self-development is entirely conditioned by itself in such a sense that all the relations which it has to other existences are merely apparent, and that the coincidence of its life with the life of the world is the result of a pre-established harmony. On both sides, therefore, the idea of self-determination would be admitted, though the tendency of the Darwinians would be to regard this self-determination as something merely formal; and on both sides it would also be admitted that the self-determination does not exclude a determination from without, though extreme opponents of Darwin might be inclined to reduce this determination to a mere stimulus or external condition of the development of the nature of the subject to which the stimulus is applied. The question, however, remains whether, after all, this opposition of without and within is an absolute one, or whether there is any point of view from which it may be transcended. To Aristotle it seemed possible to answer this question in the affirmative, because he conceived that the reason of man is a pure or universal δύναμις, the evolution of which to complete self-consciousness is one with the process whereby the objective world comes to be known. Yet, as Aristotle admitted the existence in the world of a material principle which was essentially different from the ideal principle of reason, he was obliged to limit his statement as to the possible unity of the subjective and the objective consciousness, and to say merely that "in things *without matter* the knower is identical with the known." But this would immediately lead to the conclusion that the pure development of reason must be secured by abstraction from all finite and material objects, rather than by a thorough comprehension of them. The freedom of the spirit, on this theory, must be a negative and not a positive freedom, a freedom won, not by overcoming the world, but by withdrawing ourselves from its influence. It remained, therefore, for modern philosophy to work out the Aristotelian idea that the rational being as such, in spite of its necessary relation to and dependence on an external world, is never in an absolute sense externally determined. And, as we have already seen, the Kantian philosophy brought this problem within the reach of solution, in so far as it showed, first, that objective existence can have no meaning except existence for a thinking self, and, secondly, that existence for a thinking self means existence the consciousness of which is "capable of being combined with the consciousness of self." Add further to these propositions what was shown by Kant's successors, that that only can be combined with the consciousness of self which is essentially related to it, and we arrive at an idealistic theory of the world, which enables us at once to understand the relative value of the distinction between self-determination and determination from without, and at the same time to see that its value is only relative. If it be true that nothing exists which is not a possible object of consciousness, and again that there is no possible object of consciousness which is not essentially related to self-consciousness, then the phenomena of the external world, which at first present themselves under the aspect of contingent facts, must be capable of being ultimately recognized as the manifestation of reason; and the history of the conscious being in his relations with that world is not a struggle between two independent and unrelated forces, but the evolution by antagonism of one spiritual principle. It is, on this view, the same life which within us is striving for development, and which without us conditions that development. And the reason why the two terms, the self and the not-self, thus appear to be independent of each other, or to be brought together only as they externally act or react upon each other, lies in this, that the object is imperfectly known, and the subject is imperfectly self-conscious. This, however, does not make it less true that in self-consciousness is to be found the principle in reference to which the whole process may be explained, and therefore that the self-conscious subject, as such, lives a life which belongs to him, not merely as one object among others, but as having in himself the principle from which the life and being of all proceeds.

From this point of view, as has been already indicated, the relative value of a theory of human development, such as that which might be based on the ideas of Darwin, would not be denied. The conscious being may be regarded simply as an externally determined object, and the incorrectness of this assumption will not entirely destroy the value of the results attained, especially if, as is often the case with those who seek to construct a natural science of man, the assumption itself is not very strictly adhered to, but corrected by the tacit admission of other conceptions somewhat inconsistent with it. But, at the same time, it would require to be pointed out that such a science is necessarily abstract and imperfect, as it omits from its view the central fact in the life of the object of which it treats. It can do nothing to account for man's consciousness, or his capacity of becoming conscious, of the influences by which he is supposed to be determined; or, to put it from the other side, it takes for granted that the objects that influence man are intelligible objects, "capable of being combined with the consciousness of self," without seeing how much is involved in this assumption. Now it is evident that the consciousness of an influence cannot be explained by the influence itself, nor even by that taken together with the nature of the sensitive beings subjected to it. It is evident also that an influence mediated by consciousness is not, strictly speaking, an external influence, but that it is already transformed, and in process of being further transformed, by the development of the self to which it is present. For the dawn of consciousness, in which the external object first comes into existence for us as opposed to the self, is at the same time the beginning of the process by which its externality is negated or overcome. Self-consciousness is that which makes us individuals in a sense in which individuality can be predicated of none but a self-conscious being. For, in determining himself as a self, the individual at the same time excludes from himself every other thing and being, and determines them as external objects. He emancipates himself from the world at the same time that he repels the world from himself. Yet this movement of thought, by which his individuality is constituted, is also that by which he is lifted above mere individuality, for, in becoming conscious of self and not-self in their opposition and relation, he ceases to

be simply identified with the one to the exclusion of the other. His finite individuality is regarded by him from a universal point of view, in which it has no less and no more importance than any other individuality, or in which its greater or less importance is determined only by its place in the whole. On this universality of consciousness rests the possibility of science and of morality. For all science is just a contemplation of the world *in ordine ad universum* and not *in ordine ad individuum*; and all morality is just action with a view to an interest which belongs to the agent, not as this individual, but as a member of a greater whole, and ultimately of the absolute whole in which all men and all things are included.

In this nature of the conscious subject lies also the possibility of metaphysic in the sense of Aristotle, as that science which goes back to a πρῶτον φύσει, a beginning which is prior to the existence in consciousness of the individual self, and onward to an end in which the divisions of the finite consciousness are transcended,—as including, in short, ontology, or metaphysic in the narrower sense, on the one side, and theology, or the philosophy of religion, on the other. In truth, these two extremes of science are necessarily bound together: we can only go back to the beginning if we can go on to the end; we can only recover the first unity if we can anticipate the last. Or, to free the subject more definitely from the associations of time, we cannot apprehend the unity which is involved or presupposed in all the differences of our conscious life except in so far as we can look at our individual existence from the point of view of the whole to which it belongs. This will become evident if we consider the nature of the limits which have to be transcended by such a science. The individual conscious subject, as he finds himself at first, is but one being in a world that stretches out, apparently without limits, on every side of him. Of the things by which he is immediately surrounded he sees but a small part, and the influences which he receives from them are, as he knows, like the wave that breaks upon a shore from an unknown ocean, only the last partial expression of impulses that come from regions beyond his ken. Again, he finds himself as one in a changing series of beings, of which he knows only the last preceding terms, and he is aware that in a few years he, as one of this series, will cease to be. He is thus to himself a definitely limited being, and though his knowledge of himself and his world may be gradually widened so as to reach some little way back into the past, and anticipate a little of the future, or may go outwards in space to embrace a widening circle of existences around him, yet he always stops at a limit, of which he is conscious that it is no absolute limit, but simply an arbitrary halting-place where vision grows indistinct and imperfect. When he reflects upon himself from this point of view, he is forced to regard himself as but a fragment, and a fragment of an unknown whole, by which his whole being is determined to be what it is. His highest knowledge seems to be but a consciousness of his ignorance, his highest freedom a determination by motives the ultimate meaning of which is hid from him.

So far there seems to be no room for any metaphysical knowledge, any knowledge of ourselves and our world which is other than relative and *in ordine ad individuum*. But further reflexion shows that in this very consciousness of limit there is implied a consciousness of that which is beyond limit. While we proceed from part to part, beginning with ourselves and our immediate surroundings, and following out lines of connexion that lose themselves in the distance, we are guided by a consciousness of the whole as a unity through which the parts are determined. Nay, it is just the presence of this consciousness that makes us capable of what seems the piecework of our knowledge, in which, by the aid of the principle of causality, we connect particular with particular, and so gradually extend the sphere of light into the encompassing darkness. For that principle simply means that the limited external object does not sufficiently explain to us its own existence, and that therefore we are forced to explain it by a reference to something beyond it. It means, in other words, that we cannot rest in that which is not a self-bounded, self-determined whole. The application of the category of external determination has therefore an essential reference to the higher category of self-determination. The mere endlessness of space and time has no meaning except in opposition, yet in relation, to the true infinity of which we find the type in self-conscious thought. Or, to put it in the Kantian form in which it is already familiar to us, the consciousness of the objective world in space and time stands in essential relation to the unity of self-consciousness. And if when we regard the former exclusively we are forced to view ourselves as insignificant and short-sighted finite beings in an infinite universe, when we regard the latter we are enabled to see that in all this universe there is revealed only that spiritual principle which we find also in ourselves. In this way a new light is thrown on our first consciousness of ignorance. The strivings of our reason after knowledge can no longer be regarded as strivings after an unknown goal, but rather after a goal which it has prescribed for itself. The narrow limits of our individual life are not removed, but they cease to be for us the limits of a narrow circle of definition within a formless infinite. They become the limits of a sphere within a sphere, a sphere which is defined by the idea of knowledge or self-consciousness itself, and in which therefore, however we may wander, we are everywhere at home. In religious language, the sphere is not a mere universe, but God, who is without us only as He is within us, so that "by the God within we can understand the God without."

Again, as this consciousness takes man beyond his immediate existence, and enables him to determine it in relation to an absolute unity of all things in God, so it enables him to go back to a unity which is behind or prior to that existence. For, if the individual can look at himself as he looks at others, and at others as he looks at himself, *i.e.*, from a point of view which is unaffected by his individuality, and in which that individuality is for him only what it is for impartial reason, he can have nothing in him which binds his consciousness to his individuality as mere individuality; as therefore he can go beyond himself to apprehend the whole in which his individuality has a place, there is nothing to prevent him from going back upon himself, and upon the conditions which are prior to his own individual being. He is not tied to his immediate life, and can go below it just as he can rise above it.

"O God, I think Thy thoughts after Thee," said Kepler. In reading the "thoughts" written in the planetary system, Kepler was discovering the meaning of that which is simpler and more elementary than the existence of man, as a cycle of mechanical relations are simpler and more elementary than self-consciousness. Yet it was a true feeling that led him to connect this descent into the mechanical world with God. For it is only in virtue of the same faculty which enables us to rise to the absolute life which includes and subordinates our own that we can so free us from the image of our own conscious life as to apprehend and fix in thought the simpler relations of purely physical existence. But the same faculty of going back upon ourselves has a still deeper manifestation. Not only can we abstract from ourselves so as to understand the inorganic world, we can also abstract from ourselves so as to understand the conditions which are prior

view, the intelligence, in apprehending the indivisible unity of elements in the object, is at the same time apprehending the unity of the object with itself. The mind cannot be deceived in regard to that which forms a part of its consciousness of itself. In freeing the essential conception of the object from the contingency of matter, science has freed the object from that which made it foreign to intelligence, and the relation of thought to things ceases to be one of correspondence, and becomes one of identity.

The legitimate inference from this view of the relation of the intelligence to the intelligible world would seem to be that the partial separation of thought from its object and its imperfect correspondence with it is characteristic of our first empirical consciousness of things, and of the progress from that consciousness to science, but that in completed science the division ceases. The *esse* of things is not their *percipi*, but their *intelligi*. But, if this be taken as the truth, then it can no longer be supposed that the process by which scientific knowledge is attained consists simply in an analysis of the object as it is given in immediate perception. On the contrary, it must be held that, if our thought has to submit itself to the object, and to be brought into conformity with it, by a process of induction, it is equally true that in this process the object also must be changed, that it may be brought into conformity with the principle of thought. The genesis of science, according to this view, is not merely an analysis of given facts, but a process of vital transformation by which consciousness on the one side and the object on the other are brought into unity with each other. The idea, indeed, of an empty process, a process in which the activity of the mind is merely formal, is one which will not stand the slightest examination. A mind without categories, if such a thing were conceivable, would have no questions to ask in relation to the object presented to it, and could therefore get no answers. Those who make a pretence of approaching a subject in an absolutely receptive attitude, and without any presuppositions, only show that they are unconscious of the categories by which their thought is ruled; and they will be most slavishly guided by these categories just because they are unconscious of them. The schoolmen, when they applied their logical principles to the matter of Christian dogma, did not recognize that they were doing more than analysing and bringing out clearly the meaning of that dogma. But the effect of their work was to turn the system of divinity into a collection of insoluble puzzles; for the doctrine was a doctrine of reconciliation between divine and human, infinite and finite, universal and particular, and the principle of their method was to treat all these oppositions as absolute. In like manner it might be shown that the analysis of social phenomena which was made in the last century was inadequate and superficial, just because of the latent assumption of individualism on which it proceeded, and that the greater success of writers like Comte and Spencer does not arise merely or mainly from their being more careful observers of the phenomena of social life, but in great part from the fact that, rather by the unconscious movement of opinion than by any distinct metaphysic, their minds have become possessed by more adequate categories.

The idea that the process of thought is merely formal, or analytic of given matter, is, however, an error that has a truth underlying it. This is the truth expressed by Aristotle in his much misunderstood comparison of the intelligence of man to a *tabula rasa*, upon which nothing at first is written, and again in his assertion—already quoted—that the mind is a pure δύναμις, without any distinguishing quality of its own which could prevent it from apprehending the real nature of other things. In other words, self-conscious reason is not a special thing in the world, but the principle through which all things are, and are understood; and hence, as regards the distinction of things from each other, it is in the first instance undetermined and indifferent, and therefore open to be determined in one way or another, according to the object to which it is directed. But this simply means that the conscious subject, as such, is not bound to his own individuality, but can regard things, nay, in a sense, must regard them, from a point of view which is independent of it. This is what makes possible the self-restraint and self-abnegation prescribed to the scientific man, whose whole duty, as it is often said, is to keep himself out of the way and let the objects speak, to lay aside all subjective *idola* and prejudices that stand between him and the reality of things. This at first sight may seem to be equivalent to the assertion that the mind ought to be in a state of simple passivity or receptivity towards objects. What is really meant, however, is not that the intelligence should go out of itself, or cease to be itself, that it may know its object, but simply that it should show itself in its universality, or freedom from the limits of the individual nature. The self-abnegation of science is an endeavour, so to speak, to see the object with its own eyes, but this it can do only in so far as the consciousness for which the object is is that consciousness in relation to which alone all objects are, and are understood. Or, to put it in another form, the conscious self in its scientific self-abnegation does not give itself up to another, and become purely passive; it only gives up all activity which is not the activity of that universal thought for which and through which all things are. Hence, when it has so abnegated itself, its most intense constructive activity is just beginning, though, just so far as the self-abnegation has been real, that constructive activity has become one with the self-revelation of the object. As, however, it is only through the constructive activity of thought that there exists for us any object at all, so it is only through its continued activity that the conception of the object is changed, till it is completely revealed and known. And this activity involves a continuous synthesis, by which an ever wider range of facts is brought together in an ever more definite unity, until the mind has, if we may use the expression, exhausted its store of categories upon the world, and until the world has completely revealed itself in its unity with itself and with the mind.

To combine these two ideas—on the one hand that science begins in a self-abnegation by which the mind renounces all subjective prejudices, and thereby attains a purely objective attitude, and on the other hand that this purely objective attitude is not a mere attitude of reception, but one in which the mind is continually transforming the object by its own categories,—to see that the universality of the mind in knowing is not mere emptiness, and that its activity is synthetic just when it is most free from all presuppositions extraneous to the nature of its object,—is one of the greatest difficulties of the student of metaphysic. Universality at first looks so like emptiness, and a universal activity so like a merely formal activity, that it is no wonder that the one should be mistaken for the other. But if we make such a confusion, we may soon be forced to choose between a sensationalism that makes knowledge impossible and a mysticism which makes it empty. The pure identity of thought with itself which is involved in the process of analysis is put on the one side, and the manifold matter of experience which is the object of thought on the other, and between these opposites no mediation is possible. If we take our stand upon the latter, we are forced to reject all mental synthesis as invalid, because it involves a subjective addition to the

facts; if we take our stand on the former, we are compelled to regard all objective experience as irrational, because it does not correspond to the pure identity of thought.

In Aristotle's view of logic it cannot be said that this difficulty is clearly solved, though he seems to have seen the error of both extremes. On the one hand he often recognizes the synthetic character of the process of induction, as when he speaks of the universal idea or law as a central principle, in which we must find the key to all the difficulties suggested by different aspects of a given subject. Yet in other places we trace the influence of a merely analytic conception of that process as a process in which the universal is to be reached by abstracting from the peculiarities of individuals. And this conception of it is favoured by Aristotle's metaphysical theory, according to which the forms of things in the finite world are manifested in a resisting matter, a matter which prevents them from being perfectly or universally realized. For, in so far as this is the case, the facts will not be entirely explained by the knowledge of the form, and the knowledge of the form must be obtained, not by combining all the facts, but rather by abstracting from them. Again, in Aristotle's account of the process of thought in the *Prior Analytics*, he regards it as a formal deductive process; and, though in the *Posterior Analytics* he attempts to give a synthetic meaning to the syllogism by treating it as the method in which the properties of a thing may be proved of it, or combined with it, through its essential definition, yet this adventitious meaning bestowed upon the syllogistic process does not alter its essential nature. The ultimate source of this inadequate view of the process of thought seems to lie in Aristotle's imperfect conception of the unity or identity which is for him the type of knowledge. For, though, both in the *Metaphysic* and the *De Anima*, he defines that identity as self-consciousness or as a consciousness of objects which is identical with self-consciousness, yet he does not seem clearly to distinguish between a unity in which there is no difference and a unity in which difference is transcended and reconciled. This seems to be shown by his description of the principles which reason apprehends as *individua* or indivisible unities, rather than unities which imply, while they transcend, difference. Yet, in this definition of the unity of knowledge as self-consciousness, Aristotle has implicitly admitted that there is a duality or difference in the unity itself, and this might have been expected to modify his conception of the relation of consciousness to its objects. For, as self-consciousness is not simple like a chemical element, but only in the sense that it is an indissoluble unity of opposites, it might have been anticipated that one who had realized self-consciousness as the principle of knowledge would be able to regard the opposition between the consciousness of self and the consciousness of the world as itself also capable of being conceived as a unity.

This misconception of Aristotle may be shown in another way. In the *Metaphysic* we find him laying down what is called the logical law of contradiction as the ultimate principle of knowledge. The meaning of this principle, however, as Aristotle states it, is simply that thought in its essence is definition or distinction. If, as Heraclitus says, everything at once is and is not, if we cannot attach any definite predicates to things by which they may be distinguished from each other, then, as Aristotle argues, thought is chaos, and knowledge is impossible. If determination be not negation, if the assertion of A be not the negation of not-A, then there is no meaning in words. The criticism to be made on this view is obviously, not that it is a false statement of the law of thought, but that it is an imperfect statement of it. Thought is undoubtedly distinction; and, if all distinction be confounded, no meaning can be apprehended or expressed. But thought is also relation and connexion of the things distinguished, and this aspect of it is equally important with the other. Aristotle shows his one-sidedness—a one-sidedness which throws him into opposition to Plato, but which enables him to correct Plato only by falling into the opposite error—when he exclusively fixes his attention on the "differentiating" aspect of knowledge, and takes no notice of the "integrating" aspect of it. It is easy to see that this exclusive attention to one side of the truth may lead in many ways to a distorted view both of the world and of the intelligence that apprehends it. If Heraclitus be interpreted as simply denying the right of thought to introduce its definiteness into the flux of sense, nothing but absolute scepticism can come out of his philosophy; and Aristotle was right in maintaining that it is only as the flux is brought to a stand, and the universal is fixed as a permanent and definite object of thought,[1] that knowledge becomes possible. But, on the other hand, if distinction be taken as absolute, if the definite assertion of a thing be taken as a negation of all relation to what it is not, if the fixity of thought be taken as an abstract self-identity which excludes all the movement of finite things wherein they show their finitude and pass beyond themselves into other things, then knowledge will be equally impossible. Our consciousness, on such a theory, would be disintegrated into parts which would own no connexion with each other; nor would it be possible for us to think of things as, in spite of their differences, bound together into the unity of one world. The law of contradiction or distinction, therefore, is likely to lead to serious misconceptions, unless it be complemented by a law of relation—a law expressing the truth that there is a unity which transcends all distinction. For all intelligible distinction —all distinction of things in the intelligible world—must be subordinate to their unity as belonging to that world, and therefore essentially connected with each other and with the intelligence. In such a world, in other words, there can be no absolute distinctions or differences (not even between being and not-being); for distinction without relation is impossible, and a conception held in absolute isolation from all correlated conceptions ceases to have any meaning. This does not, of course, imply a negation of the law of contradiction within its own sphere, but it does imply that that sphere is limited, and that there is no absolute contradiction. All opposition is within a presupposed unity, and therefore points to a higher reconciliation, a reconciliation which is reached when we show that the opposition is one of correlative elements.

The great step in logical theory which was taken by the idealistic philosophy of the post-Kantian period was simply to dissipate the confusion which had prevailed so long between that bare or formal identity, which is but the beginning of thought and knowledge, and that concrete unity of difference, which is its highest idea and end. It was, in other words, to correct and complete the conceptions of thought as analytical, and as externally synthetical, by the conception of it as self-determining, to show that it is a unity which manifests itself in difference and opposition, yet in all this, even when it seems to be dealing with an object which is altogether external to it, is really developing and revealing itself. This new movement of thought might, in one point of view, be described as the addition of another logic to the logic of analysis and the logic of inductive synthesis which were already in existence. But it was really more than this; for the new logic was not merely an external addition

[1] ἠρεμήσαντος τοῦ καθόλου ἐν τῇ ψυχῇ, *An. Post.*, ii. 19.

to the old logics, it also put a new meaning into these logics by bringing to light the principles that were involved in them. At the same time it broke down the division that had been supposed to exist between logic and metaphysic, between the form or method of thought and its matter. It showed that thought itself contains a matter from which it cannot be separated, and that it is only by reason of this matter that it is able to ask intelligent questions of nature, and to get from nature intelligible answers. A short space must be devoted to explain this relation of the three logics to each other.

The analytic logic fairly represents our first scientific attitude to the world, in which we concentrate our attention upon the facts as they are given in experience, with no thought of any mental synthesis through which they are given. To ourselves we seem to have to do with an object which is altogether independent of our thought, and what we need in order to know it is to keep ourselves in a purely receptive attitude. All we can do is to analyse what is given, without adding anything of our own to it. It has, however, already been pointed out that this apparent self-abnegation is possible only because, in abnegating our individual point of view, we do not abnegate the point of view that belongs to us as universal or thinking subjects. In other words, the objectivity of knowledge thus attained is not the ceasing of the activity of our thought, but rather of all that interferes with that activity. We seem to abstract from ourselves, but what we do abstract from is only the individuality that stands between us and the world. The scientific observer who has thus denied himself, however, is not necessarily conscious of the meaning of what he has done. The immediate expression of his consciousness is not "I think the object," but "it, the object, is"; and the more intensely active he is the more his activity is lost for him in the object of it. His whole work is, for himself, only the analysis of given facts, and for the rest he seems to have nothing to do but to take the world as he finds it. The voice of nature to which he listens is for him not his own voice but the voice of a stranger, and it does not occur to him to reflect that nature could not speak to any one but a conscious self. His business is to determine things as they present themselves, to enumerate their qualities, to measure their quantities; and his logic accordingly is a logic governed by the idea of the relative comprehension and extension of the things which he thus names and classifies. Such an analytic logic seems to be all that is necessary, because the only predicates by which things are as yet determined are those which are involved in their presence to us in perception, and as perceived they seem to be at once given in all their reality to the mind that apprehends them.

A step is taken beyond this first naive consciousness of things, whenever a distinction is made between appearance and reality, or whenever it is seen that the things perceived are essentially related to each other, and that therefore they cannot be known by their immediate presence to sense, but only by a mind which relates that which is, to that which is not, immediately perceived. If "the shows of things are least themselves," we must go beyond the shows in order to know them; we must seek out the permanent for that which is given as transient, the law for the phenomenon, the cause for the effect. The process of thought in knowledge therefore is no longer lost in its immediate object, but is, partly at least, distinguished from it. For just in proportion as the reality is separated from the appearance does the knower become conscious of an activity of his own thought in determining things. From this point of view nature is no longer an object which spontaneously reveals itself to us, but rather one which hides its meaning from us, and out of which we must wring its secret by persistent questioning. And, as this questioning process obviously has not its direction determined purely by the object itself, it becomes manifest that the mind must bring with it the categories by which it seeks to make nature intelligible. To ask for the causes of things, or the laws of things, presupposes that the immediate appearance of them does not correspond to an idea of reality which the mind brings with it, and by which it judges the appearance. Nature is supposed to be given to or perceived by us as a multitude of objects in space passing through successive changes in time; and what science seeks is to discover a necessity of connexion running through all this apparently contingent coexistence and succession and binding it into a system. Science, therefore, seems to question nature by means of an idea of the necessary interdependence and connexion of all things, as parts of one systematic whole governed by general laws—an idea which it does not get from nature, but which it brings to nature. Hence the logic in which this process of investigation expresses its consciousness of itself will be a synthetic logic, a logic built on certain principles which are conceived to be independent of experience, and by the aid of which we may so transform that experience, so penetrate into it or get beyond it, as to find for it a better explanation than that which it immediately gives of itself. The *Posterior Analytic*, in which Aristotle brings in the idea of cause to vivify the syllogistic process, or supply a real meaning to it, may already be regarded as a first essay in this direction. And the theory of inductive logic, as explained by Bacon and his successors down to Mill, is a continuous attempt to determine what are the principles and methods on which experience must be questioned, in order to extract from it a knowledge which is not given in immediate perception.

It was, however, Hume who first brought into a clear light the subjectivity of the principles postulated in this logic, and especially of the principle of causality, which is the most important of them. In thus contrasting the subjectivity of the principles of science with the objectivity of the facts to which they are applied, it was his intention to cast doubt on the science which is based on the application of the former to the latter. The principles, he maintains, are not legitimately derived from the facts, therefore they cannot legitimately be used to interpret them. They are due to the influence of habit, which by an illegitimate process raises frequency of occurrence into the universality and necessity of law, and so changes a mere subjective association of ideas into an assured belief and expectation of objective facts. The answer given by Kant to this sceptical criticism of science involved a rejection of that very opposition of subjective and objective upon which it was based. Without necessary and universal principles, the experience of things as qualitatively and quantitatively determined objects, coexisting in space and passing through changes in time (or even the determination of the successive states of the subject as successive), would itself have been impossible. Hence necessity of thought cannot be derived from a frequent experience of such objects. It is true that the determination of things as permanent substances reciprocally acting on each other, according to universal laws, goes beyond the determination of them as qualified and quantified phenomena in space and time. But both determinations are possible only through the same *a priori* principle, and we cannot admit the former determination without implicitly admitting the latter. As, therefore, it is through the necessity and universality of thought that objects exist for us, even before the application to them of the principles of scientific induction, and as the application of those principles is only a further step in that *a priori* synthesis which is already involved in the perception of these objects, we have no reason for treating

the former kind of synthesis as objectively valid which does not equally apply to the latter.

This vindication of the principles of induction has, however, a further consequence, which was not clearly seen by Kant. It is fatal to the antithesis of the "given" and the "known," of what is perceived and what is conceived, of *natura materialiter spectata* and *natura formaliter spectata*, which he still admitted. For that antithesis really rested on the idea that there is no universal and necessary principle of determination of things involved in the apprehension of them as qualified and quantified phenomena in space and time. So soon, therefore, as it is seen that there is such a principle, and that the first determination of things as objects of perception is due to the same *a priori* synthesis which determines them in the second place as objects of experience, the ground for that contrast between reality and appearance on which the theory of induction rested is taken away. Kant, indeed, finds a new meaning for that contrast by interpreting it as referring, not to the opposition between things as they are given and things as they are known, but to a supposed opposition between things as they are given and known in experience and things as they are in themselves out of experience. This new antithesis of reality and appearance, however, only means that the former antithesis has broken down, and that therefore the ideal of knowledge based upon it has yielded to a new ideal. The so-called things in themselves are noumena, the objects of an intuitive or perceptive understanding, *i.e.*, objects in which the contrast of perception and conception, of given and known, is transcended. We can make Kant's theory consistent only by supposing him to mean that the conception of the world as a system of substances determining each other according to universal laws does not yet satisfy the idea of knowledge which reason brings with it. In other words, just as science from the point of view of necessary law found something wanting in the conception of the world as a mere complex of quantified and qualified phenomena in space and time, so philosophy, in view of a still higher ideal of knowledge, may condemn the conception of the world as a system of objects determined by necessary laws of relation as itself inadequate and imperfect. And we have seen that this higher ideal is that which is involved in the unity of self-consciousness. Unfortunately Kant was unable, as Aristotle had been unable, to distinguish this idea from the idea of an abstract identity in which there is no room for even a relative difference of perception and conception, and therefore the perceptive understanding was named by him only to be rejected.

If, however, we correct this inadequacy of Kant's statement, as his later works enable us partly to correct it, we see that it involves a new idea of knowledge and a new logic,—a logic governed by the idea of organic unity and development, just as the analytic logic had been governed by the idea of identity, and as the inductive logic had been governed by the idea of necessary law. For, if the unity of self-consciousness be our type of knowledge, truth must mean to us, not the apprehension of objects as self-identical things, distinguished from each other in quantity and quality, nor even the determination of such things as standing in necessary relations to each other. It must mean the determination of the world (and of whatever in it is in any sense an independent reality, so far as it is so independent) as a unity which realizes itself in and through difference, a unity which is indeed determined, but determined by itself. In a view of the world which is governed by this category, correlation must be reinterpreted as organic unity, and causation as development. Its logical method must be neither analytical nor synthetical, or rather it must be both at once, *i.e.*, it must endeavour to exhibit the process of things as the evolution of a unity which is at once self-differentiating and self-integrating, which manifests itself in difference, that through difference it may return upon itself. Further, as this logic arises simply out of a deeper consciousness of that which was contained in the two previous logics, so it first enables us to explain them. In other words, the advance from the analytic to the inductive logic, and again from the inductive to what may be called the genetic logic, may itself be shown to be a self-determined development of thought, in which the first two steps are the imperfect manifestation of a principle fully revealed only in the last step. The consciousness of self-identical objects, independent of each other and of thought, is thus only the beginning of a process of knowledge which reaches its second stage in the determination of these objects as essentially related to each other, and which finds its ultimate end in the knowledge of the correlated objects as essentially related to the mind that knows them. Or if, in this last point of view, things are still conceived as having a certain relative independence of the mind, it can only be in so far as they are in the Leibnitzian sense monads, or microcosms,—*i.e.*, in so far as they are self-determined, and so have, in the narrower circle of their individual life, something analogous to the self-completed nature of the world, when it is contemplated in its unity with its spiritual principle.

Such a genetic logic is inconsistent with any absolute distinction between the *a priori* and *a posteriori* element in knowledge. For here the *a priori* is not simply a law of necessary connexion to be applied to an external matter, but a principle of organic development, a principle which, from the very nature of it, cannot be applied to a foreign matter. To treat the world as organic is to apply to it a category which is inconsistent with its being something merely given or externally presented to thought. The relation of things to thought must itself be brought under the same category of organic unity which is applied to the relation of things to each other in the world, otherwise the externality of the world to the thought for which it is will contradict the conception of the world as itself organic. Hence the distinction of *a priori* and *a posteriori*, so far as it is maintained at all, must shrink to something secondary and relative. It can be maintained only as a distinction of thought from its object, which presupposes their ultimate unity. From this point of view logic may be said to deal with the *a priori*, in so far as it treats the general conditions and methods of knowledge without reference to any particular object. Logic must exhibit abstractly the process by which the intelligence establishes its unity with the intelligible world; or, to put it in another way, it must demonstrate that the being of things can be truly conceived only as their being for thought. It is limited to the *a priori*, in the sense that it ends with the idea that the *esse* of things is their *intelligi*, and does not consider how this real intelligence or intelligible reality manifests itself in the concrete world of nature and spirit.

In this sense logic cannot be separated from metaphysic if metaphysic be confined to ontology. They are simply two aspects of one science, which we may regard either as determining the idea of being or the idea of knowing. The process of knowing is never really a formal process; it always involves the application of certain categories, and these categories are simply successive definitions of being or reality. We cannot separate the category from the movement of thought by which it is evolved and applied, nor the transition from lower to higher categories from changes of logical method. Hence a logic divorced from metaphysic inevitably becomes empty and unreal, and a metaphysic divorced from logic reduces itself to a kind of dictionary of abstract terms, which are put in no living

relation to each other. For such a logic and such a metaphysic must rest on the assumption of an absolute division between being and thought, the very two terms the unity of which it must be the utmost object of both logic and metaphysic to prove and to produce.

4. *The Relation of Metaphysic to Philosophy of Religion.*—The possibility of a "first philosophy," as we have already seen, is essentially bound up with the possibility of what we may call a last philosophy. It is only in so far as we can rise above the point of view of the individual and the dualism of the ordinary consciousness—in so far, in other words, as we can have at least an anticipative consciousness of that last unity in which all the differences of things from each other and from the mind that knows them are explained and transcended—that we are able to go back to that first unity which all these differences presuppose. The life of man begins with a divided consciousness, with a consciousness of self which is opposed to the consciousness of what is not-self, with a consciousness of a multiplicity of particulars which do not seem to be bound together by any one universal principle. Such division and apparent independence of what are really parts of one whole is characteristic of nature, and in spirit it is at first only so far transcended that it has become conscious of itself. A conscious difference, however, as it is a difference in consciousness, is no longer an unmediated difference. It is a difference through which the unity has begun to show itself, and which therefore the unity is on the way to subordinate. And all the development of consciousness and self-consciousness is just the process through which this subordination is carried out, up to the point at which the difference is seen to be nothing but the manifestation of the unity. Just so far, therefore, as this end is present to us,—so far as we are able to look forward to the solution or reconciliation of all the divisions and oppositions of which we are conscious and to see that there is an all-embracing unity which they cannot destroy,—is it possible that we should look back to the beginning or first unity, and recognize that these divisions and oppositions are but the manifestations of it. Thus the extremes of abstractness and of concreteness of thought are bound up together. The freedom of intelligence by which we get rid of the complexity of our actual life, and direct our thoughts to the simplest and most elementary conditions of being and knowing, is possible only to those who are not limited to that life, but can regard it and all its finite concerns from the point of view of the infinite and the universal. In this sense it is true that religion and metaphysic spring from the same source, and that it is possible to vindicate the rationality of religion only on metaphysical principles. The philosophy of religion is, in fact, only the last application or final expression of metaphysic; and, conversely, a metaphysic which is not capable of furnishing an explanation of religion contradicts itself.

This last remark affords us a kind of criterion of a true metaphysic. Can it or can it not explain religion? If it cannot, it must be equally unable to explain its own possibility, and therefore implicitly it condemns itself. Thus a pantheistic system, which loses the subject in the absolute substance, cannot explain how that subject should apprehend the substance of which it is but a transitory mode, nor, on the other hand, can it explain why the substance should manifest itself in and to a subject. And the same criticism may be made on all theories in which the first or metaphysical unity is abstractly opposed to the manifoldness and contingency of things. Not only of Spinoza, but also of Kant, of Fichte, and even of Schelling, it might with some truth be said that their absolute is like the lion's den, towards which all the tracks are directed, while none come from it. It is essential that the first unity should be such as to explain the possibility of difference and division, for, if it is not, then the return to unity out of difference is made as accidental as the difference itself. When Aristotle represented the Divine Being as pure self-consciousness, pure form without matter, he found himself unable to account for the existence of any world in which form was realized in matter. When therefore he speaks of the process of the finite world by which it returns to God, and attributes to nature a will, which is directed to the good as its final cause, his theory seems to be little more than a metaphor in which the analogy of consciousness is applied to the unconscious. For, if the Divine Being is not manifested in the world, any tendency of the world to realize the good becomes an inexplicable fact. A similar difficulty is, as we saw, involved in Kant's confusion of the bare identity of understanding with the absolute unity of knowledge. Reducing the unity of self-consciousness to such a bare identity, Kant could not be expected to see, what Aristotle had not seen, that pure self-consciousness is essentially related to anything but itself. Hence the various attempts which he made in his ethical works and in his *Criticism of Judgment* to find a link of connexion between the noumenal and the empirical were necessarily condemned even by himself as the expressions of a merely regulative and subjective principle of knowledge. Even Fichte, who found in the thought, which is for him the *prius* of all existence, a principle of differentiation and integration which explained how self-consciousness in us should be necessarily correlative with the consciousness of a world, was unable to free himself from the Kantian opposition of a noumenal identity in which there is no difference to a phenomenal unity which is realized in difference. Hence by him also the return out of difference is regarded as an impossibility, or as a *processus in infinitum*, and the absolute unity as that which is beyond all knowledge and only apprehended by faith.

If we look to completely elaborated theories, and disregard all tentative and imperfect sketches, it may fairly be said that all that has as yet been done in the region of pure metaphysic is contained in two works, in the *Metaphysic* of Aristotle and the *Logic* of Hegel. And up to a certain point the lesson which they teach is one and the same, viz., that the ultimate unity which is presupposed in all differences is the unity of thought with itself, the unity of self-consciousness, and that in this unity is contained the type of all science, and the form of all existence; in other words, $I = I$ is the formula of the universe. The difference between these two works has, however, already been indicated. With Aristotle, because he neglects the essential relation of self-consciousness to consciousness, or of the conscious self to the world of objects in space and time, the unity of self-consciousness tends to pass, as it did pass with the Neo-Platonists, into a pure identity without difference. In the Hegelian logic, on the other hand, self-consciousness is interpreted as a unity which realizes itself through difference and the reconciliation of difference—as, in fact, an organic unity of elements, which exist only as they pass into each other. In other words, it is shown that the differentiating movement by which the subjective and the objective self are opposed and the integrating movement by which they are reunited are both essential. Hence we cannot think of the conscious self as a simple resting identity, but only as an active self-determining principle; nor can we think of its self-determination as a pure affirmation of itself, without any negation, but only as an affirmation which involves a double negation—an opposition of two elements which yet are essentially united. Each factor in this unity, in fact, is necessarily conceived as passing beyond itself into the other; the subject is subject only as it relates itself to the object, the object is

object only as it relates itself to the subject. It is this tension against each other of elements which yet are correlated and indissolubly united, this self-surrender to each other of elements which yet are maintained in their distinction, which constitutes the organic unity of thought in itself, and separates it from the mere abstract unity of mysticism. When, however, the concrete or self-differentiating character of the unity of self-consciousness is apprehended in this way,—so that it is impossible to confuse its indivisible unity with the simplicity of that which is one merely because it has no differences in it,—the problem of the relation of pure self-consciousness to the world in space and time ceases to be insoluble. Thought, as it is seen to have difference in itself, is no longer irreconcilable with the world of difference; nor is it necessary to introduce a foreign ὕλη to make their connexion intelligible. For, as thought is a principle of difference as well as of unity, of analysis as well as of synthesis, and as it cannot realize itself in its unity except through the utmost development of difference, abstract self-consciousness, with its transparent or merely ideal difference, cannot be its ultimate form. On the contrary, the consciousness of self is possible only in distinction from, and in relation to, a world of objects. In other words, the unity of the thinking subject presupposes, not merely the opposition of the subjective and the objective self, but also the opposition of the self in its pure self-identity to a world of externality and difference. The pure intelligence, which is the *prius* of all things, must not, therefore, be regarded—as Aristotle regarded it—as merely theoretical, but also as practical. It must be conceived as a living principle, a principle which only in self-manifestation can be conscious of itself, and to the very nature of which, therefore, self-manifestation is essential. In this way Hegel—just because he grasped the concrete character of the unity of thought in itself—was enabled to understand the necessary unity of thought or self-consciousness with the world, and to heal the division of physics from metaphysic, which Aristotle had admitted.

Schelling and others who have raised objections to the Hegelian method have specially directed their criticisms against this transition from logic to the philosophy of nature, from pure self-consciousness to the external world in space and time. In doing so, they have practically fallen back upon the Aristotelian theory, with its opposition of God, as pure form, to the finite world. But this in effect is to deny that "the real is the rational" or intelligible, and to introduce into the world, as the ground of its distinction from reason, a purely irrational or contingent element. A modern follower of Schelling's later positive philosophy only draws the necessary consequence from this view when he teaches the pessimist creed that the highest good is the negation or extinction of the finite. Nor can we wonder that the same writer who denies that the absolute self-consciousness is essentially related to or manifested in the world should proceed to reduce this self-consciousness to a mystic identity which comes out of itself and becomes self-conscious only by an inscrutable act of will. The fact, indeed, that those who deny the possibility of a rational transition from self-consciousness to the world are forced by the logic of their position to reduce self-consciousness to an abstract identity may be regarded as a kind of indirect proof that the principle of self-consciousness, truly conceived, does involve that transition. Another step in the same direction may be made if we consider how the Cartesian philosophy treated the same opposition, which it also regarded as absolute. By Descartes mind and matter, thought and extension, are defined as abstract opposites, every quality of each finding its contradictory counterpart in a quality of the other. Mind is a pure self-determined unity, which is as it knows itself and knows itself as it is, which has no discretion of parts or capacity of division or determination from without. Matter is essentially discrete or infinitely divided; it is a pure passivity; and all its determination comes to it from without. The world is therefore, as it were, "cut in two with a hatchet," divided into two unrelated existences, which are held together only by the will of God. Spinoza cuts the knot, and avoids the arbitrariness of this solution, by treating extension and thought as two attributes separated only in respect of our intelligence, but each expressing fully the absolute substance. And something like the same view has been revived in recent times, by writers like Lewes and Mr Spencer, who speak of feelings and motions as two opposite "aspects" of the same fact. When we ask, however, *for whom* these attributes or aspects are a unity, it becomes clear that the intelligence which is regarded as standing on one side of the dualism must also be taken as transcending it, and relating the two sides to each other. Moreover, the correspondence of the two attributes upon which Spinoza insists and their contrariety upon which Descartes insists, when taken together, give us the idea of a correlative opposition, *i.e.*, of an opposition of elements which yet are necessary to each other. If, therefore, they cannot be simply identified as Spinoza identifies them, yet they need no external bond such as Descartes introduces to combine them; for they cannot exist apart from each other. Their opposition is held within the limits of their unity, and is no absolute contradiction, but rather an opposition which exists only as it is transcended. In other words, it is an abstract opposition, *i.e.*, it is an opposition of elements which seem to be irreconcilable till it is observed that they are correlative, that each exists or has a meaning only as it relates itself to, or passes out of itself into, the other, and that each, held in its abstraction and separation from the other, loses all the meaning that it seemed to have. For, as in an organic body each member or organ lives only in tension against the others, yet only as continually relating itself to the others, so the utmost opposition of mind to matter, of the intelligence to the intelligible world, presupposes their unity, and is only the realization of it.

There is here, however, something more than an ordinary case of correlation, for in this unity of opposites mind appears twice, once as one of the opposites, and again as the unity which transcends the opposition. This ambiguity becomes most obvious in theories like that of Mr Spencer, who speaks of "two consciousnesses," which cannot be resolved into each other, but yet which strangely form inseparable parts of one and the same consciousness. What, however, is really involved in such a statement is that the external world, which in the first instance presents itself as absolutely opposed in nature to the subject whose object it is, is yet one with that subject, and that therefore the antagonism of mind to its object is only the last differentiation through which it realizes its unity with itself. In Hegel's language, that which presents itself as other than mind is *its* other—"an other which is not another," whose difference and opposition to itself it overreaches and overcomes. We must, therefore, regard the independence and externality of nature, its indifference, and even, as it seems, opposition, to the development of the moral and intellectual life of man, as merely apparent. For man, in this point of view, is not merely one natural being among others, but the being in whom nature is at once completed and transcended. If, therefore, at first he appears to stand in merely accidental and external relations to the other existences among which he finds himself, yet the whole process of his life—the process by which he comes to know the external world, and by which, reacting upon it, he makes it the means to the realization of an individual and

fortune at that period. Metastasio was now twenty. During the last four years he had worn the costume of abbé, having taken the minor orders without which it was then useless to expect advancement in Rome. His romantic history, personal beauty, charming manners, and distinguished talents made him fashionable. That before two years were out he had spent his money and increased his reputation for wit will surprise no one. He now very sensibly determined to quit a mode of life for which he was not born, and to apply himself seriously to the work of his profession. Accordingly he went to Naples, and entered the office of an eminent lawyer named Castagnola. It would appear that he articled himself as clerk, for Castagnola, who was a stern master, averse to literary trifling, exercised severe control over his time and energies. While slaving at the law, Metastasio did not wholly neglect the Muses. In 1721 he composed an epithalamium, and probably also his first musical serenade, *Endimione*, on the occasion of the marriage of his patroness the Princess Pinelli di Sangro to the Marchese Belmonte Pignatelli. But the event which fixed his destiny was the following. In 1722 the birthday of the empress had to be celebrated with more than ordinary honours, and the viceroy applied to Metastasio to compose a serenata for the occasion. He accepted this invitation with mingled delight and trepidation; for Castagnola looked with no favour on his clerk's poetical distractions. It was arranged that his authorship should be kept a profound secret. Under these conditions Metastasio produced *Gli Orti Esperidi*. Set to music by Porpora, it won the most extraordinary applause. The great Roman prima donna, Marianna Bulgarelli, called La Romanina from her birthplace, who had played the part of Venus in this drama, was so enraptured with the beauties of the libretto that she spared no pains until she had discovered its author. Asked point-blank whether he had not written the words of the successful play, Metastasio was obliged to answer, Yes! La Romanina forthwith took possession of him, induced him to quit his lawyer's office, and promised to secure for him fame and independence, if he would devote his talents to the musical drama. It was thus that the opera, already partially developed by the Cæsarean poet, Apostolo Zeno, attained perfection. The right man had been found for maturing this form of art which the genius of the age demanded, but which was still but incomplete. In La Romanina's house Metastasio became acquainted with the greatest composers of the day,—with Porpora, from whom he took lessons in music; with Hasse, Pergolese, Scarlatti, Vinci, Leo, Durante, Marcello, all of whom were destined in the future to set his plays to melody. Here too he studied the art of singing, and learned to appreciate the style of such men as Farinelli. His singularly pliant genius discerned the conditions which the drama must obey in order to adapt itself to music in the stage it then had reached. Gifted himself with extraordinary facility in composition, and with a true poetic feeling, he found no difficulty in producing plays which, while beautiful in themselves, judged merely as works of literary art, became masterpieces as soon as their words were set to music, and rendered by the singers of the greatest school of vocal art the world has ever seen. Reading Metastasio in the study, it is impossible to do him justice. Our only chance of rendering him a portion of his due is to approach these lyrical scenes—so passionate in their emotion, so cunningly devised for musical effect—with the phrases of Pergolese or Paesiello ringing in our ears, and to imagine how a Farinelli or a Caffariello voiced those stanzas which demand for their artistic realization the "linked sweetness long drawn out" of melodies as the Italian school developed them. In short, Metastasio is a poet whose poetry leapt to its real life in the environment of music. The conventionality of all his plots, the absurdities of many of his situations, the violence he does to history in the persons of some leading characters, his "damnable iteration" of the theme of love in all its phases, are explained and justified by music. He can still be studied with pleasure and profit. But our only chance of understanding the cosmopolitan popularity he enjoyed is by remembering that at least one half of the effect he aimed at has been irrecoverably lost.

Metastasio resided with La Romanina and her husband in Rome. The generous woman, moved by an affection half maternal half romantic, and by a true artist's admiration for so rare a talent, adopted him more passionately even than Gravina had done. She took the whole Trapassi family—father, mother, brother, sisters—into her own house. She fostered the poet's genius and pampered his caprices. Under her influence he wrote in rapid succession the *Didone Abbandonata*, *Catone in Utica*, *Ezio*, *Alessandro nell' Indie*, *Semiramide Riconosciuta*, *Siroe*, and *Artaserse*. These dramas were set to music by the chief composers of the day, and performed in the chief towns of Italy. Every month added to Metastasio's renown. But meanwhile La Romanina was growing older; she had ceased to sing in public; and the poet felt himself more and more dependent in an irksome sense upon her kindness. He gained 300 scudi (about £60) for each opera; this pay, though good, was precarious, and he longed for some fixed engagement. Abandoning himself gradually to despondent whims and fancies, it became clear that some change in his condition was desirable. And the opportunity for a great change soon presented itself. In September 1729 he received the offer of the post of court poet to the theatre at Vienna, with a stipend of 3000 florins. This he at once accepted. La Romanina unselfishly sped him on his way to glory. She took the charge of his family in Rome, and he set off for Austria.

In the early summer of 1730 Metastasio settled at Vienna in the house of a Spanish Neapolitan, Niccolò Martinez, where he resided until his death. This date marks a new period in his artistic activity. Between the years 1730 and 1740 his finest dramas, *Adriano*, *Demetrio*, *Issipile*, *Demofoonte*, *Olimpiade*, *Clemenza di Tito*, *Achille in Sciro*, *Temistocle*, and *Attilio Regolo*, were produced for the imperial theatre. Some of them had to be composed for special occasions, with almost incredible rapidity—the *Achille* in eighteen days, the *Ipermnestra* in nine. Poet, composer, musical copyist, and singer did their work together in frantic haste. The impress of the peculiar circumstances under which they were created is still left upon them, not only in negligence of style, but also in an undefinable quality which marks them out as products of collaboration. But what must always surprise us is that they should be as good as they are. Metastasio understood the technique of his peculiar art in its minutest details. The experience gained at Naples and Rome, quickened by the excitement of his new career at Vienna, enabled him almost instinctively, and as it were by inspiration, to hit the exact mark aimed at in the opera.

At Vienna Metastasio met with no marked social success. His plebeian birth excluded him from aristocratic circles. But, to make up in some measure for this comparative failure, he enjoyed the intimacy of a great lady, the Countess Althann, sister-in-law of his old patroness the Princess Belmonte Pignatelli. She had lost her husband, and had some while occupied the post of chief favourite to the emperor. Metastasio's liaison with her became so close that it was even believed they had been privately married. From his letters to his friend La Romanina, and to the great singer Farinelli, who reigned supreme at the court of Madrid, we learn the little details of the poet's life in

its wearisome monotony, and come to comprehend his character, at once generous and timid, selfish and amiable, prudent almost to excess of caution, and personally cold in contradiction with the fervour of his sentimental muse. The even tenor of this dull existence was broken in the year 1734 by the one dark and tragic incident of his biography. It appears that La Romanina had at last got tired of his absence. Little satisfied with his friendly but somewhat reticent communications, impatient to see him once again, inquisitive perhaps about the terms on which he lived with his new mistress, she resolved to journey to Vienna. Could not Metastasio get her an engagement at the court theatre? The poet at this juncture revealed his own essential feebleness of character. To La Romanina he owed almost everything as a man and as an artist. But he was ashamed of her and tired of her. He vowed she should not come to Vienna, and wrote dissuading her from the projected visit. The tone of his letters alarmed and irritated her. It is probable that she set out from Rome, but died suddenly upon the road. Nothing can be said for certain about her end, or about the part which Metastasio may have played in hastening the catastrophe. All we know is that she left him her fortune after her husband's life interest in it had expired, and that Metastasio, overwhelmed with grief and remorse, immediately renounced the legacy. This disinterested act plunged the Bulgarelli-Metastasio household at Rome into confusion. La Romanina's widower married again. Leopoldo Trapassi, and his father and sister, were thrown upon their own resources. The poet in Vienna had to bear their angry expostulations upon his ill-timed generosity, and to augment the allowances he made them.

As time advanced the life which Metastasio led at Vienna, together with the climate, told upon his health and spirits. From about the year 1745 onward he writes complainingly of a mysterious nervous illness, which plunged him into the abyss of melancholy, interfered with his creative energy, and constantly distressed him with the apprehension of a general breakdown. He wrote but little now, though the cantatas which belong to this period, and the canzonet *Ecco quel fiero istante*, which he sent to his friend Farinelli, rank among the most popular of his productions. It was clear, as his latest and most genial biographer, Vernon Lee, has phrased it, that "what ailed him was mental and moral ennui." In 1755 the Countess Althann died, and Metastasio was more than ever reduced to the society which gathered round him in the bourgeois house of the Martinez. He sank rapidly into the habits of old age; and, though his life was prolonged till the year 1782, very little can be said about it. On the 12th of April he died, bequeathing his whole fortune of some 130,000 florins to the five children of his friend Martinez. He had survived all his Italian relatives.

During the long period of forty years in which Metastasio may be almost said to have overlived his originality and creative powers his fame went on increasing. In his library he counted as many as forty editions of his own works. They had been translated into French, English, German, Spanish, even into Modern Greek. They had been set to music over and over again by every composer of distinction, each opera receiving this honour in turn from several of the most illustrious men of Europe. They had been sung by the best virtuosi in every capital, from Madrid to St Petersburg, from London to Constantinople. The critics of all nations vied in raising Metastasio's credit to the skies. There was not a literary academy of note which had not conferred on him the honour of membership. Strangers of distinction passing through Vienna made a point of paying their respects to the old poet at his lodgings in the Kohlmarkt Gasse. Letters of congratulation, adulation, sympathy, respect, condolence, poured in upon him. And yet, during the whole of this long period, he was gradually outliving the artistic conditions upon which that fame was really founded. It has been already pointed out that Metastasio cannot rank as a poet in the unqualified sense of that word, but as a poet collaborating with the musical composer and performer. His poetry, furthermore, was intended for a certain style of music—for the music of omnipotent vocalists, of thaumaturgical soprani. With the changes effected in the musical drama by Gluck and Mozart, with the development of orchestration and the rapid growth of the German manner, a new type of libretto came into request. Metastasio's plays fell into undeserved neglect, together with the music to which he had linked them. Farinelli, whom he styled "twin-brother," was the true exponent of his poetry; and, with the abolition of the class of singers to which Farinelli belonged, Metastasio's music suffered eclipse. It was indeed a just symbolic instinct which made the poet dub this unique soprano his twin-brother.

The musical drama for which Metastasio composed, and in working for which his genius found its proper sphere, has so wholly passed away that it is now difficult to assign his true place to the poet in Italian literary history. Compared with Shakespeare, or even with Racine, he hardly merits the title of a dramatist. His inspiration was essentially emotional and lyrical. Instead of creating characters, he created situations for the display of very varied feelings, for all the feelings in fact to which melody allies itself. But in doing this he showed a capable playwright's faculty. His personages act and react upon each other. Their characters, though not in harmony with history or fact, are clearly traced and cleverly sustained. Each of the dramatis personæ is an emotion incarnate and consistent, admirably fitted for musical effect and contrast. The clash and combat of passions are vividly presented, with the smallest possible expenditure of rhetoric, in the dialogues intended for recitative. The climax of emotion is cadenced in appropriate stanzas, with simple but effective imagery, at the close of each important scene. The chief dramatic situations are expressed by lyrics for two or three voices, embodying the several contending passions of the agents brought into conflict by the circumstances of the plot. The total result is not pure literature, but literature supremely fit for musical effect. Language in Metastasio's hands is exquisitely pure and limpid. Of the Italian poets, he professed a special admiration for Tasso and for Marini. But he avoided the conceits of the latter, and was no master over the refined richness of the former's diction. His own style reveals the improvisatore's facility. Of the Latin poets he studied Ovid with the greatest pleasure, and from this predilection some of his own literary qualities may be derived. The pedantic rules of Aristotelian poetics never touched an artist who felt his real vocation to be the interpretation of music. For historical propriety, for the psychology of character, for unity of plot, for probability of incident, he had a supreme disregard. It was indeed his merit to have discarded all these considerations. His poetry was the twin-sister of Italian melody, and he was right in trusting entirely to music and action on the stage to render his conceptions vital. What, therefore, he gained during his own lifetime, while the musical system to which he subordinated his genius was yet living, he has since lost when, as now, he must be studied by readers who have only a faint and dim conception of that perished art. For sweetness of versification, for limpidity of diction, for delicacy of sentiment, for romantic situations exquisitely rendered in the simplest style, and for a certain delicate beauty of imagery sometimes soaring to ideal sublimity, he deserves to be appreciated so long as the Italian language lasts.

There are numerous editions of Metastasio's works. That by Calsabigi, Paris, 1755, 9 vols. 8vo, published under his own superintendence, was the poet's favourite. Another of Turin, 1757, and a third of Paris, 1780, deserve mention. The posthumous works were printed at Vienna, 1795. The collected editions of Genoa, 1802, and Padua, 1811, will probably be found most useful by the general student. Metastasio's life was written by Aluigi, Assisi, 1783; by Charles Burney, London, 1796; and by others; but by far the most vivid sketch of his biography will be found in Vernon Lee's *Studies of the 18th Century in Italy*, London, 1880, a work which throws a flood of light upon the development of Italian dramatic music, and upon the place occupied by Metastasio in the artistic movement of the last century. (J. A. S.)

METCALFE, Charles Theophilus Metcalfe, Baron (1785–1846), a distinguished administrator, was born at Calcutta on January 30, 1785; he was the second son of Thomas Theophilus Metcalfe, then a major in the Bengal army, who afterwards became a director of the East India Company, and was created a baronet in 1802. Having been educated at Eton, where he read extensively, he in 1800 sailed for India as a writer in the service of the Company. After studying Oriental languages with success at Lord Wellesley's college of Fort William, he, at the age of sixteen, received an appointment as assistant to Lord Cowley, then resident at the court of Sindhia; in 1802 he became assistant in the office of the chief secretary; in 1803 he was transferred to that of the governor-general, and in 1806 to that of the commander-in-chief. On August 15, 1806, he became first assistant to the resident at Delhi, and in 1808 he was selected by Lord Minto for the difficult post of envoy to the court of Ranjit Sinh at Lahore; here,

on April 25, 1809, he successfully concluded the important treaty securing the independence of the Sikh states between the Sutlej and the Jumna. Four years afterwards he was made principal resident at Delhi, and in 1819 he received the appointments of secretary in the secret and political department, and of private secretary to the governor-general (Lord Hastings). From 1820 to 1823 Sir Charles (who succeeded his brother in the baronetcy in 1822) was resident at the court of the nizam, but in the latter year he was compelled by the state of his health to retire from active service; in 1825, however, he was so far restored as to undertake the residency of the Delhi territories. Two years afterwards he obtained a seat in the supreme council, and in February 1835, after he had for some time been governor of Agra, he, as senior member of council, provisionally succeeded Lord William Bentinck in the governor-generalship. During his brief tenure of office (it lasted only till March 28, 1836) he originated or carried out several important measures, including that for the liberation of the press, which, while almost universally popular, complicated his relation with the directors at home to such an extent that he withdrew from the service of the Company in 1838. In the following year he was appointed by the Melbourne administration to the governorship of Jamaica, where the difficulties created by the recent passing of the Negro Emancipation Act had called for a high degree of tact and ability. Sir Charles Metcalfe's success in this delicate position was very marked (see vol. xiii. p. 551), but unfortunately his health compelled his resignation and return to England in 1842. Six months afterwards he was appointed by the Peel ministry to the governor-generalship of Canada, and his success in carrying out the policy of the home Government was rewarded with a peerage shortly after his return in 1845. He died at Malshanger, near Basingstoke, September 5, 1846. See J. W. Kaye's *Life and Correspondence of Charles Lord Metcalfe*, London, 1854.

METELLUS, the name of the most important family of the Roman plebeian gens Cæcilia. They rose to distinction during the Second Punic War, and Nævius satirized them.

Quintus Cæcilius Metellus Macedonicus, prætor 148 B.C. in Macedonia, defeated Andriscus in two battles, and forced him to surrender. He then superintended the conversion of Macedonia into a Roman province. He tried unsuccessfully to mediate between the Achæan league and Sparta, but, when the Achæans advanced, he defeated them easily near Scarpheia; Mummius soon after superseded him, and returning to Italy he triumphed in 146. Consul in 143, he reduced northern Spain to obedience. In 131 censor with Q. Pompeius (the first two plebeian censors), he proposed that all citizens should be compelled to marry. He was a moderate reformer, and was considered the model of a fortunate man; before his death in 115 three of his sons had been consuls, one censor, and the fourth was a candidate for the consulship.

Quintus Cæcilius Metellus Numidicus, whose reputation for integrity was such that when he was accused of extortion the jury refused to examine his accounts, was selected to command against Jugurtha in 109 B.C. He subjected the army to rigid discipline, and aimed solely at seizing Jugurtha himself; he defeated the king by the river Muthul, and next year, after a difficult march through the desert, took his stronghold Thala. Marius, however, accused Metellus of protracting the war, and received the consulate for 107. Metellus returned to Rome and triumphed. Saturninus, whom as censor he tried to remove from the senate, passed in 100 an agrarian law, inserting a provision that all senators should swear to it within five days. All complied but Metellus, who retired to Asia. After Saturninus was killed, he returned, but died shortly after under suspicion of poison.

Quintus Cæcilius Metellus Pius, so called from his efforts to restore his father Numidicus, commanded in the Social War, defeating Q. Pompædius (88 B.C.). Sulla on departing gave him proconsular command over South Italy. When Marius returned, the soldiers, who had no confidence in Octavius, wished Metellus to command, but he refused. Metellus retired to Africa and afterwards to Liguria, resuming his former command on Sulla's return. In 86 he gained a decisive victory over Norbanus at Faventia. In Sulla's proscriptions he pleaded in favour of moderation. Consul in 80 with Sulla, he went to Spain next year against Sertorius, who pressed him hard till the arrival of Pompeius in 76. Next year Metellus defeated Sertorius's lieutenant Hirtuleius at Italica and Segovia, and joining Pompeius rescued him from the consequences of a check at Sucro. From this time Sertorius grew weaker till his murder in 72. Metellus had previously set a price on his head. In 71 he returned to Rome and triumphed. He was an upright man, of moderate ability.

Quintus Cæcilius Metellus Pius Scipio, son of Scipio Nasica, was adopted by the preceding. He was accused of bribery in 60 B.C., and defended by Cicero. In August 52 Pompeius procured him the consulate. Scipio in return supported Pompeius, now his son-in-law. On war being resolved on, Scipio was sent to Syria. His extortions were excessive, and he was about to plunder the temple of Artemis at Ephesus when he was recalled by Pompeius. He commanded the centre at Pharsalus, and afterwards went to Africa, where by Cato's influence he received the command. In 46 he was defeated at Thapsus; in his flight to Spain he was stopped by a corsair, and stabbed himelf. His connexion with two great families gave him importance; but he was selfish and licentious, and his violence drove many from his party.

Quintus Cæcilius Metellus Celer, prætor 63 B.C., was sent to cut off Catiline's retreat northward. Consul in 61, his personal influence prevented the holding of the Compitalia, which the senate had forbidden and the tribunes permitted. He opposed the agrarian law of the tribune L. Flavius, and stood firm even though imprisoned; the law had to be given up. He also tried, though fruitlessly, to obstruct Cæsar's agrarian law in 59. He died that year under suspicion of poison given by his wife Clodia.

METEMPSYCHOSIS, the transmigration of the soul, as an immortal essence, into successive bodily forms, either human or animal. This doctrine, famous in antiquity, and one of the characteristic doctrines of Pythagoras, appears to have originated in Egypt. This indeed is affirmed by Herodotus (ii. 123):—"The Egyptians are, moreover, the first who propounded the theory that the human soul is immortal, and that when the body of any one perishes it enters into some other creature that may be born ready to receive it, and that, when it has gone the round of all created forms on land, in water, and in air, then it once more enters a human body born for it; and this cycle of existence for the soul takes place in three thousand years."

Plato, in a well-known passage of the *Phædrus*, adapts, as was his wont, the Pythagorean doctrine to his myth or allegory about the soul of the philosopher. That soul, he says, though it may have suffered a fall in its attempt to contemplate celestial things, still is not condemned, in its first entrance into another form, to any bestial existence, but, according to its attainments, *i.e.*, to the progress which it has made in its aspiration for celestial verities, it passes, in nine distinct grades, into the body of some one destined to become a philosopher, a poet, a king, a general, a seer, &c.; or, if very inferior, it will animate a sophist or an autocrat (τύραννος). Plato extends the cycle of existence to ten thousand years, which is subdivided into periods of a thousand years, after the lapse of which the souls undergo

judgment, and are admitted to everlasting happiness or condemned to punishment.[1] It is after the period of a thousand years, he adds, that the human soul comes into a beast, and from a beast again into a man, if the soul originally was human.

Pythagoras, who was said to have travelled in Egypt,[2] brought this fantastic doctrine into Magna Græcia, and made it a prominent part of his teaching. He declared that he had himself been Euphorbus, the son of Panthus, in the time of the Trojan War, and had successively inhabited other human bodies, the actions of all which he remembered.[3] Closely connected with his theory of metempsychosis was his strict precept to abstain from animal food, even from eggs, from some kinds of fish, and (for some unknown, probably symbolical, reason) from beans.[4] There can be no doubt that the Egyptian custom of preserving the mummies of cats, crocodiles, and some other creatures had its origin in the notion that they had been inhabited by souls which might some day claim these bodies for their own. We cannot suppose that Plato or the later Greeks really believed in the transmigration of souls, though there are many allusions to it, generally of a somewhat playful character. Thus Menander, in the play called *The Inspired Woman*[5] (Θεοφορουμένη), supposes some god to say to an old man, Crato, "When you die, you will have a second existence; choose what creature you would like to be, dog, sheep, goat, horse, or man." To which he replies, "Make me anything rather than a man, for he is the only creature that prospers by injustice."

Absurd and fantastic as such a doctrine as metempsychosis appears at first sight to be, it was in reality a logical deduction from primitive ideas about the nature of the soul. It is necessary to explain these ideas (which have important bearings on other questions) in order to show that metempsychosis was almost a necessary corollary to the belief that the soul was the vital or animating principle,—that the one distinction between organic and inorganic was the existence in the former of a ψυχή.

The difference between a dead body and a living body —or rather, one principal difference—was that the living animal breathed; and it was observed that, as soon as the breath left the body, not only did warmth and motion cease, but the body began to decay. Life, therefore, was breath, an opinion tacitly expressed by the Greek and Roman vocabulary, *animus, anima* (ἄνεμος), ψυχή, πνεῦμα, *spiritus*. But breath is air, and air is eternal and imperishable in its very nature. Therefore the "soul," or portion of air which gave animation to the body, did not perish at the dissolution of the body, but it was returned to the element of which it was composed, and out of which it came. It followed that, from the countless millions of "souls" emancipated from bodies in all time, and still flitting about invisibly in space, the air must literally swarm with souls,—a doctrine taught by Pythagoras.[6] Hence, any creature, human or bestial, that first drew the breath of life, might, so to say, swallow a soul, *i.e.*, take in with the act of respiration the very same particles of air which had animated some former body. For, although the soul was air, and returned to its kindred element, it was supposed to retain a peculiar character in intelligence (φρόνησις), remembrance of the past, and knowledge and experience gained in some former existence. Any creature which first breathed might or might not inhale this or that soul, just as a net thrown into the water may catch this or that fish, or no fish at all. But if no "soul" was inhaled the creature was believed for that reason to die; and the different degrees of intelligence observed in different men and animals led to the notion that there must have been a difference in the souls that first animated them. Even the belief that the soul, especially near the time of dissolution from the body, could foretell future events was based on the notion of intelligence and consciousness resulting from experiences of the past.[7]

As all the science of modern times cannot say precisely what life is, nor how it first came upon this earth, it is not wonderful that so obvious, though wholly erroneous, an explanation should have presented itself to primitive man when first he began to inquire into the causes of things. The extension of life, by the same term ψυχή, to plants and apparently non-breathing things, which, however, had birth, growth, and death, was a development of a philosophic age, and we are not surprised to find Aristotle recognizing one form of life as *vegetable*, φυτικόν.[8] The irrational confusion of "soul" with sentient bodily functions, the attribution to spirits (εἴδωλα) of motion, speech, or other muscular and material action, though still common, while metempsychosis is derided or forgotten, is in reality, perhaps, a less excusable superstition.

The Romans inherited the doctrine of metempsychosis from Ennius, the poet of Calabria, who must have been familiar with the Greek teachings which had descended to his times from the cities of Magna Græcia. In his *Annals*, or Roman history in verse, Ennius told how he had seen Homer in a dream, who had assured him that the same soul which had animated both the poets had once belonged to a peacock, a story that might seem to indicate Indian traditions. The *Pavo Pythagoreus* and the *Somnia Pythagorea* are referred to by Persius and Horace, as well as by Lucretius.[9]

Theories suggesting element-worship naturally led to the notion that air and ether (upper air) were divine.[10] Hence every soul, as being but a portion of it, was in itself divine, and therefore immortal. We thus see that the doctrine of the immortality of the soul, whether attained by a sound or a vicious course of reasoning, was an inevitable conclusion for early thinkers. Pantheism taught that all the universe was pervaded by a divine mind, and Virgil cites the opinion of some, that the intelligence of bees was due to a portion of this universal mind residing in them, a view closely allied to the doctrine of metempsychosis.[11] A divine thing might be polluted, but not destroyed; hence the notion of purifying souls by airing them or burning away a material defilement is enlarged upon by Virgil in the sixth book of the *Æneid* (724 *sq.*). (F. A. P.)

METEOR, METEORITE. The term meteor, in accordance with its etymology (μετέωρος), meant originally something high in the air. It has been applied to a large variety of phenomena, most of them of brief duration, which have place in the atmosphere. Disturbances in the air are aerial meteors, viz., winds, tornadoes, whirlwinds, typhoons, hurricanes, &c. The vapour of water in the atmosphere creates by its forms and precipitations the aqueous meteors, viz., clouds, fogs, mists, snow, rain, hail,

&c. The effect of light upon the atmosphere and its contents causes certain luminous meteors, viz., rainbows, halos, parhelia, twilight, mirage, &c. Discussion of all these, and of like phenomena, belongs to METEOROLOGY (*q.v.*).

Another class of luminous meteors, known as shooting or falling stars, fireballs, bolides, &c., have their place in the upper parts of the atmosphere. But by reason of their origin from without they, and the aerolites or meteorites which sometimes come from them, belong properly to astronomy. The term meteor is often used in a restricted sense as meaning one of these latter phenomena. The present article will treat of them alone.

The most remarkable of the meteors (and the most instructive) are those which are followed by the falling of stones to the earth. These have since the beginning of the present century attracted so much attention, and the phenomena have been so frequently examined and described by scientific men, that they are very well understood. The circumstances accompanying the fall of stones are tolerably uniform. A ball of fire crosses the sky so bright as to be visible, if it appears in the daytime, sometimes even at hundreds of miles from the meteor; and if it appears in the night it is bright enough to light up the whole landscape. It traverses the sky, generally finishing its course in a few seconds. It suddenly goes out, either with or without an apparent bursting in pieces, and after a short period a loud detonation is heard in all the region near the place where the meteor has disappeared. Sometimes only a single stone, sometimes several are found. For some falls they are numbered by thousands. About three thousand were obtained from the fall of L'Aigle in 1803, scattered over a region about 7 miles long and of less breadth. A like number was obtained from the fall of Knyahinya on June 9, 1866. At Pultusk a still larger number were collected, scattered over a larger space, by a fall in January 1868. From the Emmet county (Iowa) fall, May 10, 1879, a similarly large number have been secured.

These meteors leave behind them in the air a cloud or train that may disappear in a few seconds, or may remain an hour. They come at all times of day, at all seasons of the year, and in all regions of the earth. They come irrespective of the phases of the weather, except as clouds conceal them from view.

Let us describe one or two of these meteors more in detail. On the evening of the 2d of December 1876, persons in or near the State of Kansas saw, about eight o'clock in the evening, a bright fireball rising from near where the moon then was in the western sky. It increased in brilliancy as it proceeded, becoming so bright as to compel the attention of every one who was out of doors. To persons in the northern part of the State the meteor crossed the southern sky going to the east, to those in the southern part it crossed the northern heavens. To all it went down near to the horizon a little to the north of east, the whole flight as they saw it occupying not over a minute.

The same meteor was seen to pass in nearly the same way across the heavens from west-south-west to east-north-east by inhabitants of the States of Nebraska, Iowa, Missouri, Wisconsin, Illinois, Michigan, Kentucky, Indiana, Ohio, Pennsylvania, and West Virginia. But besides this there were heard near the meteor's path, four or five minutes after its passage, loud explosions like distant cannonading, or thunder, or like the rattling of empty waggons over stony roads. So loud were these that people and animals were frightened. East of the Mississippi river these explosions were heard everywhere within about 60 miles of the meteor's path; and in Bloomington, Indiana, sounds were heard supposed to come from the meteor even at a distance of nearly 150 miles from it. Over central Illinois it was seen to break into fragments like a rocket, and over Indiana and Ohio it formed a flock or cluster of meteors computed to be 40 miles long and 5 miles broad. The sky in New York State was wholly overcast. Persons in Ohio and Pennsylvania, who from their situation could look over the cloud last, saw the meteor passing on eastward over New York. From many places in the State itself came accounts of rattling of houses, thundering noises, and other like phenomena, which at the time were attributed to an earthquake.

At one place in northern Indiana a farmer heard a heavy thud as of an object striking the ground near his house. The next morning he found on the snow a stone of very peculiar appearance weighing three-quarters of a pound, which from its character there is every reason to believe came from the meteor. By putting together the various accounts of observers, the meteor is shown to have become first visible when it was near the north-west corner of the Indian Territory, at an elevation of between 60 and 100 miles above the earth. From here it went nearly parallel to the earth's surface, and nearly in a right line, to a point over central New York. During the latter part of its course its height was 30 or 40 miles. It thus traversed the upper regions of the air through 25° of longitude and 5° of latitude in a period of time not easily determined, but probably about two minutes. A part of the body may have passed on out of the atmosphere, but probably the remnants came somewhere to the ground in New York, or farther east.

A somewhat similar meteor was seen in the evening of July 20, 1860, by persons in New York, Pennsylvania, New England, &c., which first appeared over Michigan, at a height of about 90 miles. The light was so brilliant as to call thousands from their houses. It passed east-south-east, and over New York State, at a height of about 50 miles, broke into three parts which chased each other across the sky. At New York city it was seen in the north, while at New Haven it was in the south. At both places the apparent altitude was well observed, and its true height proved to be about 42 miles above the earth's surface between the two cities. It finally disappeared far out over the Atlantic Ocean. It is doubtful whether any one heard any sound of explosion that came from this meteor, and no part of it is known to have reached the ground. The velocity was at least 10 or 12 miles per second, or fifty times the velocity of sound. These two meteors were evidently of the same nature as those which have furnished so many stones for our museums, except that the one was so friable that it has given us but one known fragment, while the other was only seen to break in two, not even a sound of explosion being known to have come from the meteor.

Next to the stone-producing meteor is the fireball, or bolide, which gives generally a less brilliant light than the former, but in essential appearances is like it. The meteor of July 20, 1860, above described, though unusually brilliant, was one of this class, and represents thousands of bolides which have been seen to break in pieces. The bolides leave trains of light behind them just as the stone meteors do; they travel with similar velocities both apparent and actual, and in all respects exhibit only such differences of phenomena as would be fully explained by differences in size, cohesion, and chemical constitution of stones causing them.

Next to the bolide is a smaller meteor which appears as if one of the stars were to leave its place in the heavens, shoot across the sky, and disappear—all within the fraction of a second. Some meteors of this class are as bright as Venus or Jupiter. Some are so small that though you look directly at the meteor, you doubt whether you see one or

not. In the telescope still smaller ones are seen that are invisible to the naked eye. Meteors comparable in brightness to the planets and the fixed stars are usually called shooting stars.

These various kinds of meteors differ from all other luminous phenomena so as to stand in a group entirely alone. Though they have been sometimes regarded as separable among themselves into three or four different species, and for purposes of description may still be so divided, yet they all seem to have a like astronomical character, and the differences are only those of bigness, chemical constitution, velocity, &c. There appears to be no clear line of distinction between the stone-producing and the detonating meteors, nor between those heard to explode and those seen to break in pieces, nor between these and the simple fireballs, nor between the fireball and the faintest shooting star.

Altitudes of Meteors.—The first important fact about the meteors is the region in which they become visible to us. In hundreds of instances observations have been made upon the luminous path of a meteor at two or more stations many miles apart. When such stations and the path are properly situated relatively to each other, observations carefully made will show a parallax by which the height of the meteor above the earth, the length and direction of the path, and other like quantities may be computed. The general result from several hundred instances is that the region of meteor paths may be in general regarded as between 40 and 80 miles above the earth's surface. Some first appear above 80 miles, and some descend below 40 miles. But an altitude greater than 100 miles, or one below 25, except in the case of a stone-furnishing meteor, must be regarded as very doubtful. Thus the meteor paths are far above the usual meteorological phenomena, which (except auroras and twilight) have not one-tenth of the height of the meteors. But with reference to all other astronomical phenomena they are very close to us. The comets, for example, are well-nigh a millionfold, and even the moon is a thousandfold, more distant from us.

Velocities of Meteors.—When the length of a luminous path is known, and the time of describing it has been observed, it is easy to compute the velocity in miles. Unfortunately the large meteors, describing long paths, come at rare intervals, and unexpectedly, and it is a happy accident when one is observed by a person accustomed to estimate correctly short intervals of time. On the other hand, the total time of visibility of the shooting stars, which come so frequently that they may be watched for, is usually less than a second. It is not easy to estimate correctly such an interval, where the beginning and ending are not marked by something like a sharp click. Hence all estimates and computations of velocities of meteors are to be received with due regard to their uncertainty. We may only say in general that the velocities computed from good observations are rarely if ever under 8 or 10 miles a second, or over 40 or 50 miles, and that some have far greater velocities than others. The average velocity seems to be nearly 30 miles.

What makes the Luminous Meteor.—The cause of a meteor is now universally admitted to be something that enters the earth's atmosphere from without, with a velocity relative to the earth that is comparable with the earth's velocity in its orbit, which is 19 miles per second. By the resistance it meets in penetrating the air the light and other phenomena of the luminous train are produced. Under favourable circumstances, portions of these bodies reach the earth's surface as meteorites.

Meteoroids.—A body which is travelling in space, and which on coming into the air would under favourable circumstances become a meteor, may be called a meteoroid.

The meteoroids are all solid bodies. It would hardly be possible for a small quantity of gas out in space to retain such a density as would enable it on coming into the air to go 10 or 100 miles through even the rare upper atmosphere, and give us the clear line which a shooting star describes. Even if a liquid or gaseous mass can travel as such in space, it would be instantly scattered on striking the air, and would appear very unlike a shooting star or bolide.

Numbers of Meteors.—Of the larger meteors there are in the mean six or eight per annum which in the last fifty years have furnished stones for our collections. A much larger number have doubtless sent down stones which have never been found. Thus Daubrée estimates for the whole earth an annual number of six or seven hundred stone-falls.

But of the small meteors or shooting stars the number is very much larger. Any person who should in a clear moonless night watch carefully a portion of the heavens would, in the mean, see at least as many as eight or ten shooting stars per hour. A clear-sighted and practised observer will detect somewhat more than this number. Dr Schmidt of Athens, from observations made during seventeen years, obtained fourteen as the mean hourly number on a clear moonless night for one observer during the hour from midnight to 1 A.M. A large group of observers, as has been shown by trial, would see at least six times as many as a single person. By a proper consideration of the distribution of meteor paths over the sky, and in actual altitude in miles, so as to allow for mists near the horizon, it appears that the number over the whole globe is a little more than ten thousand times as many as can be seen in one place. This implies that there come into the air not less than twenty millions of bodies daily, each of which, under very favourable conditions of absence of sunlight, moonlight, clouds, and mists, would furnish a shooting star visible to the naked eye. Shooting stars invisible to the naked eye are often seen in the telescope. The numbers of meteors, if these are included, would be increased at least twentyfold.

How densely Space is filled with Meteoroids.—By assuming that the absolute velocity of the meteors in space is equal to that of comets moving in parabolic orbits (we have good reason to believe that this is nearly their true velocity), we may prove from the above numbers that the average number of meteoroids in the space that the earth traverses is, in each volume equal to that of the earth, about thirty thousand. In other words, there is in the average to every portion of space equal to a cube whose edge is about 210 miles one meteoroid large enough to make a shooting star bright enough to be visible to the naked eye. Such meteoroids would, upon an equable distribution, be each in round numbers 250 miles from its near neighbours. All these numbers rest upon Dr Schmidt's horary number fourteen, and for a less practised observer and a less clear sky they would be correspondingly changed. How much they would need to be altered to represent other parts of space than those near the earth's orbit is a subject of inference rather than of observation.

Motion in Space.—The meteoroids, whatever be their size, must by the law of gravitation have motions about the sun in the same way as the planets and comets, that is, in conic sections of which the sun is always at one focus. The apparent motions of the meteors across the sky imply that these motions of the meteoroids relative to the sun cannot as a rule be in or near the plane of the ecliptic. For if they were there, since the motion of the earth is also in the ecliptic, the motion of the meteoroids relative to the earth would be in the same plane. This would involve

that all the meteor paths as seen on the sky would if produced backward cross the ecliptic above the horizon. In fact there is no tendency of this kind. Hence the meteoroids do not move in orbits that are near the ecliptic as the planets do, but like the comets they may and usually do have orbits of considerable inclinations.

Numbers through the Night.—There are more meteors seen in the morning hours than in the evening. If the meteors had no motion of their own in space, the earth would by its motion receive the meteors only on the hemisphere that was in front. There would be no meteors seen in the other hemisphere. On the other hand, if the meteors had such large velocities of their own as that the earth's velocity might be neglected in comparison, and if the directions of the meteors' motions were towards all points indiscriminately, then as many would be seen in one part of the night as another. In fact there are about three times as many seen in the morning hours as in the evening. The law of change from evening to morning gives a means of proving that the mean velocity of meteors is so great that they must in general be moving in long orbits about the sun. In this respect also the meteoroids resemble comets, and are unlike planets, in their motions. Of the stone-furnishing meteors more are seen in the day than in the night, and more in the earlier hours of the night than in the later. This is probably due to the fact that more persons are in a position to see the stone-falls at the periods of greater abundance.

Star Showers.—While the average number of shooting stars for a single observer at midnight may be regarded as tolerably constant, there have been special epochs when many more have been seen. In certain instances the sky has been filled with the luminous trains, just as it is filled by descending snowflakes in a snowstorm, making a veritable shower of fire. One of the best-observed, though by no means the most brilliant, of these showers occurred on the evening of the 27th of November 1872. Some of the observers of that shower, counting singly, saw at the rate of eight or ten thousand shooting stars in the course of two hours. The distances of the meteoroids in the middle of the swarm which the earth then passed through, each from its nearer neighbours, would be 30 or 40 miles.

The following quotations show the impression made by star showers in times past :—

"In the year 286 [of the Hegira] there happened in Egypt an earthquake on Wednesday the 7th of Dhu-l-Ka'dah, lasting from the middle of the night until morning; and so-called flaming stars struck one against another violently while being borne eastward and westward, northward and southward, and no one could bear to look toward the heavens on account of this phenomenon."

"In the year 599 [of the Hegira], on the night of Saturday, on the last day of Muharram, stars shot hither and thither in the heavens, eastward and westward, and flew against one another like a scattering swarm of locusts, to the right and left; people were thrown into consternation, and cried to God the Most High with confused clamour."

"These meteors [November 12, 1799] might be compared to the blazing sheaves shot out from a firework."

"The phenomenon was grand and awful; the whole heavens appeared as if illuminated with sky rockets."

November 13, 1833. "Thick with streams of rolling fire; scarcely a space in the firmament that was not filled at every instant."

"Almost infinite number of meteors; they fell like flakes of snow."

November Meteors or Leonids.—These quotations all refer (except possibly the first) to a shower which has appeared in October and November of many different years since its first known occurrence on the 13th of October 902 A.D. Dates of these showers are given in the following table :—

Oct. 13, 902.	Oct. 17, 1101.	Oct. 28, 1602.	Nov. 13, 1833.
Oct. 15, 931.	Oct. 19, 1202.	Nov. 9, 1698.	Nov. 14, 1866.
Oct. 14, 934.	Oct. 23, 1366.	Nov. 12, 1799.	Nov. 14, 1867.
Oct. 15, 1002.	Oct. 25, 1533.	Nov. 13, 1832.	Nov. 14, 1868.

On several years after 1833, and before and after 1866–68, there were unusual numbers of those meteors seen on the mornings of November 13, 14, and 15, though perhaps they would have been unnoticed had there not been special watching for them. It will be seen that all these showers are at intervals of a third of a century, that they are at a fixed day of the year, and that the day has moved steadily and uniformly along the calendar at the rate of about a month in a thousand years. The change of twelve days in the 17th century is due to the change from old to new style.

The only explanation of this periodical display that is now seriously urged, and the one which is universally accepted by astronomers, is that there is a long thin stream of meteoroids, each of which is travelling about the sun in a conic section. These conic sections are all nearly parallel, and have nearly the same major axis, extending out about as far as to the orbit of Uranus, and each requiring the common period of thirty-three and a quarter years. The length of the stream is such that the most advanced members are six or eight years ahead of the hindermost, and they all cross the earth's orbit with a velocity of about 26 miles a second. Since the earth plunges through the group nearly in the opposite direction, the velocity with which they enter the air is 44 miles a second. One of the facts which have greatly aided us in arriving at this explanation is that these meteors in all the years and through all hours of the night cross the sky as we look at them in lines which diverge from a point near the centre of the sickle in the constellation Leo; hence the paths in the air are parallel. This implies that their velocities relative to the sun are all parallel and equal to each other. The radiation from Leo has given to them the name *Leonids*.

Orbit of the Leonids.—This orbit, common to all the Leonid meteors, is inclined to the ecliptic at an angle of 17° (or rather 163°, since the motion is retrograde), has a major axis of 10·34, a periodic time of 33·27 years, and a perihelion distance a little less than unity.

The above orbit, and that alone, explains the several appearances of the November meteors, the annual and the thirty-three year periods, the radiation from Leo, and the change of day of the month in the course of the centuries. This it does so completely that the result has never been questioned by astronomers. Shortly after the publication by Professor Adams in 1867 of the last link in the chain of the proof of this orbit, there was also published the definitive orbit of the comet 1866 I. That the comet was running almost exactly in the orbit of the meteors was at once recognized. In fact the comet is itself, in a sense, a meteoroid, and the principal member, so far as we know, of the group. Leonids had been seen in 1863, two years and two months in advance of the comet, while those of 1866 were ten months behind it. Those of later years (a few Leonids were seen even in 1870) were extended along the line of the comet's path behind it. The leaders of this long file of meteoroids had passed up beyond the orbit of Jupiter long before those which brought up the rear had crossed that planet's orbit going down toward the sun. The thickness of the stream is less than the ten-thousandth part of its length. In the densest part that we have recently passed through—namely, that traversed in 1833—the density of the stream may be expressed by saying that each meteoroid must in the mean have been 10 or 20 miles from its nearest neighbours.

What makes this Comet and these Meteors describe the same Orbit about the Sun?—Its path might have been inclined to the ecliptic at any angle instead of 163°. Or, with this inclination, its plane might have cut the earth's orbit at any other place than where the earth is on the 14th

of November. Or, happening to have these two elements in common, it might have passed the earth's orbit nearer the sun or farther away from it than the earth is. Or, having these three things in common, it might, by a slight difference in velocity, have had a periodic time much more or much less than thirty-three years. Or, with all these in common, it might have crossed the earth's orbit at a far different angle than the meteors. These several independent elements for the comet and the meteors are substantially identical, and this identity proves almost beyond doubt that between the two either there is now an actual or else there has been in the past a causal connexion. That there is now any physical connexion is thoroughly disproved by the immense magnitude of the stream, and by the isolation and distances from each other of the individual components. It seems difficult to find any cause that should bring into such a strangely shaped group bodies that had originally orbits distributed at random. Hence we are apparently forced to conclude that these meteoroids have something common in their past history. In fact they seem to have been once parts of a single body, and these common elements are essentially those of the parent mass. By some process not yet entirely explained they have become separated from the comet, thrown out of the control of its attractive power, and so left to travel each one in its own orbit. If the cause of separation was not too violent, each new orbit would necessarily be but slightly different from that of the comet. Very small variations in velocity, and hence in periodic time, would in the course of ages scatter the several individuals along the orbit even to the length of many hundreds of millions of miles.

The Meteor Group is not the Comet's Tail.—These meteoroids must be carefully distinguished from the comet's tails. The former follow or precede the comet exactly in the comet's path; the particles that compose the latter are driven off by the sun's repulsion directly away from the comet's path. The meteoroids and the comet have orbits with nearly common elements; the orbits of the particles of the tail have elements that are unlike each other, and unlike those of the comet. The meteoroids are undoubtedly solid masses; the tails are pulverulent or gaseous.

Twin Comets of 1366.—The comet 1866 I. is probably not the only one that has been connected with the November meteors. In 1366, a few days after the earth went through the meteor stream, a comet appeared in the northern heavens, and, passing directly in the line of the stream so close to the earth as to describe an arc of 90° in a single day, disappeared in the constellation Aquarius. Immediately upon its disappearance a second comet was seen in the north, which followed nearly in the same path. The Chinese accounts are not sufficiently exact to furnish independent orbits for them, but both comets were undoubtedly members of the Leonid stream. The comet 1866 I. may be identical with one of them.

The Andromeds and Biela's Comet.—Mention has been made of the star shower of November 27, 1872. The periodical comet known as Biela's, which makes three revolutions in twenty years, passes very near the earth's orbit at a longitude corresponding to November 27, but by reason of its direct motion the node has had considerable motion in longitude as the result of perturbations. Meteors having the same orbits as Biela's comet would have a radiant in the constellation Andromeda, that is, would cross the sky in lines diverging from a point in that constellation. They might, however, be at dates after or even before November 27.

Unusual numbers of meteors were seen December 7, 1798, by Brandes. A like abundance was seen December 7, 1838; and, as they had been expected, and radiation was now looked for, they were found to diverge from a point in Andromeda. Hence they have been called Andromeds. Since 1852 Biela's comet itself has been entirely lost. The star shower of November 27, 1872, previously referred to, had a radiant in Andromeda, and in every way appeared as though its meteors had once been parts of Biela's comet. A sprinkle three days earlier, on the night of November 24, had the same radiant, and came from a less dense outlying parallel stream. A small comet was seen in the southern sky by Pogson in the direction opposite to the radiant shortly after the shower. Biela's comet had been found in 1845-46 to be in two parts, which at its next return to perihelion in 1852 had separated to eight times their former distance. But the meteor streams of 1872 could hardly have been separated from the comet so recently, and the Pogson comet if of the same origin must also have left the parent mass at an earlier date than 1845. No ordinary perturbations would in a short period have so changed the orbits. The parts of the small stream traversed by the earth, December 1838 and December 1798, were far from the comet, and these fragments must have been thrown off much earlier.

The Perseids and the Comet 1862 III.—There is a third epoch when meteors appear in unusual numbers, viz., the 9th to 11th of August. This "sprinkle," as it may be called, has been seen constantly at the time named for nearly fifty years, and there are on record accounts of similar appearances in the earlier years before its annual character had been discovered. Some observers have thought that there were evidences of a variation having a long period, but the proof seems as yet unsatisfactory, and the display may be regarded as tolerably constant from year to year. On every 10th of August we may confidently expect a display of meteors that shall be at least four or five times as numerous as those of ordinary nights. The radiant is in the constellation Perseus, and hence the name Perseids.

The comet 1862 III., which has a period of more than a hundred years, passes close to the earth's orbit, nearly cutting it at the place of this shower, and has a velocity and direction corresponding to this radiant. Hence a connexion of the Perseid meteors with this comet is presumed, like that which the Leonids and Andromeds have with the comet 1866 I. and Biela. The meteors are distributed along this orbit more regularly than along either of the other two, and at the same time the breadth of this group is a hundred times greater than that of the Leonids. We must for the present regard it rather as a meteor ring, the meteoroids being scattered along the entire conic section which the comet describes. This ring has an inclination of 113° with the ecliptic.

Meteors of April 20-21—*Lyraids.*—About the 20th of April there have been several quite brilliant star showers, the earliest on record having been in the year 687 B.C. On that day meteors have been observed which radiated from Lyra, and to these the name Lyraids has been given. The comet 1861 I. passes near the earth's orbit in that longitude, and any meteors having such a connexion with it as is proved for the Leonids with comet 1866 I. would also radiate from Lyra.

Again, at several other periods of the year, meteors have been seen in unusual numbers which seem to be connected with certain comets.

Meteor Radiants.—We have thus definite proof that the earth at certain epochs plunges through meteor streams, and that these streams travel along the same track as certain comets. The question is at once asked—Do not the sporadic meteors, those which are seen on any and all nights of the year, belong to similar streams? An immense amount of labour has been spent in observing the paths of meteors, and classifying them, so as to detect and prove the existence of radiant points. As many as a thousand such radiants have been suggested by the different investigators. Some of these are duplicates, some will prove to be accidental coincidences; but a goodly number may reasonably be expected to endure the test of future observations. Such will show the existence of meteor streams, and perhaps will be connected with comets that are now known, or that may hereafter be discovered.

The radiants have been spoken of as if they were points in the heavens. This is so nearly true as to justify all the conclusions that have been deduced above. But in fact a radiant, even in the star showers in which it is most sharply defined, must be regarded as a small area. The apparent meteor paths when produced backward do not exactly meet in a point. If they be treated as proceeding from a small area, it does not appear that this is a long narrow one. Hence it may be shown that the paths of the meteors in the air are not exactly parallel either to a line or to a plane. This can hardly be due to a want of parallelism of the paths before the meteoroids meet the earth, but is rather due to their glancing as they strike the

air. These facts add not a little to the difficulties to be overcome by the energetic observers and investigators who are trying to deduce order out of an apparent chaos.

Meteorites.—The fragments which fall immediately after the disappearance of large meteors have been carefully collected and preserved in mineralogical museums, and have been studied with special interest. The largest collections in Europe are in Vienna, Paris, London, and Berlin, some of these representing over three hundred localities. In the United States there are large collections at New Haven, Amherst, and Louisville.

In several respects these fragments differ at first sight from terrestrial rocks.

They are when found almost always covered in part or entirely with a very thin black crust, generally less than $\frac{1}{50}$ of an inch in thickness. This crust may have a bright lustrous surface, or it may be of a lustreless black. It has evidently been melted, yet so rapidly as not to change in the least the parts of the stone immediately adjacent. Streaks showing the flow of the melted matter are often seen on the surface. Upon some surfaces are what appear to be deposits of the melted matter that has flowed off from the others. Some surfaces are only browned, showing an apparently recent fracture, and some cracks are found in stones which are not yet completely broken in two.

The surfaces very often have small cup-like cavities, sometimes several inches in diameter, sometimes like deep imprints in a plastic mass made by the ends of the fingers, and sometimes still smaller. These "cupules" have not only various sizes in different stones, but even in the same stone differ considerably from one surface to another. They appear in meteorites that are almost exclusively iron, as well as in those mainly destitute of that metal, and they may be regarded as a characteristic of meteorites.

The meteorites have usually metallic iron as one of their component parts. Native iron is very rare indeed among terrestrial minerals, and its presence in the meteorites is therefore characteristic. Sometimes the iron forms the principal part of the body, giving it the appearance of a mass of that metal. Sometimes it forms only a connected framework which is filled in with mineral matter. Sometimes particles of iron are scattered through a stony mass; and a few meteorites are said to be destitute of metallic iron altogether. The metallic iron is always accompanied with nickel.

The stony meteors when broken or cut through have usually a greyish interior, and often exhibit a peculiar globular structure. From the small rounded grains that give it this appearance, the name chondrite (from χόνδρος, a ball) has been applied to this kind of meteorite. Sometimes the irregular fragments are compacted into a kind of breccia.

The pieces as we find them are always apparent fragments of some larger mass, and there is no structural appearance which would indicate that the mass might not be a fragment of a still larger one. In some of the falls fragments picked up at a distance of miles from each other fit together in their simply browned surfaces, showing that they were true fragments recently separated. In some cases surfaces of the stones are partially polished. In some a cross section of the stone exhibits thin black lines as though the melted matter of the surface had been forced into the crevices of the partially broken stone.

The stones when seen to fall, if at once picked up, are usually too warm to be taken in the hand. But cases are on record in which the stones were excessively cold. They sometimes, on striking the ground, penetrate into it from 1 to 3 feet. In extreme cases large ones have struck much deeper into soft earth. Sometimes they are broken to pieces by the impact with the hard earth.

The stones are usually not very large. Although the light of the meteor is such as sometimes to be seen over a region 1000 miles in diameter, and the detonation gives phenomena suggestive of an earthquake over many counties, yet a stone exceeding 100 ℔ is quite exceptional in our collections. The total weight secured at any fall has rarely if ever amounted to a thousand pounds. The average weight of nine hundred and fifty perfect specimens of the Pultusk fall in the Paris museum is 67 grammes, or less than $2\frac{1}{2}$ oz. One of the Hessle meteorites in the Stockholm museum weighs less than 1 grain. Many of the Emmet county meteorites (May 10, 1879) are not much larger, though the largest specimen of that fall weighs nearly 500 ℔.

Meteors traversing the Atmosphere.—We can now get a very good idea of the history of that part of a meteorite's life between its entrance into the air and its arrival at the earth. It is entirely invisible until it has reached that height at which the density of the air is enough to create considerable resistance. Up to that time it moves almost exclusively in obedience to the sun's attraction. The earth's attraction may be neglected, especially during the passage through the air. Since the velocity is a hundred times that of sound, the elasticity of the air is impotent to remove it from in front of the meteorite, or to prevent a high degree of condensation. Perhaps the air is liquefied immediately in front of the stone. Heat is developed in it enormously, and the stone being pressed closely against the hot air is melted, with an intense light. The condensed air charged with the melted matter is pushed aside, and left behind nearly in the wake of the meteor to form the train. The brightness of the train rapidly diminishes behind the meteor, so that the light of the meteor and the train, modified by irradiation, make the whole appear to a distant eye of the shape of a pear or candle-flame. The stone being a poor conductor of heat, and itself rigid, is not heated in the interior either by condensation or conduction, and may reach the ground with its surface only heated, while the interior is as cold as it had been out in space.

If the stone is a small one it will soon be used up by this intense fire. Until its front surface is rounded by the flame, the irregular resistances may cause such a stone to glance. But if the stone is larger it will lose velocity less rapidly. As it comes down into the region where the air is more dense, it will in spite of loss of velocity meet greater resistance. The air pressed hard against it burns it unequally, forming cupules over its surface. The pressure of the air cracks the stone,—perhaps scaling off small fragments, perhaps breaking it into pieces of more uniform size. In the latter case the condensed air in front of the meteor being suddenly relieved will expand, giving the terrific explosion which accompanies such breaking up. In either case a fragment may have still velocity enough to burn on for an instant in its new path and then come invisibly to the earth, covered with a coating, the greater part obtained after the principal explosion. In the latter part of the course the original velocity has almost all disappeared, so that the sound travels faster than the meteor. The air's resistance exceeds the earth's attraction, and the stones strike the ground only with the force of a spent cannon ball. It is no doubt in violent disruption that some of the fractures are made in such a way as to give the rubbed and polished surfaces.

Trains of Meteors.—The smaller meteors generally have no perceptible train. Only in exceptional cases do the trains of ordinary shooting stars remain visible longer than a fraction of a second. An unusual number of the Leonids have a bluish train. But the brighter shooting stars and the larger meteors sometimes have trains that endure for minutes, and in extreme cases for an hour. Such trains are at first long narrow lines of light, though much shorter

than the track of the meteor. They begin at once to broaden in the middle and to fade away at one or both ends. Presently they become curved, sometimes with two or three convolutions. The white cloud floats slowly away among the stars, coiling up more and more, and finally fades out of sight. The cause of all this seems to be as follows. The heated air charged with the debris of the meteor is by the meteor's impact driven off horizontally, causing the narrow train to spread into a cloud. The currents of air differing in direction at different altitudes twist the cloud into its varied fantastic forms. Attempts to obtain the spectrum of the trains have been made, and sodium and magnesium lines have been thought to be detected in them. The observation, however, is one that is not easy to make or confirm. The trains have often colours other than white, and in the case of the brighter meteors different colours are seen in the different parts of the train.

Magnitude.—Some computations have been made of the size of the shooting star meteoroids from the mechanical equivalent of the light developed by their disintegration. If all the energy of the meteor is changed into light, then these computations would be conclusive. But a part is spent in disintegrating and burning the stone, a part in heating the air, and a part in giving direct motion to portions of air. A computation based on the light developed gives only a lower limit to the size.

It seems probable that the larger meteors might be safely regarded as weighing on entering the air only a few hundreds or at most a few thousands of pounds. The smallest visible shooting stars may be equal in size to coarse grains of sand, and still be large enough to furnish all the light exhibited by them. The largest shooting stars furnish matter enough to fill with thin trains cubic miles of space, but this need not require a very large mass.

Meteoric Irons.—There have been found at various times on the surface of the earth masses of metallic iron combined with nickel. These have been so like the irons which have been known to fall, both in their structure and in composition, that they have been without hesitation classed among the meteoric irons. A mass of this character weighing 1635 ℔, found in Texas, is in the Yale College Museum. The Charcas (Mexico) iron in the Paris museum is about the same size. A ring-shaped mass somewhat smaller, from Tuczon, is in the United States National Museum in Washington. A still larger mass is in the British Museum, and many other large masses are in public collections or private possession.

Widmannstätten Figures.—If in any of the meteoric irons, whether seen to fall or found on the earth, a section is cut and polished and then etched with acids, a series of peculiar lines are developed which are known as Widmannstätten figures. The lines of iron unattacked by the acid consist of an irregular grouping of parallel rulings often lying along the faces of a regular octahedron. The exhibition of these figures and the combination of iron with nickel have been usually considered conclusive evidence of the meteoric origin of any iron mass.

Nickel Iron of Ovifak.—In 1870 Baron Nordenskiöld, in his voyage to Greenland, found on the shore of the island of Disco fifteen iron masses, the largest of which weighed 20 tons, all in an area of half an acre. In the basaltic rocks not far distant other iron masses were found embedded in the basalt. The presence of nickel with the iron, and the development of lines like the Widmannstätten figures, were at once accepted as proof of their meteoric origin, in spite of the combination with basalt. A more complete examination has, however, established the terrestrial origin of these irons, and given reasons to hope for new discoveries of relations existing between the earth and the meteors. The additional discovery of small particles of metallic iron in certain other igneous rocks proves that the union of the Ovifak irons with basalt is not exceptional.

Chemical Constitution of the Meteorites.—No new element has been found in the meteorites. Three elements most widely distributed and most important among the meteorites—iron, silicon, and oxygen—are also most abundant in our earth. Daubrée gives the following lists of elements, arranged somewhat in the degree of their importance, in meteorites (Maskelyne adds lithium and antimony):—

Iron.	Titanium.	Arsenic.
Magnesium.	Tin.	Phosphorus.
Silicon.	Copper.	Nitrogen.
Oxygen.	Aluminium.	Sulphur.
Nickel.	Potassium.	Chlorine.
Cobalt.	Sodium.	Carbon.
Chromium.	Calcium.	Hydrogen.
Manganese.		

Minerals in Meteorites.—Among the minerals in the meteorites there are several which occur in the rocks on the earth. Among these are cited by Daubrée peridote, pyroxene, enstatite, triclinic felspar, chromite, magnetic pyrites, iron oxide, graphite, and probably water. Several minerals, however, are found which, so far as now known, are peculiar to the meteorites:—metallic nickel-iron, phosphide of iron and nickel (schreibersite), sesquisulphide of chromium and iron (daubréelite), sulphide of calcium (oldhamite), and chloride of iron (lawrencite).

Meteorites of different falls are in general unlike; but there are many instances in which the stones of two falls are so similarly constituted that it is not easy to distinguish them.

In four falls (Alais, Cold Bokkeweld, Kaba, and Orgeuil) the stones contain little or no iron. In these carbon appears not as graphite but in union with hydrogen and oxygen, and also with soluble and even deliquescent saline matters. The combinations are such as to suggest the existence of humus and organic remains. But after careful search nothing of this kind has been detected in them. In general the meteorites show no resemblance in their mechanical or mineralogical structure to the granitic and surface rocks on the earth. One condition was certainly necessary in their formation, viz., the absence of free oxygen and of enough water to oxidize the iron and other elements. Perhaps it is to this fact that are due the resemblances between these minerals and those of the deep-seated rocks of the earth in the formation of which free oxygen and water were also not present.

Gases in Meteorites.—The meteoric stones and irons when reduced to fine particles and placed in the vacuum of a Sprengel air-pump give off small quantities of gases which may be reasonably presumed to have been occluded by the irons at some time in their earlier history. Professor Graham found hydrogen in meteoric irons. Professor Wright has shown that a moderate heat drives off from the stony meteorites carbonic acid and carbonic oxide with a small amount of hydrogen. As the heat increases the proportion of hydrogen (and even some nitrogen) increases till at a full red heat the hydrogen given off is by far the largest portion. From the irons similar gases are given off, but the carbon compounds are not so large a component as hydrogen. The spectra seen in the tails of comets are not strikingly like those of any of these gases. But it is impossible to reproduce in the laboratory the conditions under which the matter of comet's tails is giving off its light. We cannot therefore say that these gases may not be the important parts of the cometic coma and tails.

Meteoroid as Part of a Comet.—Assuming that the meteorite and meteoroid once formed an integral part of a comet, not a little information is given us of the nature of this mysterious body. There is room also for speculation.

First, the comet may be a single hard body which comes from the cold of space into the heat of the sun, and there has fragments broken off, just as a stone is shattered in a hot fire. The nucleus of some of the comets must be very small because invisible in the telescope, and an impulse that would raise a stone on the earth only a few inches would send it permanently away from such a comet. The exposure of new surfaces to the heat of the sun might give occasion for the development of gas to form the comet's tail.

Or, secondly, the comet may be a tolerably compact aggregation of small bodies not in contact, each one being of the size of a meteoroid, and kept near to the rest, not by cohesion, but by their combined attraction. The total mass being small, some members of the group near the comet's perihelion passage can be by the sun's perturbing action thrown out into orbits quite independent of the comet itself, and yet such as relative to the sun shall resemble that of the main group. Perturbations resembling tidal waves might be preparing other members to be cast off at the next perihelion passage of the comet.

In either case, if we suppose, as seems probable, that the comet came from outside the solar system, and that a disturbance by a large planet changed the original hyperbolic orbit into an ellipse, the comet must have passed that planet as a very compact group, if not in a single mass, else the disturbance that changed the orbit would have scattered the group beyond the power of a future recognition of the common origin of the fragments.

Meteoroids as Fuel of the Sun.—The idea has been held by distinguished physicists that the meteoroids in falling into the sun furnish by their concussion a supply for the heat which the sun is constantly sending off into space,—that they are in fact the fuel of the sun. Such a view, however, receives but little support from facts which we know about meteors. The meteoroids of the August and two November periods are evidently permanent

members of the solar system moving in closed orbits. The same is by inference highly probable for most of the other meteoroids, and may be true of all of them. Permanent members of the solar system, however, if they ever fall into the sun, do so only after a long period of perturbation. If any meteoroids come from stellar spaces and have any uniform or random distribution of velocities or directions, only a very small portion of these would hit the sun's surface. The far greater portion would go on in hyperbolic orbits. But the earth receives the impact of its portion of these foreign meteoroids, both in their inward and outward course, and in addition encounters a full share of the permanent members of the solar system, of which the sun receives very few or none. It is not hard to show that a supply of meteoroids to the sun sufficient to make good its daily loss of heat would require that the twenty million meteoroids which the earth daily encounters, even if all were from stellar space, should have an average weight of hundreds of tons. The facts do not warrant the admission of any such magnitude even for the large meteors, much less for the ordinary and small shooting stars. Whatever be the source of the sun's heat, all the meteoroids of which we know anything are totally inadequate to supply the waste.

The literature of meteors and meteoroids is very much scattered. It is mainly contained in the scientific journals and in transactions of learned societies. The series of valuable *Reports* of the Luminous Meteor Committee of the British Association contains not only the record of an immense amount of original observations, but also year by year a digest of most of the important memoirs.

Meteoric science is a structure built stone by stone by many builders. In this article no attempt has been made to assign to each builder the credit for his contribution. (H. A. N.)

METEORA, a remarkable group of rock-built monasteries in Thessaly, in the northern side of the valley of the Peneus, not quite 20 miles north-east of Triccala, and in the immediate vicinity of the village of Kalabaka, Stagus, or Stagoi (the ancient Æginium). From the Cambunian chain two vast masses of rock are thrust southward into the plain, surmounted by a number of huge isolated columns from 85 to 300 feet high, "some like gigantic tusks, some like sugar-loaves, and some like vast stalagmites," but all consisting of iron-grey or reddish-brown conglomerate of gneiss, mica-slate, syenite, and greenstone. On the summit of these rocky pinnacles—accessible only by aid of rope and basket let down from the top, or in some cases by a series of almost perpendicular ladders climbing the cliff to the mouth of a tunnel—stand the monasteries of Meteora (τὰ Μετέωρα). At one time they were twenty-four in number; but Holland (1812) and Hughes (1814) found them reduced to ten; at Curzon's visit (1834) there were only seven; and in 1853 not more than four of these were inhabited by more than two or three monks. Meteora *par excellence* is the largest and perhaps the most ancient. The present building was erected, according to Leake's reading of the local inscription, in 1388 (Björnståhl, the Swedish traveller, had given 1371), and the church is one of the largest and handsomest in Greece. St Barlaam's and St Stephen's (the latter founded by the emperor John Cantacuzene) are next in importance. The decorations of the churches contain a large amount of material for the history of Byzantine art, not much inferior in value to the similar treasures at Athos.

Unless the identification with the Ithome of Homer be a sound one, there is no direct mention of the rocks of Meteora in ancient literature, and Professor Kriegk suggests that this may simply be due to the fact that they had not then taken on their present remarkable form. Æginium, however, is described by Livy as a strong place, and is frequently mentioned during the Roman wars; and Stagus appears from time to time in Byzantine writers.

METEOROLOGY

METEOROLOGY, in its original and etymological sense, included within its scope all appearances of the sky, astronomical as well as atmospherical, but the term is now restricted to the description and explanation of the phenomena of the atmosphere which may be conveniently grouped under weather and climate. These phenomena relate to the action of the forces on which the variations of pressure, temperature, humidity, and electricity of the atmosphere depend, but in an especial sense to the aerial movements which necessarily result from these variations.

In the more exact development of meteorology, the scientific investigation of climate long preceded that of weather. Humboldt's work on *Isothermal Lines*, published in 1817, must be regarded as the first great contribution to meteorological science. The importance of this inquiry into the distribution of terrestrial temperature it is scarcely possible to overestimate, for, though the isothermals were necessarily to a considerable extent hypothetical, there cannot be a doubt that they presented a first sketch of the principal climates of the globe. Dove continued and extended the investigation, and in his great work *On the Distribution of Heat on the Surface of the Globe*, published in 1852, gave charts showing the mean temperature of the world for each month and for the year, together with charts of abnormal temperature. To this, more than to any other work, belongs the merit of having popularized the science of meteorology in the best sense, by enlisting in its service troops of observers in all parts of the civilized world.

In 1868 another series of important charts were published representing by isobaric lines the distribution of the mass of the earth's atmosphere, and by arrows the prevailing winds over the globe for the months and the year. By these charts the movements of the atmosphere and the immediate causes of these movements were for the first time approximately stated, and some knowledge was thereby attained of some of the more difficult problems of meteorology. It was shown that the prevailing winds are the simple result of the relative distribution of the mass of the earth's atmosphere, in other words, of the relative distribution of its pressure, the direction and force of the prevailing winds being simply the flow of the air from a region of higher towards a region of lower pressure, or from where there is a surplus to where there is a deficiency of air. It is on this broad and vital principle that meteorology rests, which is found to be of universal application throughout the science, in explanation, not only of prevailing winds, but of all winds, and of weather and weather changes generally. One of the more important uses of the principle is in its furnishing the key to the climates of the different regions of the earth; for climate is practically determined by the temperature and moisture of the air, and these in their turn are dependent on the prevailing winds, which are charged with the temperature and moisture of the regions they have traversed. The isobaric charts show further that the distribution of the mass of the earth's atmosphere depends on the geographical distribution of land and water in their relations to the sun's heat and to radiation towards the regions of space in different seasons.

In 1882 Loomis published a map showing the mean rainfall of the globe. This map and others that have been constructed for separate countries show conclusively that the rainfall of any region is determined by the prevailing winds considered in relation to regions from which they have come, and the physical configuration and temperature of the part of the earth's surface over which they blow. The maximum rainfall is precipitated by winds which,

having traversed a large breadth of ocean, come up against and blow over a mountainous ridge lying across their path, and the amount deposited is still further increased if the winds pass at the same time through regions the temperature of which constantly becomes colder. On the other hand, the rainfall is unusually small, or *nil*, when the prevailing winds have not previously traversed some extent of ocean, but have crossed a mountain ridge and advance at the same time into lower latitudes, or regions the temperature of which is markedly higher.

While the observational data for the determination of the geographical distribution of the prime elements of climate, viz., the pressure, temperature, moisture, and movements of the atmosphere and the rainfall were being slowly but surely collected, the great importance of the study of weather came gradually to be recognized. Additional impetus was given to this branch of study from its intimate bearings on the eminently practical question of storm warnings. Synchronous weather maps, showing the weather over a considerable portion of the earth's surface, were constructed, and some advance was made in tracing the progress of storms from day to day. Unquestionably one of the first problems of meteorology is to ascertain the course storms usually follow and the causes by which that course is determined, so as to deduce from the meteorological phenomena observed, not only the certain approach of a storm, but also the particular course that storm will take. The method of practically conducting this large inquiry in the most effective manner was devised by the genius of Leverrier, and begun to be carried out in 1858 by the daily publication of the *Bulletin International*, to which a weather map was added in September 1863. This map showed graphically for the morning of the day of publication the atmospheric pressure, and the direction and force of the wind, together with tables of temperature, rainfall, cloud, and sea disturbance from a large number of places in all parts of Europe. From such weather maps forecasts of storms are framed and suitable warnings issued; but above all a body of information in a very handy form is being collected, the careful study and discussion of which is slowly but gradually leading to the issue of more exact and satisfactory forecasts of weather, and to a juster knowledge of these great atmospheric movements which form the groundwork of the science.

The most cursory glance is sufficient to show that the ever-changing physical phenomena with which it is the business of meteorology to deal are all referable to the action of the sun, it being evident that if the sun were blotted out from the sky a cold lifeless uniformity would rapidly take possession of the whole surface of the globe. Meteorological phenomena naturally group themselves into two great classes,—those dependent on the revolution of the earth on its axis, and those dependent on its revolution round the sun taken in connexion with the inclination of its axis to the plane of its orbit. The science thus divides itself into two great divisions, the first comprising diurnal phenomena and the second annual phenome

Diurnal March of Phenomena.

Temperature.—Of the daily changes which take place in the atmosphere, the first place must be assigned to those which relate to temperature, seeing that on these all other changes are either directly or indirectly dependent. Observations of the temperature of the air are therefore of the first importance in meteorology. A perfectly accurate observation of the temperature of the air is unquestionably among the most difficult to make of all physical observations, the difficulty being to eliminate the effects of radiation of surrounding objects. The nearest approach yet made to the solution of this important problem of physical inquiry was made by Dr Joule in a communication to the Philosophical Society of Manchester (November 26, 1867, *Proc.*, vol. vii. p. 35). But the manipulative skill and time demanded by the method there detailed render it quite unsuitable for general adoption anywhere in collecting the observational data required in the determination of this important element of climate. It is therefore necessary to fall on some method which, while it gives results that can only be regarded as approximate, secures the essential element of uniformity among the observations.

Fig. 1 represents Stevenson's louvre-boarded box for the thermometers, which is now very widely used for temperature observations. The box is made of wood, and louvred all round so as to protect the thermometers inside from radiation, and at the same time secure as free a circulation of air as is consistent with a satisfactory protection from radiation. The box is painted white, both inside and outside, and screwed to four stout wooden posts, also painted white, firmly fixed in the ground. The posts are of such a length that when the thermometers are hung in position the bulbs of the minimum thermometer and hygrometer are exactly at the same height of 4 feet above the ground, the maximum thermometer being

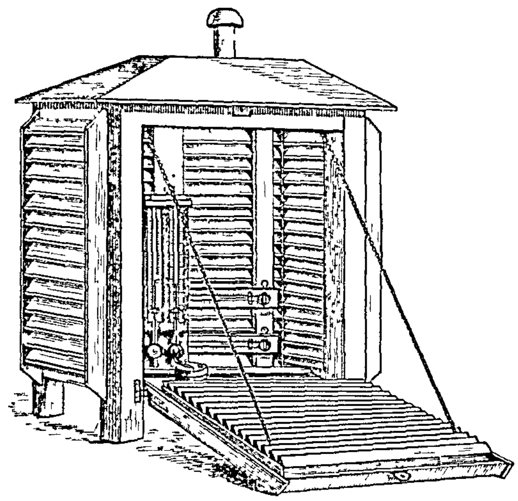

Fig. 1.—Thermometer Box.

hung immediately above the minimum thermometer. This thermometer box is placed over a plot of grass, and in a free open space to which the sun's rays have free access during as much of the day as surrounding conditions admit of. It will be observed that the thermometers are suspended on cross-laths in the centre of the box and face the door, which should always open to the north. It is not possible to overestimate the importance of seeing that uniformity of height above ground and method of protecting the thermometers is secured, since in no other way is it possible to obtain results from different places which shall be comparable with each other and thus supply satisfactory materials for the investigation and development of comparative climatology.

A desired uniformity is yet far from being attained among the meteorological systems of different countries. Thus in Russia the box for the protection of the thermometers is made of zinc, on the supposition that such a box follows more closely the changes of temperature of the air than a box of wood. Owing to these international diversities of observation, it is extremely desirable that steps were taken to ascertain, by Joule's method of observing, the approximate errors peculiar to each sort of thermometer box, in order that the temperatures of different countries may be compared together in a more satisfactory manner than has yet been possible.

Interchanges of temperature among bodies take place by conduction, convection, and radiation. In meteorology the most important illustrations of conduction are the propagation downwards through the earth's strata of the changes of the temperature of the surface as it is heated during the day and cooled during the night, and the propagation of the same changes of temperature through the lowest stratum of the air which rests on the surface. Since sand and light loose soils are much worse conductors of heat than clay and dense soils, it follows that loose soils

and tracts of sand are subject during the day to higher temperature and during the night to lower temperature near the surface than dense soils, and that frosts and extreme temperatures do not penetrate so far into loose as into dense soils. It is on these differences that some of the more striking features of climates depend. As snow is one of the worst conductors of heat, owing to the quantity of air filling the interstices among the ice crystals, it protects the soil it covers by setting a limit to the depth to which the severe frosts of the surface penetrate, and by arresting the escape of the heat of the soil upwards to the air.

The communication of heat from one part of the earth to another by convection is seen on a grand scale in the winds and in the currents of the ocean. It is seen also in the ascending and descending currents of the atmosphere everywhere, which have their origin in the daily and unequal changes of temperature to which the surface of the earth is subject. The direct and beneficial effect which results from atmospheric and oceanic circulation is a more equable distribution of temperature over the globe, thus moderating the rigours of the polar regions and the heat of the tropics.

An interchange of heat is constantly going on among bodies exposed to each other, whatever be their temperature. This mode by which heat is communicated from one body to another is called radiation. Radiant heat proceeds in straight lines, diverging in all directions from the source, is only in a limited degree influenced by the air through which it passes, and is not diverted from the straight course by the wind. The intensity is proportional to the temperature of the source, and is greater according to the degree of inclination of the surface on which the rays fall.

If then a body be placed in the presence of other bodies, some colder and some warmer than itself, it will from this mutual interchange of temperature receive more heat from the warmer bodies than it radiates to them, and consequently becomes warmer; but it will receive less heat from the colder bodies than it radiates to them, and its temperature consequently falls. This is precisely the condition in which the earth is placed in space. When a part of the surface is turned towards the sun, that part of the surface receives more heat than is radiated from it; and the temperature consequently rises most in that region which for the time is perpendicular to the sun's rays, and least round the annulus where the inclination of the surface is greatest. On the other hand, since the hemisphere turned from the sun radiates more heat than it receives from the cold regions of space, the temperature there falls. Owing to the essentially distinct conditions under which the earth is placed with respect to radiation, the subject falls naturally to be divided into two heads, solar radiation and terrestrial radiation.

Solar Radiation.—Of the sun's rays which arrive at the earth's surface, those which fall on the land and solid bodies generally are wholly absorbed by the thin surface layer exposed to the heating rays, the temperature of which consequently rises. Whilst the temperature of the surface increases, a wave of heat is propagated downwards through the soil. The intensity of the daily wave of temperature rapidly lessens with the depth at a rate depending on the conductivity of the soil, until at about 4 feet below the surface it ceases to be measurable. Part of the heat of the surface layer is conveyed upwards through the air by the convection currents which have their origin in the heating of the lowermost stratum of air in direct contact with the heated surface of the land.

Altogether different is the influence of the sun's rays on water. In this case the sun's heat is not all, indeed very far from all, arrested at the surface, but penetrates to a considerable depth. The depth to which the influence of the sun is felt has been shown by the observations made during the cruise of the "Challenger" to be, roughly speaking, about 500 feet below the surface of the sea. The rate at which, in perfectly clear water, this heat is distributed at different depths is a problem that has not yet been worked out. Since water is a bad conductor, the heat thus distributed does not, as takes place with respect to land, penetrate to still lower depths by conduction, but only by different densities prevailing at the same depths, whether these different densities be due to different temperatures or different degrees of salinity. Thus one of the more important distinctions between land and water surfaces in their bearings on climate is that nearly all the sun's heat falling on land is arrested on the surface, whereas on water it is at once diffused downwards to a great depth. In examining temperatures of the sea taken at different depths, it is surprising to note the rapidity with which changes of temperature are felt at considerable depths, especially in cases when the temperature of the air rises rapidly, accompanied with strong sunshine.

In shallow water the sun's heat raises the temperature much higher than that of deep water, this being obvious from the consideration that nearly the whole of the sun's heat which falls on the surface is utilized in raising the temperature of the shallow layer of water; in other words, it is, so to speak, concentrated through a small depth of water instead of being diffused through a great depth.

Surface Temperature of the Sea.—The importance of a knowledge of this datum of meteorology will be at once recognized when it is kept in view that three-fourths of the earth's surface is water, that the temperature of the air resting on this surface is in close relation to the temperature of the surface, and that the latter has, through the intervention of the winds, direct and important bearings on the temperature of the air over large portions of the land surfaces of the globe. During the years 1859–63 Captain Thomas, while engaged on the survey of the islands on the north-west of Scotland, made observations of the temperature of the surface of the sea every hour of the day at all seasons, and with sufficient frequency for the determination of the diurnal range of the temperature of the surface. The daily minimum, 0°·17 below the mean, occurred near 6 A.M.; the mean was reached about 11 A.M., the maximum, 0°·13 above the mean, between 3 and 4 P.M., and the mean again shortly before 2 A.M. Thus the daily oscillation of the temperature of the surface of the sea amounted on the north-west of Scotland only to 0°·3. In lower latitudes the amount of the daily fluctuation is somewhat larger, but everywhere it is comparatively small, if care be taken to make the observations properly, or at a distance from land, where the influence of the heated or cooled land is not allowed to vitiate the results.

During the voyage of the "Challenger" a complete system of meteorological observations, including the temperature of the surface of the sea, was made every two hours as part of the scientific work of the cruise. These are now being discussed, and the writer of this article is, by permission of the Lords Commissioners of H.M. Treasury, allowed to use such of the results as have been already arrived at.

The diurnal march of the temperature of the surface of the North Atlantic has been determined from observations made on one hundred and twenty-six days from March to August 1873 and in April and May 1876, the mean latitude of all the points of observation being nearly 30 N., and the longitude 42° W. The following variations from the mean show the phases of this diurnal oscillation:—

2 A.M.	−0°·24	10 A.M.	0°·06	6 P.M.	0°·26
4 ,,	−0·33	Noon	0·24	8 ,,	0·02
6 ,,	−0·29	2 P.M.	0·47	10 ,,	−0·19
8 ,,	−0·12	4 ,,	0·47	Midnight	−0·35

Thus in mid Atlantic, about 30° N. lat., where the sun's heat is strong, and at the time of the year when the sun is north of the equator, the diurnal fluctuation of the temperature of the surface is only 0°·80. It is highly probable that nowhere over the ocean does the mean daily fluctuation of the temperature of the surface quite amount to a degree. This small daily fluctuation is a prime factor in meteorology, particularly in discussions relating to atmospheric pressure and winds.

Temperature of Air over the Open Sea.—The following shows the daily march of the temperature of the air over the North Atlantic on a mean of the same one hundred and twenty-six days for which the temperature of the sea has been given:—

2 A.M.	−1°·13	10 A.M.	0°·78	6 P.M.	0°·73
4 ,,	−1·40	Noon	1·45	8 ,,	−0·30
6 ,,	−1·41	2 P.M.	1·80	10 ,,	−0·80
8 ,,	−0·21	4 ,,	1·56	Midnight	−1·02

The amplitude of the daily fluctuation of the air is thus 3°·21, or nearly four times greater than that of the sea over which it lies. During the same months the "Challenger" was lying near land on seventy-six days. The observations made on these days show a greater daily range of temperature of the air than occurred out in the open sea. The minimum, − 2°·05, occurred at 4 A.M., and the maximum, 2°·33, at noon, thus giving a daily range of 4°·38. The occurrence of the maximum so early as noon is doubtless occasioned by the greater strength of the sea breeze after this hour, this maintaining a lower temperature. Part of the increased range of the temperature of the air as compared with that of the sea was no doubt due to the higher temperature during the day and the lower during the night on the deck of the "Challenger" as compared with that of the air. But, after making allowance for this disturbing influence, it is certain that the temperature of the air has a considerably larger daily range than that of the sea on which it rests. The point is one of no small interest in atmospheric physics from the important bearings of the subject on the relations of the air and its aqueous vapour to solar and terrestrial radiation.

The hourly deviations from the mean daily temperature of the air at two places, one near the equator and the other in the north temperate zone, and both near the sea, viz., Batavia (6° 8′ S. lat., 106° 48′ E. long., mean temperature 78°·7) and Rothesay (55° 50′ N. lat., 5° 4′ W. long., mean temperature 47°·3), are these:—

Batavia.		Rothesay.	Batavia.		Rothesay.
1 A.M.	−3°·2	−1·7	1 P.M.	+5°·7	+2°·4
2 ,,	−3·6	−2·0	2 ,,	+5·6	+2·7
3 ,,	−4·0	−2·1	3 ,,	+5·2	+2·8
4 ,,	−4·3	−2·2	4 ,,	+4·3	+2·6
5 ,,	−4·7	−2·2	5 ,,	+3·3	+2·1
6 ,,	−4·9	−2·0	6 ,,	+1·9	+1·5
7 ,,	−4·3	−1·5	7 ,,	+0·6	+0·9
8 ,,	−2·2	−0·9	8 ,,	−0·4	+0·2
9 ,,	−0·5	−0·2	9 ,,	−1·2	−0·4
10 ,,	+2·8	+0·5	10 ,,	−1·8	−0·8
11 ,,	+4·4	+1·2	11 ,,	−2·3	−1·2
Noon	+5·4	+1·9	Midnight	−2·8	−1·5

The times of the four phases of the daily temperature at Batavia are—minimum about 5.50 A.M., mean 8.45 A.M., maximum 1.20 P.M., and mean 7.40 P.M.; while for Rothesay the same times are 4.30 A.M., 9.15 A.M., 3 P.M., and 8.20 P.M. At Batavia, where the days and nights are nearly equal during the year, there is little variation in these times through the months; but at Rothesay, where the days are much longer in summer than in winter, there is considerable variation in the times of occurrence of these phases. The following table shows the times of the phases for a number of selected places in the northern hemisphere for the two extreme months, January and July:—

	January.				July.			
	Min.	Mean.	Max.	Mean.	Min.	Mean.	Max.	Mean.
	A.M.	A.M.	P.M.	P.M.	A.M.	A.M.	P.M.	P.M.
Sitka	6.0	9.40	1.30	6.35	3.40	7.40	0.50	7.30
Toronto	6.20	10.0	1.50	9.40	3.50	8.15	3.45	8.10
Philadelphia	6.50	10.0	2.40	8.45	5.0	8.40	3.10	8.0
Havana								
Archangel	6.0	10.40	1.30	9.0	2.40	8.36	2.50	8.50
Rothesay	5.30	10.10	2.30	8.0	3.30	9.0	3.15	8.50
Oxford	7.20	10.10	2.0	7.0	3.40	8.45	3.10	8.25
Madrid	6.50	10.5	2.40	8.35	4.40	8.50	2.50	8.35
Geneva	6.0	10.0	2.0	8.0	3.15	8.15	2.50	8.10
St Bernard	4.30	8.25	0.55	6.45	3.0	8.10	1.20	7.50
Bogoslovsk	5.30	9.25	1.30	8.15	3.40	7.35	2.5	8.4

Madras	5.40	8.0	0.40	6.45	5.0	8.45	1.25	6.50

During the night in summer the temperature falls continuously from the effects of terrestrial radiation till the earliest dawn, when the daily rise in the temperature sets in owing to the heat reflected from the upper strata of the atmosphere, which have begun to be heated and lighted up by the rays of the morning sun. It will be observed that the time of the daily minimum temperature occurs earliest in high latitudes and latest in low latitudes. During winter, on the other hand, the minimum temperature takes place in several regions some time before dawn. At this season the two chief causes on which changes of temperature depend are the sun and the passage of cyclones and anticyclones; and it is probable that those cases where the minimum occurs markedly before the dawn are, where not occasioned by purely local disturbing causes, due to the mean diurnal times of occurrence of the changes of temperature which accompany the great atmospheric disturbances of cyclones and anticyclones.

In July the daily maximum temperature occurs generally from 2 to 4 P.M. At places, however, near the sea, which are within the immediate influence of the sea breeze, and in places at some distance from the sea, such as Calcutta, where the wind, being essentially a sea wind, attains its greatest daily velocity and the sky at the same time is much clouded, the maximum occurs nearly two hours earlier. In high situations, such as the St Bernard hospice, the highest daily temperature also occurs nearly two hours sooner than on the plains below. In the winter months the maximum is about an hour earlier than in the summer.

In investigating the daily curves of temperature, Sir David Brewster drew several interesting conclusions from them. By dividing the daily curve of temperature, deduced from the mean of the year, into four portions, at the points representing the two daily means and the two extremes, he showed that the four portions approximate to parabolas, in which the temperatures are the abscissæ and the hours the ordinates. The correspondence between the observed and calculated results is so close that the difference did not in any case exceed a quarter of a degree Fahrenheit. This interesting result is true for places at which the horizon is open all round, so that no shadows of hills, trees, or buildings fall on the places where the thermometers are kept during the day. If a hill rises to the

north of the place, by which the sun's rays are never obstructed, it exercises little, if any, influence on the observations; but if one or more hills obstruct the rays of the sun after it has risen above the horizon, such obstruction affects the temperature while, and for some time after, the position in which the thermometer is placed is shaded from the sun.

Brewster further made the important remark that the mean of observations made at any pair of hours of the same name, such as 8 A.M. and 8 P.M., 9 A.M. and 9 P.M., &c., does not differ much from the mean temperature of the day. The pairs of hours which approximate closest to the true daily mean are 9 A.M. and 9 P.M., 10 A.M. and 10 P.M., 3 A.M. and 3 P.M., and 4 A.M. and 4 P.M. The mean of four hours at equal intervals from each other gives a result still closer to the true mean temperature.

In organizing any system of meteorological observation, by which it is intended to develop the climatology of the country, the determination of the hours of observation is a question of the first importance. If only two observations be made daily the best hours are 9 A.M. and 9 P.M., or 10 A.M. and 10 P.M.; and if there be four observations the best hours are 3 and 9 A.M. and 3 and 9 P.M., or 4 and 10 A.M. and 4 and 10 P.M. If there be three observations the best hours are 9 A.M. and 3 and 9 P.M., or 10 A.M. and 4 and 10 P.M.; but in these cases it is essential that the observations of a minimum thermometer be added to the temperature observations. These hours are further strongly recommended by the consideration that they are approximately coincident with the diurnal phases of atmospheric pressure, an exact knowledge of which lies at the root of nearly all climatological inquiries. The three equidistant hours which have been adopted in several countries, viz., 6 A.M. and 2 and 10 P.M., are only good as regards the temperature, not as regards atmospheric pressure. With respect to two daily observations, the hours 8 A.M. and 1 P.M., which have been adopted in some countries, are singularly unsuitable for the furnishing of the observational data required in the development of the climatologies of these countries; and, what is still more serious in a science where international co-operation is so imperatively demanded, these observations cannot be used with any satisfaction in such deeply important inquiries as the comparative climatologies of Europe.

The times of occurrence of the highest, lowest, and mean daily temperatures, and the amount of the daily range of temperature, are in a great degree influenced by the covering or want of covering of the earth's surface on which the air rests. When the ground is covered with vegetation, the whole of the solar heat falls on the vegetable covering; and, as none falls immediately on the soil, its temperature does not rise so high as happens where there is no vegetable covering to shade the surface from the sun. The temperature of plants exposed to the sun is not so high as that of exposed soil in the vicinity. As regards forests, the four diurnal phases of temperature occur later than in the open country, and the maximum and minimum are less decided; and, since the maximum temperature of the air in forests falls short of the maximum in the open to a considerably greater extent than the minimum under trees is above the minimum in the open, it follows that the mean temperature of the air in forests is less than that of the open country adjoining. The reason of the difference is that the chilling effects of nocturnal radiation penetrate lower down among the trees than do the heating effects of solar radiation; and as the soil is not heated directly by the sun its temperature is lower, and consequently that of the air over it is also lower. A cleared space in a forest, sheltered by the surrounding trees, but open to the sun, has a warmer and moister atmosphere in spring and summer and very much moister in autumn than prevails in the open country adjoining, and has also the diurnal differences of range peculiar to a warmer and moister atmosphere.

One of the most important elements of climate is disclosed by the difference between the hour of lowest and the hour of highest mean temperature respectively, or, as it is usually expressed, by the daily range of temperature. We have seen that as regards the sea in the north-west of Scotland the difference is only 0°·3 and in the Atlantic about 30° N. lat. 0°·8, and that probably the diurnal range of temperature of the surface of the sea nowhere amounts to a degree. In the same part of the Atlantic the daily range of the temperature of the air resting on the ocean is 3°·2, and on the sea near land 4°·4. On advancing on the land, the daily range of temperature rapidly increases, and the rate of increase is greatly augmented when an inland position is arrived at to which any sea breezes that may prevail do not extend.

The true daily range of temperature is stated by observations made with maximum and minimum thermometers. Generally speaking, the amount of the range increases as the latitude is diminished, and as the distance from the sea is increased, but above all it increases in proportion to the dryness of the climate.

The differences of this vital element of climate are strikingly shown in the meteorology of India. In the *Report* for 1880 the following are the mean daily ranges of March of that year at a few places: at Goa 5°·4, Bombay 11°·2, Kurrachee 23°·5, Jacobabad 37°·4, and Pachbudra (lat. 25° 55′ N., long. 72° 18′ E.) 41°·3. In the last case, undoubtedly one of the greatest mean daily ranges of temperature meteorology has yet recorded, the mean of the days was 103°·4 and of the nights 62°·1. As March is altogether within the season of the north-east monsoon, the general drift of the wind over western India, where these are situated, is from the interior towards the sea, subject as regards Bombay and Goa to the influences of the land and the sea breeze. On the other hand, in June, when the south-west monsoon has fairly set in, the following are the mean daily ranges of temperature at the same places: at Goa 5°·6, Bombay 8°·2, Kurrachee 16°, Jacobabad 27°·6, and Pachbudra 24°·1. These show in a striking manner the powerful influence of the moister atmosphere spread over India by the south-west monsoon, under which the daily range of temperature falls at Kurrachee from 23°·5 to 16°, and in the excessively arid climate of Pachbudra from 41°·3 to 24°·1. In these dry climates of the basin of the Indus, whilst the rainfall both in March and in June is practically nil, yet the relative humidity of the atmosphere is widely different. Thus the humidities for March and June respectively at 4 P.M., when the temperature is nearly the maximum for the day, are 48 and 77 for Kurrachee, 18 and 30 for Jacobabad, and 11 and 36 for Pachbudra. It is not so much the amount of cloud that determines the degree of fierceness of the sun's heat in these climates as the relative humidity, or the dryness of the air, as pointed out by Strachey in 1866. Thus at Jacobabad less than half the amount of cloud appears in the sky in June as compared with March, but the relative humidities are 30 and 18, and the daily range of temperature 27°·6 and 37°·4. If we except the dry arid wastes of Persia and Arabia, there is perhaps no other region of the globe where the daily range of temperature approaches that of the valley of the Indus. Thus in the dry climates of such places as Sacramento (California) in summer it amounts only to about 30°, at Madrid to 27°, and Jerusalem 24°. In central districts in the south of England it is about 20°; farther north it falls to 15°; and in the islands in the north, whose climate is strictly insular in its character, the summer daily range is only 10°. In Arctic regions, such as Spitzbergen and Boothia Felix, the range in winter varies from 0°·0 to 1°·0; in May, when the sun has reappeared and continues to rise and set, it rises to 14°; but in July, when the sun does not set, the range sinks to 10°.

But maximum and minimum thermometers not only show the mean daily range of temperature, they are also of great utility in giving observations for the determination of mean temperature. The mean temperature may be accepted as the mean of the twenty-four hourly observations of the day. If with such a system of observation daily readings of the maximum and minimum thermometer be compared, the value of the latter observations in questions of mean temperature may be arrived at. Double series of observations of this description have been made at many places. The following shows a comparison of the mean of maximum and minimum daily temperatures with means from observations made twenty-four times daily, the former exceeding the latter means in nearly all cases:—

	Spring.	Summer.	Autumn.	Winter.	Year.
Batavia	−0·3	−0·2	−0·2	−0·2	−0·2
Calcutta	1·0	0·7	0·7	0·9	0·8
Peking	0·6	0·6	0·6	0·7	0·6
Nertchinsk	0·1	0·3	0·6	1·0	0·5
Barnaul	0·5	0·5	0·7	0·8	0·6
Ekaterinburg	0·5	0·7	0·7	0·6	0·6
Tiflis	0·5	0·5	0·5	0·4	0·5
St Petersburg	0·6	0·6	0·3	0·1	0·4
Valentia	0·4	0·5	0·1	−0·1	0·2
Greenwich	0·7	0·8	0·6	0·0	0·4
Rothesay	0·4	0·3	0·3	0·3	0·3

These results show remarkable uniformity, and it may be inferred from them that mean temperatures deduced from maximum and minimum observations are about half a degree above the true mean temperature. In general climatological inquiries, observations with these thermometers have the strong recommendation of supplying from observations taken once a day the data for the determination of the mean temperature and mean daily range of localities; to which falls to be added the further advantage of giving results more uniformly comparable for different places than could be afforded by observations made with a common thermometer at any single hour or pair of hours daily.

Daily Variation of the Humidity of the Air.—The gaseous envelope surrounding the earth is composed of two atmospheres, quite distinct from each other,—an atmosphere of dry air and an atmosphere of aqueous vapour. The dry air, which consists of oxygen and nitrogen, is always a gas, and its quantity remains constant; but the aqueous vapour does not continue permanently in the gaseous state, and the quantity present in the air is, by the ceaseless processes of evaporation and condensation, constantly changing. If the aqueous vapour remained permanently and unchanged in the atmosphere, or were not liable to be condensed into cloud or rain, the mixture would become as complete as that of the oxygen and nitrogen of the air. The equilibrium of the vapour atmosphere, however, is being constantly disturbed by every change of temperature, by every instance of condensation, and by the unceasing process of evaporation. Since dry air further materially obstructs the free diffusion of the aqueous vapour, it follows that the law of the independent pressure of the vapour and of the dry air of the atmosphere holds good only approximately. The aqueous vapour, however, constantly tends to approach this state. Since, then, the independent and equal diffusion of the dry air and the aqueous vapour is, owing to these disturbing causes, never reached, the important conclusion follows that the hygrometer can never indicate more than the local humidity of the place where it is observed. Hygrometric observations can therefore be regarded only as approximations to a true indication of the quantity of aqueous vapour in the atmosphere over the place of observation. It is, however, to be added that, while in certain cases the amount of vapour indicated is far from the truth, yet in averages, particularly long averages, a close approximation to the real amount is reached if the hygrometer be at all tolerably well exposed and carefully observed.

Aqueous vapour is constantly being added to the air from the surfaces of water, snow, and ice, from moist surfaces, and from plants. The rate of evaporation increases with an increase of temperature, because the capacity of the air for vapour is thereby increased. The atmosphere can contain only a certain definite amount of vapour, according to the temperature; when therefore the air has its full complement of vapour, or when, in other words, it is saturated, evaporation ceases. Thus the rate of evaporation is greatest when the air is driest or freest from vapour, and least when the air is nearest the point of saturation. Since currents of air remove the moister and substitute drier air over the evaporating surfaces, evaporation is much more rapid during wind than in calm weather. As air expands under a diminished pressure, its temperature consequently falls, and it continues to approach nearer to the point of saturation, or become moister; and, as it contracts under an increased pressure, its temperature rises and it recedes from the point of saturation or becomes drier. Hence ascending currents of air become moister with every addition to the ascent, and descending currents drier as they continue to descend. Thus as winds ascend the slopes of hills they become moister, but when they have crossed the summit and flow down the other side they become drier in proportion to the descent, and all the changes may be experienced from extreme dryness to saturation in the same mass of air, which all the time has practically had its amount of aqueous vapour neither added to nor diminished.

In an atmosphere of air and aqueous vapour perfectly mixed, the elastic force of each at the surface of the earth is the pressure of each. In this case the elastic force of aqueous vapour would be the pressure of the whole vapour in the atmosphere over the place of observation. This pressure is expressed in inches of mercury of the barometer. If we suppose the total barometric pressure to be 30·000 inches, and the elastic force of vapour to be 0·745 inch, the pressure or weight of the dry air, or air proper, would be 29·255 inches, and of the aqueous vapour 0·745 inch. From this it follows that the elastic force of vapour may be regarded as indicating the quantity of aqueous vapour in the air at the place of observation, or it may be designated the absolute humidity of the air.

The diurnal variation in the elastic force of vapour in the air is seen in its simplest form on the open sea. Grouping together all the hygrometric observations made on board the "Challenger" on the North Atlantic at a distance from land, from March to July 1873 (eighty-four days), we have for that time a mean elastic force of 0·659 inch, and the following diurnal variation:—

	Inch.		Inch.		Inch.
2 A.M.	−·015	10 A.M.	+·004	6 P.M.	+·007
4 ,,	−·020	Noon	+·017	8 ,,	+·002
6 ,,	−·016	2 P.M.	+·020	10 ,,	−·005
8 ,,	−·007	4 ,,	+·017	Midnight	+·003

Hence the minimum (−·020 inch) occurs at the hour when the temperature of the surface of the sea and air resting over it falls to the daily minimum; it then rises to the mean a little after 9 A.M., and to the daily maximum (+·020 inch) at 2 P.M., when the sea and air are also near the daily maximum, and falls to the mean shortly before 9 P.M.

Treating the observations made near land by the "Challenger" during the same months, the following is the diurnal variation disclosed:—

	Inch.		Inch.		Inch.
2 A.M.	−·003	10 A.M.	+·014	6 P.M.	·000
4 ,,	−·009	Noon	+·011	8 ,,	−·004
6 ,,	−·010	2 P.M.	+·007	10 ,,	−·005
8 ,,	−·003	4 ,,	+·015	Midnight	−·007

The disturbance induced by proximity to land in the distribution of the aqueous vapour in the lower strata of the atmosphere is very striking. The maximum and minimum no longer follow the corresponding phases of the temperature of the surface of the sea and of the air. The disturbing agents are the sea and land breezes and their effects. Under the influence of the land breeze the time of the minimum humidity is delayed till about 6 A.M.; and under the influence of the sea breeze and its effects the amount of the aqueous vapour shows a secondary minimum from noon to 2 P.M. It is to be here noted that this midday

minimum occurs at the hours of the day when the surface of the land is most highly heated, the ascending current of heated air rising from it therefore strongest, and the resulting breeze from the sea towards the land also strongest. Now it does not admit of a doubt that the diminution in the amount of the aqueous vapour noted on board the "Challenger" near the shore points to an intermixture with the air forming the sea breeze of descending thin air-filaments or currents to supply the place of the masses of air removed by the ascending currents which rise from the heated surface of the land. At Batavia, on the north coast of Java, and at Bombay, the aqueous vapour is also subject to a secondary minimum during the warmest hours of the day.

During the summer months this secondary minimum is best marked at inland places such as Peking, Nertchinsk, Barnaul, Tiflis, and Ekaterinburg, but the time of its occurrence is about two hours later than it is over the North Atlantic. Over all these places at this season the ascending current from the heated land in the interior of Asia is very strong. On the other hand the lowering of the amount of aqueous vapour scarcely if at all appears as a feature in the summer climate of St Petersburg, and not at all in that of Sitka, where the sea breeze is equally not a constant feature of the climate of the district.

In the excessively dry, rainless, and hot climate of Allahabad, in April the diurnal minimum of the aqueous vapour occurs from 11 A.M. to 6 P.M., the time of absolute minimum being 2 and 3 P.M. During all other hours of the day the amount of the vapour is above the mean, a secondary minimum occurring from 1 to 4 A.M. At Allahabad, at this time, the absolute maximum vapour pressure occurs at 8 A.M. Quite similar to this is the diurnal distribution of the aqueous vapour in July at Lisbon and Coimbra, the minimum occurring from 10 A.M. to 8 P.M. At this time of the year the climate of this part of the peninsula is hot and dry and the rainfall insignificant in amount. As this region lies between the high atmospheric pressure so characteristic a feature of the meteorology of the Atlantic in summer and the comparatively low pressure over the continents southward and eastward, the winds are almost wholly north-westerly. In this connexion it is instructive to note that the time of maximum vapour pressure is from 4 to 7 A.M., when the velocity of the wind is near the minimum, and the chief minimum vapour pressure from noon to 4 P.M., when the velocity of the wind and ascending currents reach the daily maximum. These results show that the diminution in the vapour pressure during the hours when temperature is highest, which characterizes the climates of large tracts of the globe, is due to descending air-filaments or currents, which necessarily accompany the ascending currents that rise from the heated land.

At Geneva during the summer months the vapour curve exhibits two daily minima very strongly marked, the one shortly before sunrise and the other from 2 to 4 P.M., and two maxima, one from 8 to 11 A.M. and the other from 6 to 10 P.M.; and with these the diurnal variations of cloud are in accordance. The peculiarly marked features of the vapour curve at Geneva are probably due to the size of the lake, which is large enough to give rise to a decided breeze during the day from the lake all round its shores and during the night to a breeze from the land all round upon the lake. On the setting in of the breeze, the mass of air composing it, having been for some time resting on the lake, is rather moist, and thus one of the daily maxima is brought about from 8 to 11 A.M. As the breeze continues the air supplying it is necessarily drawn from the higher strata of the atmosphere more copiously than in different situations; and, having thus acquired increased dryness in the descent, and having blown over the lake for too short a distance to materially influence its moisture, the air becomes constantly drier, till the minimum from 2 to 4 P.M. is reached. The lake breeze thereafter begins to diminish in force, and the air consequently becomes moister till the maximum vapour pressure of the day occurs when the lake breeze dies away and the land breeze has not yet sprung up. In the winter months, when these breezes do not prevail, the curve of diurnal vapour pressure shows only one maximum and minimum.

The *relative humidity* of the atmosphere must not be confounded with its vapour pressure or absolute humidity. The relative humidity, or, as it is more frequently called, the humidity, of the air is the degree of its approach to saturation. Complete saturation is represented by 100 and air absolutely free of vapour by 0, the latter state of things never occurring in the atmosphere, a humidity of 10 being of rare occurrence even in such arid regions as those of Arabia. The great significance of this element of climate is in its relations to the diathermancy of the air, and consequently to solar and terrestrial radiation. It is supposed that perfectly dry air would allow rays of heat to pass through it with at most only a very slight increase to its temperature therefrom. Let, however, a little aqueous vapour be added to it, a partial obstruction to the passage of radiant heat is offered, and the temperature of the mixture, or common air, is sensibly raised. Hence, other things being equal, the less the amount of vapour the more are the effects of radiation felt, or the greater the heat of the days and the cold of the nights. The mere amount of vapour in the air does not determine the degree of radiation, but it is the amount of vapour together with a certain temperature—in other words, the absolute and relative humidity of the air taken together—that determines the heating power of the sun and the degree of cold produced by terrestrial radiation.

The diurnal variation of the relative humidity is very different from that of the vapour pressure, and presents features of the simplest character. The following are the diurnal variations from the mean humidity 80 over the North Atlantic, from the "Challenger" observations in 1873:—

2 A.M.	+2	10 A.M.	−1	6 P.M.	−1
4 ,,	+2	Noon	−2	8 ,,	0
6 ,,	+1	2 P.M.	−3	10 ,,	+1
8 ,,	0	4 ,,	−2	Midnight	+2

Thus the maximum humidity occurs from midnight to 4 A.M., or when the daily temperature is at the minimum, and the minimum humidity at 2 P.M., when the temperature is at the maximum, the curve of humidity being thus inverse to that of the temperature. With two slight modifications this is the diurnal humidity curve for all climates and seasons. In the calm which intervenes in the morning between the land and the sea breeze the humidity continues high, or even increases, though at the time the diurnal increase of temperature has already set in. The other modification is seen in the humidity curves for Nertchinsk and Barnaul during winter, these curves being not inverse but coincident with the daily curves of temperature. In the climates of Central Asia in winter, the amount of vapour is very small, and the increase to the relative humidity during the day is probably occasioned by the more active evaporation from the snow during the day and the stillness of the air favouring the accumulation of aqueous vapour near the surface of the earth.

Next to the winds, the aqueous vapour of the atmosphere, in the diverse ways in which in different localities it is distributed through the hours of the day, plays the most important part in giving to the different parts of the globe its infinitely diversified climates.

Dew.—Dew is deposited over the earth's surface on comparatively clear and calm nights. As the cooling by terrestrial radiation continues, the temperature of objects on the surface is gradually lowered to the dew-point, and when this point is reached the aqueous vapour begins to be condensed into dew on their surfaces. The quantity deposited is in proportion to the degree of cold produced and the quantity of vapour in the air. Dew is not deposited in cloudy weather, because clouds obstruct the escape of heat by radiation, nor in windy weather, because wind continually renews the air in contact with the surface, thus preventing the temperature from falling sufficiently low. When the temperature is below 32°, dew freezes as it is deposited, and *hoar-frost* is produced. The dew-point practically determines the minimum temperature

of the night,—because if the temperature falls a little below the dew-point the liberation of heat as the vapour is condensed into dew speedily raises it, and if it rises higher the loss of heat by radiation speedily lowers it. This consideration suggests an important practical use of the hygrometer, it being evident that by ascertaining the dew-point the approach of frost or low temperature likely to injure vegetation may be foreseen and provided against.

Diurnal Oscillations of the Barometer.—The general character of the daily oscillations of atmospheric pressure is shown by the two curves of fig. 2. The solid line gives the mean oscillation for Bombay and the

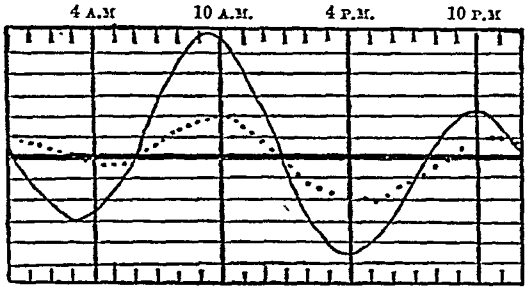

FIG. 2.—Daily Oscillations of Atmospheric Pressure.

dotted line that for Vienna, these two curves being to a large extent typical of diurnal barometric oscillations in tropical and temperate regions as regards the two maxima and minima and the time of their occurrence.

A series of twelve maps of the globe were prepared for June, showing, for all stations whence observations have been obtained, the deviations at noon, 2 P.M., 4 P.M., &c., Greenwich mean time, from the mean daily pressure; and four lines were drawn indicating the positions of the two daily maxima and minima at these hours. For fully 30° north and south of the equator the lines of maxima and minima run north and south, but in higher latitudes these directions are changed, and the changes are chiefly conspicuous as regards the A.M. maximum and the P.M. minimum. Thus, for example, at 6 P.M. (G. M. T.) the line of P.M. minimum is for the latitude of London near 16° W. long.; in 30° N. lat. it is in 35° W. long., in which the line runs south as far as 30° S. lat.; its course thence turns south-westwards to near the Falkland Islands, 60° W. long. Hence in June the P.M. minimum occurs about three hours earlier in the Falkland Islands than to the south-west of Ireland, thus showing in a striking manner the influence of season on this phenomenon. In the middle and higher latitudes in summer, proximity to the sea delays the time of occurrence of the A.M. maximum and the P.M. minimum; whilst in continental situations the A.M. maximum occurs much earlier than in lower latitudes, and the P.M. minimum nearly as late as at places near the sea. In cases where the lines of maxima and minima cross a region such as southern and western Europe, whose surface is diversified by large tracts of land and sheets of water, the deflexions are of a remarkable character.

The retardation of the time of occurrence of the A.M. maximum is greatest in situations which, while eminently insular in character, are at the same time not far from an extensive tract of land. Of this Holland presents the best example in Europe; and there the A.M. maximum, which at Paris occurs at 8 A.M., does not occur at Utrecht till 9.30 A.M., at Amsterdam till 12.30 P.M., and at Helder till 2 P.M. There is thus as regards the same diurnal phenomenon in June a difference of six hours between Paris and Helder. Sicily and the south of Italy on the one hand and Madrid on the other present also the most striking contrasts. Again at Sitka (56° 50′ N. lat., 135° W. long.), which has one of the most truly insular climates in the world, the A.M. maximum is delayed to 2.30 P.M.; whereas at Astoria, ten degrees to southward, it occurs at 9.30 A.M., and at Fort Churchill, in Nevada, as early as 7 A.M. There is thus as regards the same phenomenon a difference of $7^h\ 30^m$ between Sitka and Fort Churchill.

From hourly observations made in this month at the base, the top, and two intermediate points on Mount Washington (N. H.) it was found that the time of occurrence of the A.M. maximum at the base of the mountain, which is 2898 feet above the sea, was 8 A.M.; at 4059 feet, 10 A.M.; at 5533 feet, 11 A.M.; and at the top, 6285 feet, noon. Hence, as regards the time of occurrence, the influence of an isolated mountain like Mount Washington brings about a result similar to what is observed in insular situations. But the analogy is even closer. In insular climates the minimum in the early morning is very greatly in excess of that in the afternoon; and the same relation is observed on the top of Mount Washington, where the former is −0·020 inch and the latter −0·004 inch. Again in continental climates the minimum in the early morning is much the smaller of the two, and the same relation was observed at the base of the mountain, where the observed minima were respectively 0·006 inch and 0·020 inch. The differences presented by the daily curve of pressure at the top as compared with that at the base of the mountain have their explanation in the effects which follow the diurnal range of temperature. As the temperature is at the minimum at the time of least pressure in the morning, the atmosphere is more condensed in the stratum between the base and the top, and consequently the barometer at the top reads relatively lower. As the temperature continues to rise during the day, the stratum of air above the base of the mountain expands, thus placing more air above the barometer at the top, so that, while at the base pressure begins to fall at 8 A.M., at the top it continues to rise till noon, simply from the mechanical upheaval of the air owing to the higher temperature. In the afternoon, when the minimum at the base falls to −0·020 inch, it is only −0·004 inch at the top, this relatively higher pressure at the top being due to expansion from temperature. The peculiar feature of the pressure curve at the top is essentially a temperature effect.

The diurnal oscillations of the barometer occur alike over the open sea and over the land surfaces of the globe. The atmosphere over the open sea, as already shown, rests on a floor or surface subject to a diurnal range of temperature so small as to render that temperature practically a constant both day and night. This consideration leads to the vital and all-important conclusion that the diurnal oscillations of the barometer are not caused by the heating and cooling of the earth's surface by solar and terrestrial radiation and by the effects which follow these diurnal changes in the temperature of the surface, but that they are primarily caused by the direct and immediate heating by solar radiation, and cooling by nocturnal radiation to the cold regions of space, of the molecules of the air, and of its aqueous vapour. These changes of temperature are instantly communicated through the whole atmosphere from its lowermost stratum resting on the earth's surface to the extreme limit of the atmosphere, which the flight of meteors proves to be not less than 500 miles. There are important modifications affecting the amplitude and times of occurrence of the four prominent phases of the phenomena observed over land surfaces, the temperature of which is being superheated during the day and cooled during the night; but it is particularly to be noted that the barometric oscillations themselves are independent of any changes of temperature of the floor on which the atmosphere rests.

Let us first look at the phenomena in the simplest form as found in the Pacific, or in the midst of the largest water

surface of the globe. The following are the mean variations of pressure from observations made on board the "Challenger," September 1 to 12, 1875, in mean latitude 1° 8′ S. and long. 150° 40′ W., the mean being 29·928 inches:—

	Inch.		Inch.		Inch.
2 A.M.	−0·012	10 A.M.	0·032	6 P.M.	−0·028
4 ,,	−0·022	Noon	0·006	8 ,,	0·004
6 ,,	0·003	2 P.M.	−0·043	10 ,,	0·013
8 ,,	0·028	4 ,,	−0·055	Midnight	0·012

The most striking feature in these oscillations is the amplitude of the range from the A.M. maximum to the P.M. minimum, amounting to 0·087 inch, and the rapidity of the fall from 10 A.M. to 2 P.M. The same feature appears in all means deduced from observations made at least 12° on each side of the equator.

From October 12 to 22, 1875, in mean lat. 35° 1′ S., long. 134° 35′ W., the mean atmospheric pressure was 30·298 inches, and the difference between the A.M. maximum and the P.M. minimum was only 0·036 inch; and from July 12 to 19, 1875, in mean lat. 36° 16′ N. and long. 156° 11′ W., the mean pressure was 30·328 inches, and the difference between the A.M. maximum and P.M. minimum was only 0·025 inch. Thus, with a mean pressure in the Pacific about lat. 35°–36° N. and S. much greater than near the equator, the oscillation is much less, being in the North Pacific less than a third of what occurs near the equator. Similarly, this oscillation is small (or even smaller) in the high-pressure areas in the North and South Atlantic as compared with the same oscillation near the equator.

It is well known that aqueous vapour absorbs the heat rays of the sun considerably more than does the dry air of the atmosphere; how much more physicists have not yet accurately determined. Consequently air heavily charged with aqueous vapour will be heated directly by the sun's rays as they pass through it in a greater degree than comparatively dry air is. Now it is shown further on that the prevailing surface winds outflow in every direction from the areas of high mean pressure in the Atlantic and Pacific about lat. 36° N. and S. Since, notwithstanding, the pressure continues high, it necessarily follows that the high pressure is maintained by an inflow of upper currents, and as the slow descending movement of the air connects the inflowing upper currents with the outflowing prevailing winds of the surface, it follows that the air over high-pressure areas is very dry, and that it is driest where pressure is highest and the high-pressure area best defined. Hence over the best-defined anticyclonic regions the air will be least raised in temperature through all its height by the heat rays of the sun.

On the other hand, between these high-pressure areas of the great oceans there is a belt of comparatively low pressure towards which the north and south trades pour their vapour unceasingly. The atmosphere of this belt of low pressure is thus highly saturated with aqueous vapour which rises in a vast ascending stream of moist air to the higher regions of the atmosphere. These equatorial regions thus present to the sun a highly saturated atmosphere reaching to a very great height. It is in these regions therefore that the atmosphere will be most highly heated by the sun's heat rays as they pass through it. One of the most striking facts of meteorology is the suddenness with which this barometric oscillation increases in amplitude on entering on these parts of intertropical regions; and the rapidity with which its amplitude diminishes on advancing on the high-pressure regions of the horse latitudes is equally striking. The following are the mean oscillations in the middle regions of the four great oceans about lat. 36° from the A.M. maximum to the P.M. minimum about the time of the year in each case when the sun is highest in the heavens:—South Pacific, 0·036 inch; North Pacific, 0·025 inch; South Atlantic, 0·024 inch; and North Atlantic, 0·014 inch. These amplitudes diminish as the ocean becomes more land-locked with continents, or as the anticyclonic region becomes better defined and currents of air are poured down more steadily from the higher regions of the atmosphere.

If the temperature of the whole of the earth's atmosphere were raised, atmospheric pressure would be diminished, for the simple reason that the mass of the atmosphere would thereby be removed to a greater distance from the earth's centre of gravity. Quite different results, however, would follow if the temperature of only a section of the earth's atmosphere were simultaneously raised, such as the section comprised between long. 20° and 60° W. The immediate effect would be an increase of barometric pressure, owing to expansion from the higher temperature; and a subsequent effect would be the setting in of an ascending current more or less powerful, according to the differences between the temperature of the heated section and that of the air on each side. These are essentially the conditions under which the morning maximum and afternoon minimum of atmospheric pressure take place.

The earth makes a complete revolution round its axis in twenty-four hours, and in the same brief interval the double-crested and double-troughed atmospheric diurnal tide makes a complete circuit of the globe. The whole of the diurnal phenomenon of the atmospheric tides is therefore rapidly propagated over the surface of the earth from east to west, the movement being most rapid in equatorial regions, and there the amplitude of the oscillations is greater than in higher latitudes under similar atmospheric, astronomical, and geographical conditions. Owing to the rapidity of the diurnal heating of the atmosphere by the sun through its whole height, some time elapses before the higher expansive force called into play by the increase of temperature can counteract the vertical and lateral resistance it meets from the inertia and viscosity of the air. Till this resistance is overcome, the barometer continues to rise, not because the mass of atmosphere overhead is increased, but because a higher temperature has increased the tension or pressure. When the resistance has been overcome, an ascending current of the warm air sets in, the tension begins to be reduced, and the barometer falls and continues to fall till the afternoon minimum is reached. Thus the forenoon maximum and afternoon minimum are simply a temperature effect, the amplitude of the oscillation being determined by latitude, the quantity of aqueous vapour overhead, and the sun's place in the sky.

All observations show that over the ocean, latitude for latitude, the amplitude of the oscillations is greater in an atmosphere highly charged with aqueous vapour and less in a dry atmosphere. It is also to be noted that in very elevated situations, particularly in tropical regions, the amplitude is greater proportionally to the whole pressure than at lower levels. This is what is to be expected from the law of radiant heat by which more of the heat rays of the sun is absorbed by the air, and particularly by its aqueous vapour, mass for mass, in the higher than in the lower strata.

When the daily maximum temperature is past, and the temperature has begun to fall, the air becomes more condensed in the lower strata, and pressure consequently at great heights is lowered. Owing to this lower pressure in the upper regions of the air, the ascending current which rises from the longitudes where at the time the afternoon pressure is low flows back to eastward, thus increasing the pressure over those longitudes where the temperature is now falling. This atmospheric quasi-tidal movement occasions the P.M. increase of pressure, which reaches the maximum from 9 P.M. to midnight, according

to latitude and geographical position. This maximum is therefore caused by accessions to the mass of the atmosphere overhead, contributed by the ascending currents from the longitudes of the afternoon low pressure immediately to westward.

As midnight and the early hours of morning advance, these contributions become less and less and at length cease altogether, and pressure continues steadily to fall. But between the time when the increase of pressure from the overflow through the upper regions of the atmosphere ceases and the time when pressure increases from the heat rays, direct or indirect, of the returning sun, or during the hours of the night when the effects of nocturnal radiation are the maximum, pressure is still further reduced from another cause. Radiation towards the cold regions of space takes place, not only from the surface of the globe, but also directly from the molecules of the air and its aqueous vapour. The effect of this simultaneous cooling of the atmosphere through its whole height is necessarily a diminution of its tension. Since this takes place at a more rapid rate than can be compensated for by any mechanical or tidal movement of the atmosphere from the regions adjoining, owing to the inertia and viscosity of the air, pressure continues to fall to the morning minimum. This minimum is thus due, not to the removal of any of the mass of air overhead, as happens in the case of the afternoon minimum, but to a reduction of the tension or pressure of the air consequent upon a reduction in the temperature through radiation from the aerial molecules towards the cold regions of space. In the open ocean the morning minimum is largest in the equatorial regions, and it diminishes with latitude; but the rate of diminution with latitude through anticyclonic and other regions is generally less and more uniform than in the case of the afternoon minimum.

The amplitude and times of occurrence of the phases of the diurnal barometric tides are subject to great modifications over the land. The amplitude of the oscillation from the morning maximum to the afternoon minimum is greatest where the atmosphere is driest and the sky clearest, and least where the atmosphere is highly saturated and the sky more frequently and densely covered with clouds, being thus generally the reverse of what is observed to take place over the open sea. The meteorology of India affords the most striking illustrations of this remark. At Bombay in April during the dry atmosphere and clear skies of the north-east monsoon, the oscillation is 0·118 inch; but in July during the humid atmosphere and clouded skies of the south-west monsoon it falls to 0·067 inch. In the Punjab, where the air is drier, it is much greater, rising in exceptional years, such as 1852, to 0·187 inch. The much greater amplitude of this oscillation on land as compared with the open sea is entirely due to the heating of the earth. By this heating of the surface the lower strata of the air become also highly heated and the tension is increased; and, since the air does not expand freely, vertically and laterally, from its inertia and viscosity, the barometer rises. When, however, the resistance is overcome, the ascending current which sets in is stronger owing to its higher temperature. Since this higher temperature which has its origin in the superheated surface is in addition to the direct heating of the air by the heat rays of the sun as they pass through it, the morning maximum and the afternoon minimum over land are both more extreme than over the open sea. It follows that this oscillation is much larger over land, and largest in climates where insolation is strongest.

In places already referred to where the morning maximum is greatly retarded, such as Helder, Sitka, Valentia, and Falmouth, the afternoon minimum in the summer months is singularly small,—so small indeed that it does not fall so low as the mean pressure of the day. This peculiarity in the diurnal barometric tide is in all probability due to their insular position to the westward of a more or less extensive tract of land, by which a tidal overflow is propagated through the upper regions from the continental towards the insular situations. This tidal overflow receives its impulse from the ascending current from the land, which rises sooner and stronger from inland than from insular situations. On the other hand, on the open sea, and away from land in regions where the morning maximum and afternoon minimum are both small, the minimum always falls below the mean of the day, and the time of occurrence of the maximum is not retarded as is the case in insular situations. A map of deviations from the daily mean pressure of the morning minimum in summer shows, as regards the middle and higher latitudes, that it is greatest near the sea, and least in inland continental situations. Indeed in the interior of the Old-World continent the dip in the curve in the early morning is so small that the minimum does not fall below the daily mean pressure, but at most places remains considerably above it. The same relations are seen in north-western Europe, where the morning minimum is − 0·020 inch at Valentia and Falmouth, − 0·018 inch at Helder, and − 0·012 inch at Amsterdam, whilst at Kew it is only − 0·002 inch. From its compact form and relations to the surrounding ocean, the Spanish Peninsula well illustrates the peculiarities of this phase of the pressure. The deviations from the daily mean pressure of the morning minimum are at Lisbon − 0·022 inch and Coimbra − 0·011 inch, but at Madrid in the interior + 0·009 inch,—pressure in the last case, just as happens in the interior of Asia, not falling so low as the daily mean.

The larger minimum near the sea arises from the higher temperature there during the night as compared with more inland situations, from which results a tidal overflow through the upper regions from the sea towards the land, as the temperature of the latter falls lower than the sea during the night. The effect of this overflow is to reduce the pressure over those regions whence it proceeds and to increase it in those regions over which it advances. The shallowing of the morning minimum is greatest in the higher latitudes of continental climates and most complete at great elevations, where in some cases the minimum vanishes,—in other words, where the amount of aqueous vapour is small and the time is short during which no part of the atmosphere overhead is touched by the sun's rays. Since the peculiarity is observable in the curves over nearly the whole continent, appearing even in the low latitudes of Calcutta and Madras, it might be suggested whether we have not evidence here of a vast tidal movement propagated through the higher regions towards that trough-like section of the atmosphere as it moves westwards over the continent where the temperature of the lower strata of the air is about the minimum of the day and pressure also about the minimum.

Reference has been made under ATMOSPHERE to the smallness of the range from the A.M. maximum to the P.M. minimum in the North Atlantic during summer. This phase in the diurnal distribution of pressure is represented in fig. 3, which shows for June the mean amount of the oscillation by lines of 10, 20, 40, 60, 80, and 100 thousandths of an inch, or 0·010 inch, 0·020 inch, &c. This abnormality begins in March, attains the maximum in June, and terminates in October. It is thus confined to the warmer months of the year, and, unlike most meteorological phenomena, is not cumulative, but follows the sun, so that its maximum occurs in June, and not in July as that of the temperature of the air, or in August as

the temperature of the sea. The smallness of this range over the North Atlantic, which is less than occurs in any other ocean in the same latitudes, is to a large extent caused by the small dip in the diurnal curve of the afternoon minimum.

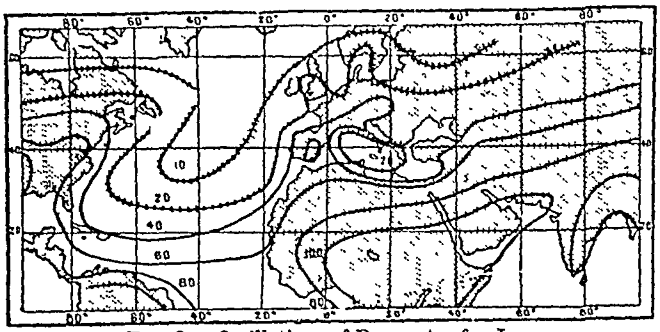

Fig. 3.—Oscillations of Barometer for June.

If the map of the distribution of pressure over the globe for July be examined (fig. 17) it is seen that this part of the Atlantic is occupied by a well-defined area of high mean pressure,—higher indeed than occurs at any season over any ocean; and it is shown below that out of this area the surface winds blow in all directions. But, since air is constantly being drained out of this region by the wind without diminishing the pressure, it follows of necessity that the high pressure must be maintained by accessions of air received from above through the upper currents. Now the regions whence such accessions can come are the upper currents which have their origin in the ascending currents that rise from the heated plains of Africa, Europe, the belt of calms, and the two Americas surrounding the North Atlantic. It is evident that the major portion of each day's overflow of air from the continents through the upper regions of the air upon the Atlantic, whether this overflow takes place by convection currents or from a tidal movement similar to what has been already described, will take place during mid afternoon. In other words, the overflow will occur about the time of the afternoon minimum of the Atlantic, thus diminishing the dip of this minimum, and so producing the abnormally small range now under examination. It is in favour of this view that the abnormality follows the sun's course and is not cumulative, and is felt also on both sides of the Atlantic, even although the weather on the east side is dry and all but rainless, and on the west moderately moist and characterized by a rather copious rainfall. It is also full of significance that the peculiarity is most strikingly seen in that part of the ocean of the globe which is closely hemmed in by large masses of land.

Influence of the Moon on Atmospheric Pressure.—Fifteen years' hourly observations have been made at Batavia and discussed by the late Dr Bergsma in their relation to the lunar day, which was assumed in the calculations to commence with the time of the upper transit of the moon. The result of the inquiry is that atmospheric pressure at Batavia has a lunar tide quite as distinctly marked as the ordinary diurnal barometric tide, except that its amplitude is much less. The four phases are these:—

1st max.	+ 0·0022	inch at lunar hour	1
1st min.	− 0·0021	,, ,, ,,	7
2d max.	+ 0·0025	,, ,, ,,	13
2d min.	− 0·0024	,, ,, ,,	19

The lunar tide has the important difference that its phases follow the moon's apparent course much more closely than the ordinary diurnal fluctuations of the barometer follow that of the sun. The two maxima occur about the 1st and 13th, and the two minima about the 7th and 19th, whereas about four daily phases of the diurnal barometric fluctua- is highest with respect to the sun's apparent course from one to six hours later. It is interesting to note that in the higher latitudes in inland situations during winter, or at times and in situations where the disturbing influences of temperature and humidity tend towards a minimum, the times of occurrence of the four phases of the daily oscillation of the barometer approximate to those of the daily lunar atmospheric tide.

Since a distinct lunar tide is traced to the attractive influence of the moon, it follows that the attractive influence of the sun will enter as one of the several causes which determine the phases and amplitude of the diurnal barometric curve. It also follows from the much less attractive influence of the sun than that of the moon on the earth's atmosphere that the effects of the sun's attraction on the pressure will be wholly concealed by the much larger effects of the other forces concerned in determining the diurnal oscillation, except in the case or cases where the variation in the fluctuation is small at 1 and 7 A.M. and 1 and 7 P.M. Now at places north of lat. 45° N. the variation at 1 A.M. is small during the winter, and it is a singular fact that some years ago Rykatchew of St Petersburg drew the attention of meteorologists to the existence at these northern stations of a faintly marked third maximum; and it is further of importance to remark that, at many places where on the mean of years the third maximum is scarcely or not at all marked, it appears in the mean of some of the separate years. Thus, though it does not appear in the mean of the twenty years ending 1873 at Greenwich for January, it appears in nine of the individual years. It is highly probable that this maximum, which may be named Rykatchew's maximum from its discoverer, is due to the attractive influence of the sun, its amplitude and time of occurrence being in accordance with such a supposition.

Diurnal Variation of the Force of the Wind.—During the three and a half years' cruise of the "Challenger," ending with May 1876, observations of the force and direction of the wind were made on 1202 days, at least

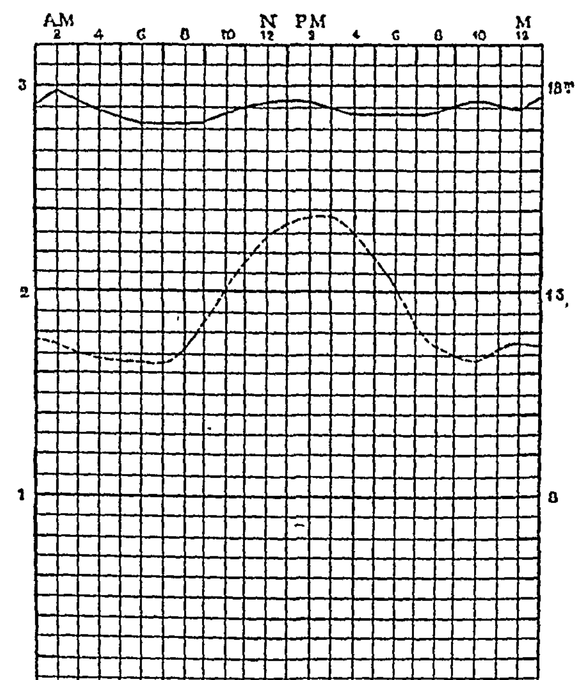

Fig. 4.—Diurnal Force of Wind at Sea and near Land.

twelve times each day,—650 of the days being on the open sea and 552 near land. The observations of force were made on Beaufort's scale 0–12, being the scale of wind-force observed at sea. The mean diurnal force of the wind on the open sea and near land respectively is shown

in fig. 4, where the figures on the left are Beaufort's scale, and those on the right the equivalents in miles per hour. The solid line shows at the different hours of the day the mean force on the open sea, and the dotted line the mean force near land.

As regards the open sea it is seen that the diurnal variation is exceedingly small, there being two apparent slight maxima, about midday and midnight respectively. On examining, however, the separate means for the North and South Atlantic, North and South Pacific, and the Southern Ocean, there is no uniform agreement observable among their curves, the slight variations which are met with being different in each case. It follows therefore that the force of the winds on the open sea is subject to no distinct and uniform diurnal variation. The difference between the hour of least and greatest mean force is less than a mile per hour.

Quite different is it, however, with the winds encountered by the "Challenger" near land, the force of the wind there giving a curve as pronouncedly marked as the ordinary diurnal curve of temperature. The minimum occurs at 2 to 4 A.M. and the maximum from noon to 4 P.M., the absolute highest being at 2 P.M. The curves constructed for each of the five oceans from the observations near land give one and the same result, or a curve closely accordant with the curve of diurnal temperature. The differences between the hours of least and greatest force are as follows:—Southern Ocean $6\frac{1}{2}$ miles, South Pacific $4\frac{1}{2}$ miles, South Atlantic $3\frac{1}{4}$ miles, and North Atlantic and North Pacific 3 miles per hour.

In the case of each ocean the velocity of the wind on the open sea is considerably in excess of that near land, but in no case does the maximum velocity near land, attained about midday, reach the velocity of the wind on the open sea. The 650 daily observations on the open sea give a mean hourly velocity of $17\frac{1}{2}$ miles, whereas the 552 near land give a velocity of only $12\frac{1}{2}$ miles per hour. The difference is greatest at 4 A.M., when it amounts to upwards of 6 miles an hour, but is diminished by the rising temperature till at 2 P.M. it is less than 3 miles an hour.

At Mauritius, which is situated within the south-east trades, the minimum velocity of the wind is 9·7 miles per hour, occurring from 2 to 3 A.M., from which it rises to the maximum 18·5 miles from 1 to 2 P.M., the influence of the sun being thus to double the wind's velocity. At Batavia, situated in a region where the mean barometric gradient is much smaller, the differences are still more decided. From 1 to 6 A.M. 85 per cent. of the whole of the observations are calms, whereas from noon to 2 P.M. only 1 per cent. are calms. In all months, the minimum velocity occurs in the early morning, when the temperature is lowest, and the maximum from 1 to 3 P.M., when the temperature is highest, the mean minimum and maximum velocities being to each other as 1 to 21. At Coimbra the mean maximum hourly velocity is five times greater than the minimum hourly velocity in summer, whereas in winter it is only about a half more. At Valentia, in the southwest of Ireland, one of the windiest situations in western Europe, the three summer months of 1878 gave a mean hourly velocity of 13·3 miles per hour, the minimum oscillating from 10 to 11 miles an hour from 9 P.M. to 6 A.M., and the maximum exceeding 16 miles an hour from 11 A.M. to 5 P.M. The absolute lowest hourly mean was 10 miles at 11 P.M., and the highest 18 miles at 1 P.M., the velocity about midday being thus nearly double that of the night. Many observations might be added to these, including those published by Hann, Köppen, Hamberg, and others, which go to establish the fact that the curves of the diurnal variation of the velocity of the wind generally conform to the diurnal curves of temperature. The curves are most strongly marked during the hottest months; and the maximum velocity occurs at 1 P.M. or shortly thereafter, being thus before the time of occurrence of the maximum temperature of the day, and the minimum in the early morning, or about the time when the temperature falls to the lowest. The rule also holds good with all winds, whatever be their direction. The exceptions to this rule are so few and of such a kind that they are probably to be attributed to causes more or less of a local character.

Hann has shown, for a number of places in northern Europe, that with a clear sky the velocity is doubled from the minimum to the maximum, with a sky half covered the velocity is three-fourths greater, and with a sky wholly covered the velocity is only a half more. On the other hand at the strictly inland situation of Vienna, with a clear sky the velocity is double, and with a sky half covered it is two-thirds greater, but with a covered sky the diurnal variation in the wind's velocity becomes irregular and faintly marked. Hann has also examined the winds at Vienna, and found that winds of a velocity not exceeding 30 kilometres an hour show a mean diurnal increase from 11 kilometres at 6 A.M. to 16·8 at 1 P.M., but that winds of velocity exceeding 30 kilometres an hour exhibit only a faintly marked and irregular increase of velocity during the day.

In offering an explanation of this remarkable fact regarding the diurnal variation in the velocity of the wind in all climates, it is to be remarked that the minimum velocity occurs when terrestrial radiation and its effects are greatest, but the increase of the velocity closely follows the sun, and the maximum is reached nearer the time the sun crosses the meridian than perhaps any of the other maxima or minima of meteorology which are dependent on the sun's diurnal course. It is also to be noted that the winds over the open sea are practically uninfluenced by solar and terrestrial radiation, for there the diurnal curve of variation in the force of the wind is all but a straight line. On nearing land, however, the wind's force exhibits a diurnal curve of variation as distinctly marked as, and bearing a close resemblance to, the analogous curve of temperature; while on the land itself these features become still more decidedly pronounced. Lastly, the amount of the diurnal variation of the temperature of the surface of the sea is less than a degree, whereas over all land surfaces the diurnal variation of the temperature is large, even where the ground is covered by vegetation, and enormously large over sandy wastes.

From this it follows that, so far as concerns any direct influence on the air itself, solar and terrestrial radiation exercise no influence on the diurnal increase of the velocity of the air with the increase of its temperature,—or, if any influence at all, such influence must be altogether insignificant, as is conclusively shown by the wind observations of the "Challenger" over each of the five great oceans of the globe. The same observations show that on nearing land the wind is everywhere greatly reduced in force. The retardation is greatest during the hours when the daily temperature is at the minimum; and it is particularly to be noted that, though the temperature rises considerably, no marked increase in the velocity sets in till about 9 A.M., when the temperature has begun to rise above the daily mean. From this time the increase is rapid (see fig. 4); the maximum is reached shortly after the period of strongest insolation; and the velocity falls a little (but only a little) during the next three to five hours, according to season, latitude, and position, and falls again to near the minimum shortly after the hour when the temperature is at the mean. Even at the maximum, the velocity near land falls considerably short of the velocity which is steadily maintained over the open sea by night as well as by day.

The period of the day when the wind's velocity is increased is practically limited to the hours when the temperature is above the daily mean, and the influence of this higher temperature is to counteract to some extent the retardation of the wind's velocity resulting from friction and from the viscosity of the air. The increase in the diurnal velocity of the wind is in all probability due to the superheating of the surface of the ground and to the consequent ascensional movement of the air, tending to counteract the effect of friction and of viscosity between the lowermost stratum of the air and the ground. It is of importance in this connexion to keep in view the fact that in cloudy weather a temperature much higher than might have been supposed is often radiated from the clouds down upon the earth's surface,[1] which accounts for the phenomenon of the

[1] *Journal of Scottish Meteorological Society*, vol. ii. p. 280.

diurnal variation in the wind's velocity occurring frequently also in cloudy weather. On the other hand, during the night, when terrestrial radiation is proceeding, the temperature of the surface falls greatly, and instead of an ascensional movement in the lower stratum of the air there is rather a tendency towards a descensional movement (if the wind be light there is an actual movement) of the lowest air stratum down the slopes of the country; and since the friction between the wind and the surface of the earth is thereby increased the diurnal velocity of the wind falls to the minimum during these hours (see also p. 156).

Among the most marked exceptions to the general rule of the diurnal distribution of wind force may be cited the bitterly cold furious blasts of wind encountered in narrow valleys in such mountainous regions as the Alps during clear and comparatively calm nights. These are simply the out-rush of the cold air poured into the upper basins of the valleys by the descensional currents from the slopes which the chilling effects of terrestrial radiation set in motion. On the other hand, the air of the valleys becomes heated and expands during the day, thus giving rise to a warm wind blowing up the valleys, which, on account of the vapour it carries with it from the lower levels, frequently covers the higher slopes and tops of the mountains with cloud and drizzling rain.

Diurnal Variation in the Direction of the Wind.—In all climates near seas and other large sheets of water, where the distribution of atmospheric pressure is tolerably equable, or the barometric gradient small, and the sun heat moderately strong, land and sea breezes are of daily occurrence. In such places a breeze from the sea gradually sets in in the morning, which gradually rises to a stiff breeze during the heat of the day and again towards evening sinks to a calm. Soon after this a breeze sets in from the land, blows strongly seaward during the night, and dies away in the morning, giving place to the sea breeze as before. These breezes are occasioned by the surface of the land being heated in a much higher degree than that of the sea during the day; the air over the land being thereby made lighter ascends, and its place is supplied by the cooler air of the sea breeze drawn landward, and partly also by descending currents, as shown by the humidity observations of the "Challenger," which indicate increasing dryness when the sea breeze is strongest. Again during the night the temperature of the land and of the air over it falls below that of the sea, and the air of the land thus becoming heavier and denser flows over the sea as a land breeze. As the best-marked and most frequently occurring cases of the sea breeze begin some distance out at sea and gradually approach the land, it is very probable that, as suggested by Blanford, the ascending heated air flows seaward as an upper current, and that the increased barometric gradient thus caused largely accounts for these breezes.

Sea and land breezes are thus determined by the relative positions of the land and its coasts, subject to a further modification arising from the rotation of the earth. Thus on the coast of the Gulf of Lyons the sea breeze from the south veers to south-west and dies away as a west wind, while the land breeze from the north gradually veers to north-east and dies away as an east wind. On the coast of Algeria, on the other hand, the sea breeze veers from north to north-east and dies away in the east, whereas the south land breeze veers to south-west and dies away in the west. Sea breezes also occur in such unsettled climates as that of Scotland, when the weather conditions are favourable. These conditions are presented when an anticyclone overspreads the country, with its accompanying fine settled weather, small variation in the distribution of atmospheric pressure, clear skies, and consequently strong sunshine. Under these conditions the following are the veerings of the wind off the coast of Berwickshire. In the morning the wind is north-west till about 10 A.M., when it veers to north, falling all the time till finally it sinks to a calm. A little before noon it springs up from north-east or east, veers to south-east from 2 to 3 P.M., where it continues till 7 P.M., about which time it veers to south and then south-west, diminishing in force and finally sinking to a calm. About sunset it springs up from west, veering to north-west during the night, where it continues till the following morning. The wind thus virtually makes the round of the compass, is strongest from north-west and south-east and weakest at north-east and south-west, being thus strongest when its course is perpendicular to the line of coast.

The observations made by the "Challenger" in the region of the north-east trades in 1873 show a small diurnal variation in the direction of the wind, the variation being from E. 47° 5′ N. at 2 to 6 A.M. to E. 56° N. at 10 A.M. to 2 P.M., the variation being thus 8° 55′ towards north during the hottest hours of the day. At Mauritius observatory, which is several miles from the sea, the daily period in the direction of the wind is from E. 22° 15′ S. at 4 A.M., being the most southerly point, to E. 7° S. at 1 P.M., and thence back to E. 22° 15′ S. at 4 A.M. The diurnal variation is 15° 15′, and thus the influence of the sun impresses on the wind at this observatory a more truly easterly character.

At the Austrian naval station at Pola, near the head of the Adriatic, the daily variation in the direction of the wind is well-marked. Starting from a point east of south at 5 A.M., it gradually veers round to westward, the most westerly point, almost due west, being reached at 5 to 6 P.M., after which it gradually shifts back to its starting point in the morning. Here we have evidently a diurnal wind-system different from that of the land and the sea breeze. Pola is situated near the south-western extremity of the peninsula of Istria, and the direction in the early morning of east by south is the direction the wind would take if a small anticyclone overspread the peninsula; and the direction from the west in mid afternoon is the direction the wind would have at Pola if the peninsula were occupied by a small cyclone with the lowest pressure in the centre. Now the influence of solar radiation is to form, through the ascending current from the heated land, a diminution of pressure over the land,—in other words, what is essentially a cyclone. On the other hand, during the night the influence of terrestrial radiation is to generate, through the cooling of the land and the air resting above it, a relatively higher atmospheric pressure in the interior of the peninsula with its characteristic system of outblowing winds.

At Coimbra, in July 1878, the diurnal variation of the wind's direction was from W. 49° 37′ N. at 2 to 6 A.M. to W. 33° 15′ N. at 4 to 6 P.M., the amount of the variation being thus 16° 22′ in the direction of west. At Valentia, in the south-west of Ireland, during the summer months of 1878 the diurnal variation of the wind's direction was from W. by S. at 7 to 9 A.M. to S.W. by W. at 5 to 7 P.M. The variation was thus from a point nearly south to a point nearly south-west, or through nearly 45° in the direction of west. On the other hand, at Aberdeen during the same months of 1878, the diurnal variation of the wind's direction was from S.W. at 6 to 7 A.M. to S. by E. at 12 to 4 P.M., the variation being thus 56° from south-west in the direction of east through south. Attention is here drawn to the exactly opposite ways in which the diurnal veering or shifting of the wind takes places at Valentia and Aberdeen, but particularly to the important circumstance that in each case the diurnal changes in the wind's direction which actually occur are precisely those that would take place on the supposition that during the hottest hours of the day an ascensional movement of the air sets in from the heated lands of the British Islands, and that an in-draught takes place all round, which with the descending currents makes good the loss caused by the up-draught. Thus then both the diurnal increase in the wind's velocity and the change in its direction which observation shows to take place during the hottest hours of the day are traced to the same cause, viz., the heating of the surface by the sun, the heating of the lowest stratum of air resting on the surface, and the ascensional movements which are the necessary result.

It is instructive to note that at Nukuss, at some distance to the south of the Sea of Aral, where the summer direction of the wind is northerly, the north component is at the daily maximum at 4 P.M., having shifted into this direction from north-east, where it is at 9 A.M. Much or nearly everything remains to be done in working out this problem in its practical details as one of the important elements of climatology, with the view of arriving at some definite knowledge of the influence of physical configuration and different vegetable coverings of the surface on radiation and on the velocity and direction of the wind.

Diurnal Variation in the Amount of Cloud.—Mists and fogs are visible vapours floating in the air near the surface of the earth, and clouds are visible vapours at a considerable height. These forms of visible vapour are all produced by whatever lowers the temperature of the air below the dew point,—such as radiation from the molecules of the atmosphere towards the cold regions of space, the simple

expansion of the air of ascending currents, the mixing of cold air with air that is warm and moist, and the cooling of the air in contact with the surface of the earth when its temperature has been lowered by nocturnal radiation.

The forms of clouds are endless. Since clouds are subject to certain distinct modifications from the same causes which produce other atmospheric phenomena, the face of the sky may be regarded as indicating the operation of these causes, just as the face of man indicates his mental and physical states. Hence the importance of the study of clouds, and hence the necessity of a nomenclature of clouds as the basis of accurate and comparable observations. An adequate nomenclature of clouds is still a desideratum. Luke Howard's classification, which continues to hold its ground as a provisional nomenclature, was proposed by him in 1803, and by it clouds are considered as divided into seven kinds. Of these, three are simple forms, the *cirrus*, the *cumulus*, and the *stratus*; and four intermediate or compound, the *cirro-cumulus*, the *cirro-stratus*, the *cumulo-stratus*, and the *cumulo-cirro-stratus*, *nimbus*, or *rain cloud*.

The cirrus cloud consists of wavy, parallel, or divergent filaments, which may increase in any or all directions. It is the cloud of the least density, the greatest elevation, and the greatest variety of figure. It is probable that the particles composing it are minute crystals of ice or snow-flakes. The cirrus is intimately connected with the great movements of the atmosphere; and it is solely from the movements of the cirrus that we have any direct knowledge of the upper currents of the atmosphere. In recent years much has been done, particularly by Professor Hildebrandsson of Upsala and Clement Ley, in investigating the relations of this cloud to storms and other changes of weather.

The cumulus is the name applied to those convex or conical heaps of clouds which increase upwards from a horizontal base. They are generally of a very dense structure, are formed in the lower regions of the atmosphere, and are carried along by the aerial current next the earth. They form the tops of the ascending currents which rise from the heated ground, and have a diurnal period so well marked that they are often named the "cloud of the day." The form of stratus comprehends those mists and fogs which in the calm evening of a warm summer day make their appearance in the bottom of valleys and over low-lying grounds, and sometimes spread upwards over the surrounding country like an inundation; they have an equally well marked daily period, and are frequently called the "cloud of night." The cirro-cumulus is made up of small roundish masses, lying near each other, and quite separated by intervals of sky. It may be considered as formed from the cirrus by the fibres of that cloud breaking, as it were, and collapsing into roundish masses, thus destroying the texture but retaining the arrangement of that cloud. This singularly beautiful cloud is commonly known as a mackerel sky, and is of most frequent occurrence during dry warm summer weather. The cirro-stratus consists of horizontal masses thinned towards the circumference, bent downwards or undulating, and either separate or in groups. Since this cloud has great extent and continuity of substance, but little perpendicular depth or thickness, it is the cloud which most frequently fulfils the conditions for the phenomena of coronæ, solar and lunar halos, parhelia or mock suns, and paraselenæ or mock moons. The cumulo-stratus is formed by the cirro-stratus blending with the cumulus, or spreading underneath it as a horizontal layer of vapour. The cumulo-cirro-stratus, or nimbus, is the well-known rain-cloud, which consists of a cloud or system of clouds from which rain is falling. At a considerable height a sheet of cirro-stratus cloud is extended, under which cumulus clouds drift from windward; these rapidly increasing unite and appear to form one continuous grey mass from which the rain falls. The breaking up of the lower grey mass indicates that the rain will soon cease. When a rain-cloud is seen at a distance, cirri appear to shoot out from its top in all directions; and it is observed that the more copious the rainfall the greater is the display of cirri. The cirrus, cirro-cumulus, cirro-stratus, cumulo-stratus, and nimbus are connected more or less closely with the great atmospheric movements of the cyclone and anticyclone. In what follows here only the amount of sky covered will be taken into account, and not the species of cloud covering.

The diurnal variation in the amount of cloud in the sky on the open sea is very small. The following are the means of two hundred and seventy-seven days' observations on board the "Challenger," stated in percentages of sky covered:—

2 A.M.	59	10 A.M.	58	6 P.M.	57
4 ,,	59	Noon	56	8 ,,	57
6 ,,	62	2 P.M.	58	10 ,,	57
8 ,,	62	4 ,,	59	Midnight	57

Two maxima are here indicated, the one about or shortly after sunrise and the other in the early part of the afternoon; and two minima, the one at noon and the other from sunset to midnight. The difference between the extremes is only 6 per cent. of the sky.

At Batavia the daily maximum is from 6 to 11 P.M., and the minimum from 8 to 11 A.M., the extremes being 52 per cent. at 9 A.M. and 69 per cent. at 7 P.M.,—a difference of 17 per cent. Of four daily observations at Mauritius, the maximum is 50 per cent. at 1 P.M. and the minimum 38 per cent. at 6 A.M. At Coimbra, observations of clouds have been made five times daily, and six years' results give the maximum 63 per cent. at 9 P.M. and the minimum 52 per cent. at 9 A.M. At this place, during July and August, the greatest amount of cloud occurs at 6 P.M., and in these months the rainfall at Coimbra is very small. The minimum is more pronounced at 9 A.M. than at any other period; in winter this phase occurs about four hours later. At the continental situation of Vienna, during the warm months of the year the maximum is at 2 P.M., with a secondary maximum about 6 A.M., and the minimum from 10 P.M. to 2 A.M.; but during the cold months the maximum is at 6 A.M. and the minimum during the evening and night. In the Rocky Mountains, the chief maximum, 57 per cent., is at 3 P.M., with a secondary one 30 per cent. at 5 A.M.; and the chief minimum 20 at 3 A.M. and a secondary one 29 at 11 P.M. At Helsingfors the maximum of cloud occurs from 10 A.M. to 2 P.M., and the minimum from 10 P.M. to 2 A.M.

Much yet remains to be done with regard to the determination of the diurnal variation of cloud, but from the above one or two deductions of a general character may be drawn. A maximum occurs in the morning and continues till shortly after the sun has risen, and this maximum is more decidedly pronounced over the open sea than over land. Its appearance is without a doubt due to the general cooling of the atmosphere through its whole height by terrestrial radiation, and its disappearance to the heating of the air, which commences about sunrise. Then follows one of the diurnal minima, which continues till midday, or a little later; in other words, it continues till, owing to the diurnal heating of the air by the sun, the ascending current has fairly set in. The period of this ascending current marks the second maximum, which during the warmer months is larger than the morning maximum over land. The cumulus is the characteristic cloud of this maximum. These clouds are merely the summits of the ascending currents which rise from the heated land, where the aqueous vapour is condensed in cloud by the expansion which takes place with increase of height.

These cumulus clouds throw a not unimportant light on the behaviour of the ascending currents which rise from the surface when heated by the sun,—inasmuch as they

during the six months from October to March. The mean of the six hottest months shows the maximum to take place from 3 to 4 P.M. and the minimum from 4 to 5 A.M., these being the times of occurrence of the two minima of pressure. At this season, however, the morning minimum pressure is but faintly marked in such climates as those of Siberia. During the twelve hours from 9 A.M. to 9 P.M., when the temperature is above the daily mean, 717 of the whole number occurred, thus leaving only 139 for the twelve hours when the temperature is below the daily mean. The great majority of the thunderstorms occur during the part of the day when the ascensional movement of the air from the heated ground takes place, and they attain the maximum when the temperature and this upward movement are also at the maximum. Owing to the westerly winds from the Atlantic which prevail over Europe and western Siberia during summer, the maximum rainfall of the year occurs over this extensive region in this season; and the importance and significance of the inquiry into this element of climate lie in the fact that the greater portion of the summer rains is discharged over these regions by the thunderstorm. The "Challenger" observations on the open sea show the maximum occurrence of thunderstorms to be from 10 P.M. to 8 A.M., 22 being observed during these ten hours and 10 during the other fourteen hours of the day,—a result which suggests that over the ocean terrestrial radiation is more powerful than solar radiation in causing vertical disturbances in the equilibrium of the atmosphere.

Atmospheric vapour and ascending currents thus play an important part in the history of these thunderstorms. Where the climate is dry and rainless, like that of Jerusalem in summer, thunder is altogether unknown. On the other hand, where during a particular season an anticyclone with its vast descending current in the centre remains over a region, as happens over the centre of the old continent during the winter, over that region thunder is equally unknown during that season. Further, in such places as Lisbon and Coimbra, where the summer rainfall is small and its occurrence infrequent, thunderstorms become less frequent, and the hours of their occurrence are later in the day than they are before and after the dry season.

The thunderstorms at Mauritius call for special notice. There are two maxima in the diurnal curve, the larger from noon to 4 P.M. and the smaller from 3 to 6 A.M., which are near the times of the barometric minima; and two minima, from 9 P.M. to 1 A.M. and from 8 to 10 A.M., these being near the times of the barometric maxima. But the important point as regards the thunderstorms of Mauritius is that for twelve years none were recorded in June and July, one only in August, one in September, and three in October. The annual period of the thunderstorms of this island extends from near the end of October to the middle of May, or during the time of the greatest rainfall, practically none occurring during the rest of the year. But rain continues to fall during the four months of no thunder, the mean monthly rainfall being then about 2 inches, falling, however, in September to 1·37 inches. During these four months, therefore, there is in the air the aqueous vapour, and, these being dry months, there is the condition of ascending currents. There appears, however, to be then wanting another element which seems essential to the electrical manifestations of the thunderstorm, viz., the conditions which give masses of descending cold air along with the ascending current of warm moist air. During the months when thunder is of no unusual occurrence the high pressure of Asia repeatedly advances, as Dr Meldrum has pointed out, close on Mauritius; and so frequently is this the case that he considers the belt of calms between the two trade winds to stretch in a slanting direction from Madagascar to Ceylon. As long as this state of things occurs with more or less frequency, the conditions of a descending cold current of large volume are provided, and thunderstorms occur. But during June, July, August, and September, when atmospheric pressure is low in Central Asia, and there is an unbroken increase of pressure from Asia southwards to Mauritius, and while Mauritius remains in the heart of the south-east trades, the conditions of descending cold currents of any considerable volume are not present, and thunder is there unknown at that season.

Now in situations which afford the three conditions of aqueous vapour, ascending currents, and descending cold currents, whilst the diurnal and annual periods are quite distinctly marked, the phenomena are more uniformly distributed through the hours of the day and months of the year than elsewhere. Pola and Fiume, at the head of the Adriatic, being shut in and encompassed by lofty Alps, are illustrations. At Fiume the greater maximum occurs from 11 A.M. to 4 P.M. and the smaller from 2 to 4 A.M., and the minima from 10 P.M. to 1 A.M. and 5 to 9 A.M. While during the twelve hours the temperature is above the mean of the day from May to September the number of the thunderstorms here was 245 for the nine years ending 1879, the number during the twelve hours the temperature is under the mean was 185. The comparatively large number during the colder hours of the night is no doubt due to the warm moist atmosphere of this confined sea and the close proximity of the Alps.

There is still another set of conditions favouring the development of thunderstorms in certain climates which the observations made at Stykkisholm in the north-west of Iceland illustrate. During the fourteen years ending 1879 there occurred here twenty-three thunderstorms, but there was only one in the six warm months from April to September; in other words, the thunderstorms of this climate are essentially winter phenomena. Further, of the twenty-three hours in which they occurred, only three were at a time of the day when the sun was above the horizon, viz., twice in March and once in September; in other words, the thunderstorms of Stykkisholm are nocturnal phenomena. It is instructive to observe that in the north and north-west of Scotland thunder occurs most frequently during the night and in winter, whereas in central, southern, and eastern districts it occurs most frequently during the day and in summer,—the thunderstorms in the former case approximating in type to those of Iceland and in the latter to those of Ekaterinburg. A little reflexion shows that in north-western Europe it is during winter and during night that warm moist ascending and cold dry descending currents are most frequently brought into close proximity during the great Atlantic storms of the season; and it is at the changes of wind, humidity, and temperature accompanying the passage of the centres of the cyclones that the thunder peals are heard. On the other hand, in the east and south of Scotland it is during the hot months of the year that these ascending columns of warm moist air and descending columns of cold dry air are most frequently brought together, and there, accordingly, thunder with the heavy rains which accompany it is of most frequent occurrence from 11 A.M. to 5 P.M. from May to September. These essentially different types of thunderstorms have been classed by Mohn as heat thunderstorms and cyclonic thunderstorms.

Given an initial difference of electric potential, it is easy to understand from the effects which follow the sudden extraordinary condensations of the aqueous vapour that take place how the most violent thunderstorms are produced. The difficulty is to account for the production of the initial difference of electric potential,—how, for example, in the same great aerial current of the south-west monsoon, this difference of potential is produced in the molecules of aqueous vapour at Calcutta but not in the aqueous vapour at Mauritius. It is to the physicist that meteorologists still look for the explanation.

Diurnal Period in the Occurrence of the Whirlwind, Waterspout, Dust Storm, and Tornado.—Whirlwinds, waterspouts, dust storms, and tornadoes are essentially the same, differing from each other only in their dimensions, their intensity, or the degree in which the moisture is condensed into visible vapour, while the hailstorm and the rainstorm are simply the manner and degree of the precipitation accompanying them. In several important respects they differ widely and radically from cyclones (see ATMOSPHERE, vol. iii. p. 33). The largest tornadoes are of so decidedly smaller dimensions when compared with the smallest cyclones as to admit of no shading of the one into the other. Cyclones occur at all hours of the day and night, whereas whirlwinds and tornadoes show a diurnal period as distinctly marked as any in meteorology. Finally, cyclones take place under conditions which involve unequal atmospheric pressures or densities at the same heights of the atmosphere, due to inequalities in the geographical distribution of temperature and humidity; but whirlwinds occur where for the time the air is unusually warm or moist, and where consequently temperature and

during the six months from October to March. The mean of the six hottest months shows the maximum to take place from 3 to 4 P.M. and the minimum from 4 to 5 A.M., these being the times of occurrence of the two minima of pressure. At this season, however, the morning minimum pressure is but faintly marked in such climates as those of Siberia. During the twelve hours from 9 A.M. to 9 P.M., when the temperature is above the daily mean, 717 of the whole number occurred, thus leaving only 139 for the twelve hours when the temperature is below the daily mean. The great majority of the thunderstorms occur during the part of the day when the ascensional movement of the air from the heated ground takes place, and they attain the maximum when the temperature and this upward movement are also at the maximum. Owing to the westerly winds from the Atlantic which prevail over Europe and western Siberia during summer, the maximum rainfall of the year occurs over this extensive region in this season; and the importance and significance of the inquiry into this element of climate lie in the fact that the greater portion of the summer rains is discharged over these regions by the thunderstorm. The "Challenger" observations on the open sea show the maximum occurrence of thunderstorms to be from 10 P.M. to 8 A.M., 22 being observed during these ten hours and 10 during the other fourteen hours of the day,—a result which suggests that over the ocean terrestrial radiation is more powerful than solar radiation in causing vertical disturbances in the equilibrium of the atmosphere.

Atmospheric vapour and ascending currents thus play an important part in the history of these thunderstorms. Where the climate is dry and rainless, like that of Jerusalem in summer, thunder is altogether unknown. On the other hand, where during a particular season an anticyclone with its vast descending current in the centre remains over a region, as happens over the centre of the old continent during the winter, over that region thunder is equally unknown during that season. Further, in such places as Lisbon and Coimbra, where the summer rainfall is small and its occurrence infrequent, thunderstorms become less frequent, and the hours of their occurrence are later in the day than they are before and after the dry season.

The thunderstorms at Mauritius call for special notice. There are two maxima in the diurnal curve, the larger from noon to 4 P.M. and the smaller from 3 to 6 A.M., which are near the times of the barometric minima; and two minima, from 9 P.M. to 1 A.M. and from 8 to 10 A.M., these being near the times of the barometric maxima. But the important point as regards the thunderstorms of Mauritius is that for twelve years none were recorded in June and July, one only in August, one in September, and three in October. The annual period of the thunderstorms of this island extends from near the end of October to the middle of May, or during the time of the greatest rainfall, practically none occurring during the rest of the year. But rain continues to fall during the four months of no thunder, the mean monthly rainfall being then about 2 inches, falling, however, in September to 1·37 inches. During these four months, therefore, there is in the air the aqueous vapour, and, these being dry months, there is the condition of ascending currents. There appears, however, to be then wanting another element which seems essential to the electrical manifestations of the thunderstorm, viz., the conditions which give masses of descending cold air along with the ascending current of warm moist air. During the months when thunder is of no unusual occurrence the high pressure of Asia repeatedly advances, as Dr Meldrum has pointed out, close on Mauritius; and so frequently is this the case that he considers the belt of calms between the two trade winds to stretch in a slanting direction from Madagascar to Ceylon. As long as this state of things occurs with more or less frequency, the conditions of a descending cold current of large volume are provided, and thunderstorms occur. But during June, July, August, and September, when atmospheric pressure is low in Central Asia, and there is an unbroken increase of pressure from Asia southwards to Mauritius, and while Mauritius remains in the heart of the south-east trades, the conditions of descending cold currents of any considerable volume are not present, and thunder is there unknown at that season.

Now in situations which afford the three conditions of aqueous vapour, ascending currents, and descending cold currents, whilst the diurnal and annual periods are quite distinctly marked, the phenomena are more uniformly distributed through the hours of the day and months of the year than elsewhere. Pola and Fiume, at the head of the Adriatic, being shut in and encompassed by lofty Alps, are illustrations. At Fiume the greater maximum occurs from 11 A.M. to 4 P.M. and the smaller from 2 to 4 A.M., and the minima from 10 P.M. to 1 A.M. and 5 to 9 A.M. While during the twelve hours the temperature is above the mean of the day from May to September the number of the thunderstorms here was 245 for the nine years ending 1879, the number during the twelve hours the temperature is under the mean was 185. The comparatively large number during the colder hours of the night is no doubt due to the warm moist atmosphere of this confined sea and the close proximity of the Alps.

There is still another set of conditions favouring the development of thunderstorms in certain climates which the observations made at Stykkisholm in the north-west of Iceland illustrate. During the fourteen years ending 1879 there occurred here twenty-three thunderstorms, but there was only one in the six warm months from April to September; in other words, the thunderstorms of this climate are essentially winter phenomena. Further, of the twenty-three hours in which they occurred, only three were at a time of the day when the sun was above the horizon, viz., twice in March and once in September; in other words, the thunderstorms of Stykkisholm are nocturnal phenomena. It is instructive to observe that in the north and north-west of Scotland thunder occurs most frequently during the night and in winter, whereas in central, southern, and eastern districts it occurs most frequently during the day and in summer,—the thunderstorms in the former case approximating in type to those of Iceland and in the latter to those of Ekaterinburg. A little reflexion shows that in north-western Europe it is during winter and during night that warm moist ascending and cold dry descending currents are most frequently brought into close proximity during the great Atlantic storms of the season; and it is at the changes of wind, humidity, and temperature accompanying the passage of the centres of the cyclones that the thunder peals are heard. On the other hand, in the east and south of Scotland it is during the hot months of the year that these ascending columns of warm moist air and descending columns of cold dry air are most frequently brought together, and there, accordingly, thunder with the heavy rains which accompany it is of most frequent occurrence from 11 A.M. to 5 P.M. from May to September These essentially different types of thunderstorms have been classed by Mohn as heat thunderstorms and cyclonic thunderstorms.

Given an initial difference of electric potential, it is easy to understand from the effects which follow the sudden extraordinary condensations of the aqueous vapour that take place how the most violent thunderstorms are produced. The difficulty is to account for the production of the initial difference of electric potential,—how, for example, in the same great aerial current of the south-west monsoon, this difference of potential is produced in the molecules of aqueous vapour at Calcutta but not in the aqueous vapour at Mauritius. It is to the physicist that meteorologists still look for the explanation.

Diurnal Period in the Occurrence of the Whirlwind, Waterspout, Dust Storm, and Tornado.—Whirlwinds, waterspouts, dust storms, and tornadoes are essentially the same, differing from each other only in their dimensions, their intensity, or the degree in which the moisture is condensed into visible vapour, while the hailstorm and the rainstorm are simply the manner and degree of the precipitation accompanying them. In several important respects they differ widely and radically from cyclones (see ATMOSPHERE, vol. iii. p. 33). The largest tornadoes are of so decidedly smaller dimensions when compared with the smallest cyclones as to admit of no shading of the one into the other. Cyclones occur at all hours of the day and night, whereas whirlwinds and tornadoes show a diurnal period as distinctly marked as any in meteorology. Finally, cyclones take place under conditions which involve unequal atmospheric pressures or densities at the same heights of the atmosphere, due to inequalities in the geographical distribution of temperature and humidity; but whirlwinds occur where for the time the air is unusually warm or moist, and where consequently temperature and

humidity diminish with height at an abnormally rapid rate. Cyclones are thus phenomena resulting from a disturbance of the equilibrium of the atmosphere considered horizontally, but whirlwinds and tornadoes have their origin in a vertical disturbance of atmospheric equilibrium.

Among the most remarkable of the tornado-swept regions of the globe are certain portions of the United States; and to the examination of these the meteorological service of the States has given special attention by a systematic, careful, and minute observation of the attendant phenomena and the destructive effects. The tornadoes of the last eighty-seven years, numbering about six hundred, have been classed under the different States where they are reported to have occurred, and fig. 5 shows this relative distribution over the States. The areas of greatest frequency are at long distances from each other. That part of the great basin lying west of the Mississippi, including the States of Iowa, Missouri, Kansas, and Nebraska, is the region in which tornadoes are most frequent. Tornadoes occur at all seasons, being most frequent, however, from April to September, and least frequent in December and January.

The hour of occurrence of one hundred and sixty-two of the tornadoes is given in the official report as follows:—

Midt. to 2 A.M.	2	8 A.M. to 10 A.M.	1	4 P.M. to 6 P.M.	52
2 A.M. ,, 4 ,,	5	10 ,, ,, Noon	7	6 ,, ,, 8 ,,	17
4 ,, ,, 6 ,,	3	Noon ,, 2 P.M.	13	8 ,, ,, 10 ,,	7
6 ,, ,, 8 ,,	4	2 P.M. ,, 4 ,,	47	10 ,, ,, Midt.	4

Thus the diurnal period of tornadoes is analogous to the period for temperature, wind velocity, and thunderstorms. The atmospheric conditions which appear invariably to precede the formation of the tornado are violent contrasts of temperature and humidity immediately to the north and south of the path to be traversed by the storm. It is highly interesting to observe from fig. 5 that the region of most frequent occurrence of tornadoes is the region where a large number of the cyclones of the United States appear to originate (and the same region Loomis has shown to be remarkable for violent contrasts of temperature occurring within limited spaces and times), and that, as appears in the regions of the Alleghanies, they decrease in frequency with height.

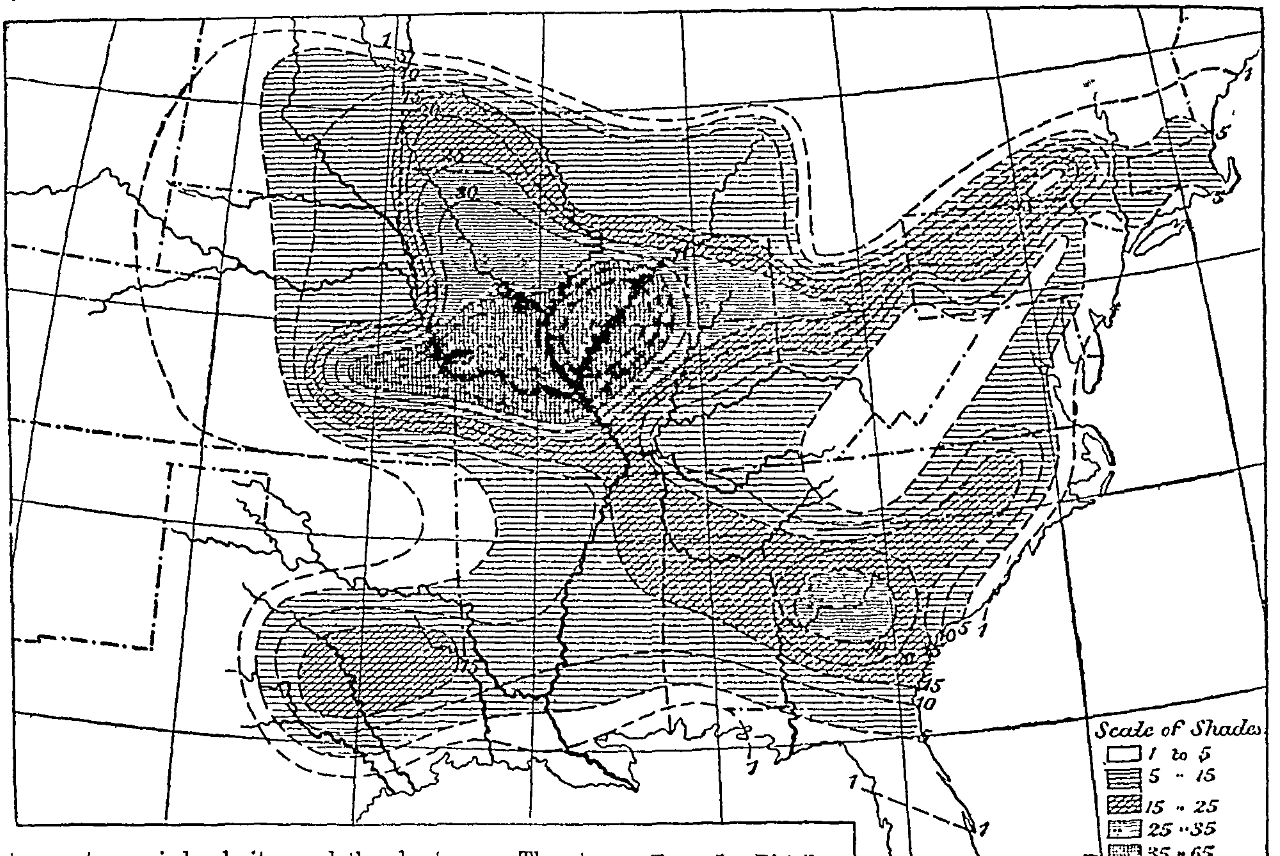

FIG. 5.—Distribution of Tornadoes in the United States.

Fig. 6 shows the waterspout in different aspects. A black cloud covers the sky, from which a projection is let down in the form of an inverted cone, as at A, which continues to increase and extend downwards. The sea immediately beneath is soon thrown into violent agitation, showing that the whirling movement which began in the clouds has extended to the sea, and is doubtless continuous throughout, though the portion of the column from A downwards is not yet made apparent by the condensation of its contained vapour into cloud. As the whirling movement of the column becomes more intensely developed, the increased rapidity of the gyrations brings about increased rarefaction of the air within, with the inevitable result of increased condensation of the vapour into cloud downward. The protrusion of the cloud and its extension downwards are thus not due to the descent of vapour from the clouds, but to the visible condensation of the vapour of the spirally ascending air-currents arising from an increasing rarefaction due solely to the accelerated rate of the gyrations, the condensation being analogous to that of the cloud seen in exhausting an air-pump.

Under each of the columns of fig. 6 the surface of the sea is seen to be more or less heaped up, as well as in violent agitation, showing that atmospheric pressure immediately under the gyrating columns is less than it is all round. On land, when the tornado passes directly over a dwelling house or other closed building, it often happens that the whole building, walls and roof, is thrown outward with great violence, the wreckage presenting the appearance of a sudden explosion, proving that atmospheric pressure outside the building was instantaneously and largely reduced, and the building shattered to fragments by the expansion of the air within. It is in this way that the tornado does some of its most dreadful work.

The wind of the tornado reaches a velocity probably never equalled in cyclones. During the Ohio tornado of February 4, 1842, large buildings were lifted entire from their foundations, carried several rods through the air, and then dashed to pieces, some of the fragments being carried distances of 7 and 8 miles; and large oaks nearly 7 feet in girth were snapped across like reeds. This tornado swept on its course at the rate of 34 miles an hour, and at one

place did its fearful work in the brief space of a minute. The tornado which passed over Mount Carmel (Illinois), June 4, 1877, swept off the spire, vane, and gilded ball of the Methodist church, and carried it bodily 15 miles to north-eastward. The velocity of the ascending currents which kept this heavy object suspended in the air for 15 or 20 miles must have been very great.

Of the tornadoes the progressive courses of which were recorded, 310 advanced towards N.E., 38 towards S.E., 16 towards E.N.E., 14 towards E., 7 towards N.N.E., 5 towards E.S.E., and 3 towards S.S.E. The course is thus always towards some easterly direction, the great majority being towards the north-east. The velocity of their onward movement varied from 12 to 60 miles an hour, the average being 30 miles an hour. The time occupied in passing a particular spot varied from 10 seconds to half an hour, the mean time being nearly six minutes and a half. The width of the path of destruction marked with debris and other relics of the violence of the tornado varied from 40 to 10,000 feet, the average being 362 yards. The direction of the whirling movement of the tornado was invariably from right to left, or the opposite of the movement of the hands of a watch, resembling in this respect the vorticose movement of cyclones in the northern hemisphere. The passage of the tornado cloud is often described as accompanied with remarkable noises, which observers variously characterize as terrible, deafening, a terrific crash, the roar of a thousand trains of cars, or the uproarious din of innumerable pieces of machinery.

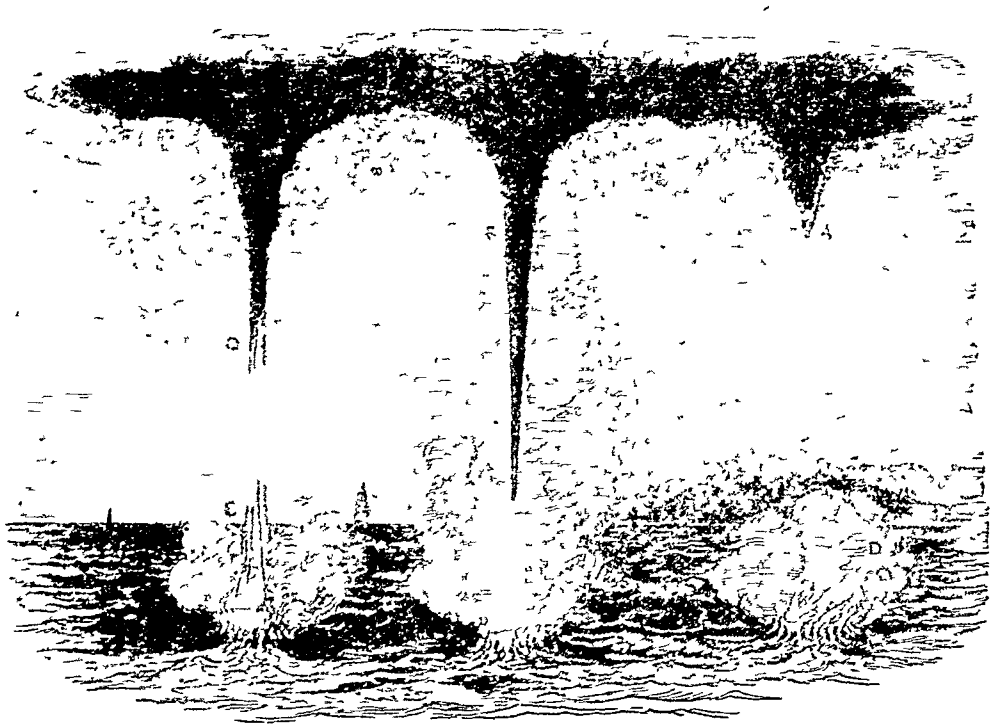

FIG. 6.—Forms of Waterspouts.

The usual position of the gyrating columns of cloud is vertical; but occasionally a curving form or slanting direction is assumed. It is probable that to these latter forms many stationary or slowly moving dangerous squalls are to be referred, which spring up with unexpected suddenness in lakes and arms of the sea in mountainous regions.

The dust storm of India, Arabia, and Africa is a well-marked type of the whirlwind. Previous to the outbreak of a dust storm the air is unusually calm and sultry, just as happens in the case of the tornado. The simplest form of the dust storm is that of a tall aerial column of sand moving onwards, and drawing into itself, as it whirls round in its course, dust and other light bodies within the sweep of the strong air-currents which blow along the surface of the ground and converge vorticosely round the base of the column. A form commonly seen is shown in fig. 7, which represents several dust columns grouped together, each whirling independently round its own axis with incurving air-currents at the base, while the whole group of columns is borne bodily forward, and presents striking aspects as the forms and relative positions of the columns are changed. The importance of the observations made on dust storms as leading to a correct understanding of the whirlwind consists in this that it affords conclusive evidence that there is a strong inflow of the air along the surface of the ground all round vorticosely towards the base of the whirlwind, and that these same inflowing air-currents afterwards ascend through the air along the central axis of the whirlwind, carrying with them the evidence of their ascent in the visible solid particles of dust, sand, and other light objects they whirl up with them in their ascending course.

Owing to the extreme dryness of the air-currents involved in the dust storm, the rarefaction generated by the rapidity of the gyrations is insufficient to produce condensation of the aqueous vapour in the interior of the column. Quite different, however, is it with waterspouts and tornadoes, where, in the great majority of cases, the air near the surface before being drawn into the ascending vortex is of a high temperature and near the point of saturation. From the extreme rarefaction to which these air-currents are subjected, owing to their sudden ascent in a rapidly gyrating column, excessive condensation follows, with an aqueous precipitation at times so astonishing that it can only be fittingly described as an aerial torrent of solid water, or an aerial avalanche of hail and ice.

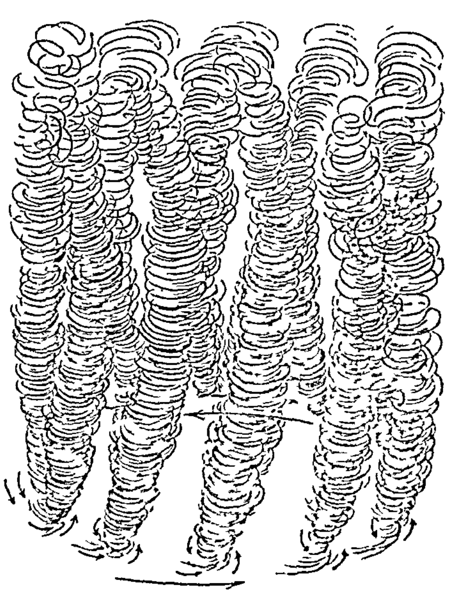

FIG 7.—Dust Storm.

Certain tracts of the ocean included within what may be called permanent anticyclones, or where atmospheric pressure is higher than all round, are characterized by an absence or comparative absence of rain. These regions are also remarkable for clear skies and strong sun heat. Similarly small anticyclonic areas occurring between or in the vicinity of cyclones are characterized by dry air and clear skies, and it is under these conditions that the strongest sun heat is felt. When, as repeatedly

happens in the warmer months of the year, anticyclones remain practically stationary for some time, the lowermost strata of the air become abnormally heated,—thus bringing about a vertical disturbance of the equilibrium of the atmosphere out of which whirlwinds originate. It is under these conditions that white squalls or fair-weather whirlwinds occur, the originating cause of this special form being the great dryness of the air due to its place in the anticyclone, and the abnormally rapid diminution of temperature and humidity with height owing to the strong insolation through the clear dry atmosphere. The clouds accompanying the white squalls are at a great height, but the commotion and boiling of the sea under them and following them as they drift onwards show that the squalls are true whirlwinds, the vapour column of the waterspout not being formed solely on account of the extreme dryness of the air which ascends the columns. The white squall accompanies fine weather, and its appearance is sudden, its duration brief, and its destructive power at times so dreadful that it has been known to strip a ship of every sail and mast in a few seconds, and leave it rolling a helpless log amidst the tremendous sea which follows it. In sailing through such regions a close lookout should be made, particularly when the weather looks singularly fine, the skies beautifully clear, the air calm or nearly so, and the temperature and moisture of the air on board the vessel noticeably high.

Diurnal Period of Hail.—The hail here referred to is round, hard, and compact, and in the form of clear or granular ice, the hailstones sometimes being found when broken across to be composed of alternate layers of these two states of ice. The following figures show the number of times it has occurred during the different hours of the day at Coimbra during the last six years:—

Midt. to 2 A.M.	0	8 A.M. to 10 A.M.	3	4 P.M. to 6 P.M.	3
2 A.M. ,, 4 ,,	1	10 ,, ,, Noon	20	6 ,, ,, 8 ,,	1
4 ,, ,, 6 ,,	2	Noon ,, 2 P.M.	15	8 ,, ,, 10 ,,	0
6 ,, ,, 8 ,,	1	2 P.M. ,, 4 ,,	13	10 ,, ,, Midt.	0

A diurnal period is thus well-marked at Coimbra, where forty-eight out of the fifty-nine cases have occurred from 10 A.M. to 4 P.M. This period is essentially the same as those calculated for a large number of places in representative climates, care having been taken to limit the inquiry to the particular hail described above. The important point to be noticed in the diurnal period of hail is that the time of maximum is about two hours earlier than the maximum period of thunderstorms. The maximum period for the thunderstorm is when the ascending current from the heated land is at its greatest force for the day; but the maximum period for hail is some time before the ascending current has fully established itself, or at that time of the day when the vertical disturbance of the atmosphere is greatest,—in other words, when atmospheric temperature and vapour fall with height at a much greater rate than the normal. In the higher latitudes hail falls almost exclusively during the warmer months of the year. In regions where the summer climate is practically rainless no hail falls; and where the rainfall is small and at distant intervals few cases of hail occur. Thus at Coimbra, where little rain falls in summer, hail was recorded as having fallen only once in the six years during the four dry hot months from June to September.

All hail is probably connected immediately with whirlwinds, more or less developed; and it is when the hailstorm is one of the phenomena attendant on the tornado or on a great thunderstorm that it assumes its most destructive form. The theory of the formation of hail has been stated by Ferrel in his *Meteorological Researches for the Use of the Coast Pilot*, part ii. p. 85. The vapour carried aloft by the gyrations of the tornado is below a certain height condensed into cloud and rain, but above that height into snow. Let the raindrops formed below be carried up into the snow region by the powerful ascending currents of the tornado and be kept suspended there a little while, and they become frozen into hail. If now these be thrown quite outside the gyrations of the tornado, they fall to the earth as a shower of compact homogeneous hailstones of clear ice of ordinary size. If, however, they are caught in the descent and carried in toward the vortex by the inflowing currents on all sides, they are again rapidly carried aloft into the freezing region. A number of such revolutions of ascent and descent may be made before they fall to the earth. While high up in the snow region, the hailstones receive a coating of snow; but, while traversing the region lower down where rain yet unfrozen is carried up, they receive a coating of solid ice. Thus alternate coatings of snow and ice are received, and the number of each sort indicates the number of revolutions described before the hailstones fell to the ground. When the nucleus is composed of compact snow, as is generally the case, the hailstone had its origin high up in the snow region as a small ball of snow, or soft hail (*Graupel* in German and *grésil* in French); but when it is composed of clear ice throughout it was formed in the rain region, carried up into the snow-region and there frozen, and immediately afterwards fell to the ground.

Monthly, Annual, and Irregularly Recurring Phenomena.

The Temperature of the Sea.—Figs. 8 and 9, representing the distribution of the temperature of the surface water of the ocean for the two extreme months February and August, are reproduced chiefly from *The Wind and Current Charts for Pacific, Atlantic, and Indian Oceans*, published by the British Admiralty in 1872.

In February (fig. 8) the temperature of the surface of the sea falls to the annual minimum over the northern hemisphere, and rises to the maximum in the southern hemisphere. The course of the isothermals more closely follows the latitudes in the Pacific, Indian, and South Atlantic Oceans; but the divergence from the latitudes is great and striking over the North Atlantic. The wider and more open the ocean the more does the distribution of the temperature approach the normal; and the more confined the ocean the greater is the divergence from the normal. The key to the anomalous distribution of the temperature of the ocean is furnished by the charts of the distribution of atmospheric pressure and the prevailing winds of the globe. So far as observation has gone it would appear that the surface currents are practically altogether caused by the prevailing winds over the respective oceans, subject to such deflexions in their courses as are occasioned by the land.

In the southern hemisphere the currents on the west side of the Indian Ocean flow southwards along the east coast of Africa, and, since the currents here pass from lower to higher latitudes, the temperature along the whole extent of this coast is raised considerably above the normal. On the other hand, since the currents on the west coast of Africa flow from south to north—in other words, from higher to lower latitudes—the ocean currents which impinge on this coast have a temperature much under the normal. The winds and currents on the coasts of South America are precisely analogous to those of Africa, and the distribution of the temperature of the sea is also similar. The temperature of the ocean on the east coast of that continent is for the same latitudes everywhere higher than on the west coast. Even in the smaller continent of Australia the same law holds good.

In the northern hemisphere a different distribution of the temperature of the sea is seen at this season. In the Atlantic the temperature is very much higher on the west of Europe than on the east of America. On the east of America from Wilmington to Boston occur the most rapid transitions in the mean temperature of the ocean anywhere on the globe, the temperature falling in that short distance from 70° to 30°, whereas on the eastern side of the Atlantic these isothermals pass Cape Verd Islands and Spitzbergen respectively. In the winter months the prevailing winds of the east side of North America are north-westerly, whilst in the central and eastern portion of the Atlantic they are south-westerly, thus pouring along the east coast of America the icy currents of the Arctic regions, but over the central Atlantic and along the western shores of Europe the warm waters of southern climates. The

easterly and south-easterly winds of Scandinavia in winter lower the isothermals along these coasts. A striking feature of the winter isothermals of the Atlantic is the singularly high temperature along the centre stretching from Spitzbergen towards the south-west and extending in a modified degree as far south as the West Indies. In the Pacific this feature of the mid-ocean temperature is much less pronounced, and the excess of temperature on the west of America over what occurs in the same latitudes of eastern Asia is not so great as the difference observable between the two sides of the Atlantic.

The highest mean temperature in February (85°) occurs in the Indian Ocean to the south-west of Sumatra, and there is a patch the

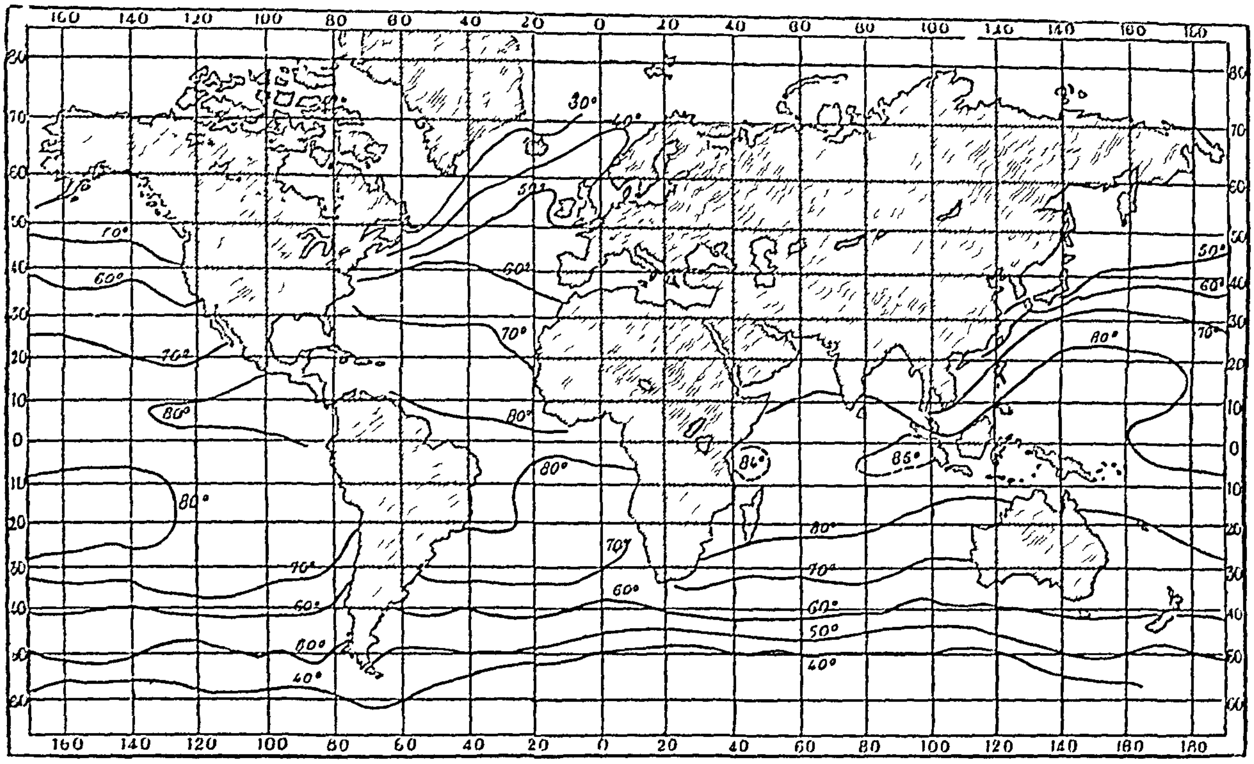

Fig. 8.—Isothermals of the Surface of the Sea for February.

temperature of which is 84° to the north of Madagascar. The highest means in the Atlantic are 82° in the north-east angle of the Gulf of Guinea, and 81° off the north east coast of Brazil. In the Pacific the highest are 83° to the north of the Fiji Islands and 81° near the Marshall Islands.

In August (fig. 9) the southern half of the Red Sea shows a mean temperature of 90°, being the highest mean recorded for the ocean anywhere at any season. Patches showing a summer mean of 85° occur in the Chinese Sea to the east of Tonquin, in the Bay of Bengal to the east of southern India, about Socotra, and to the

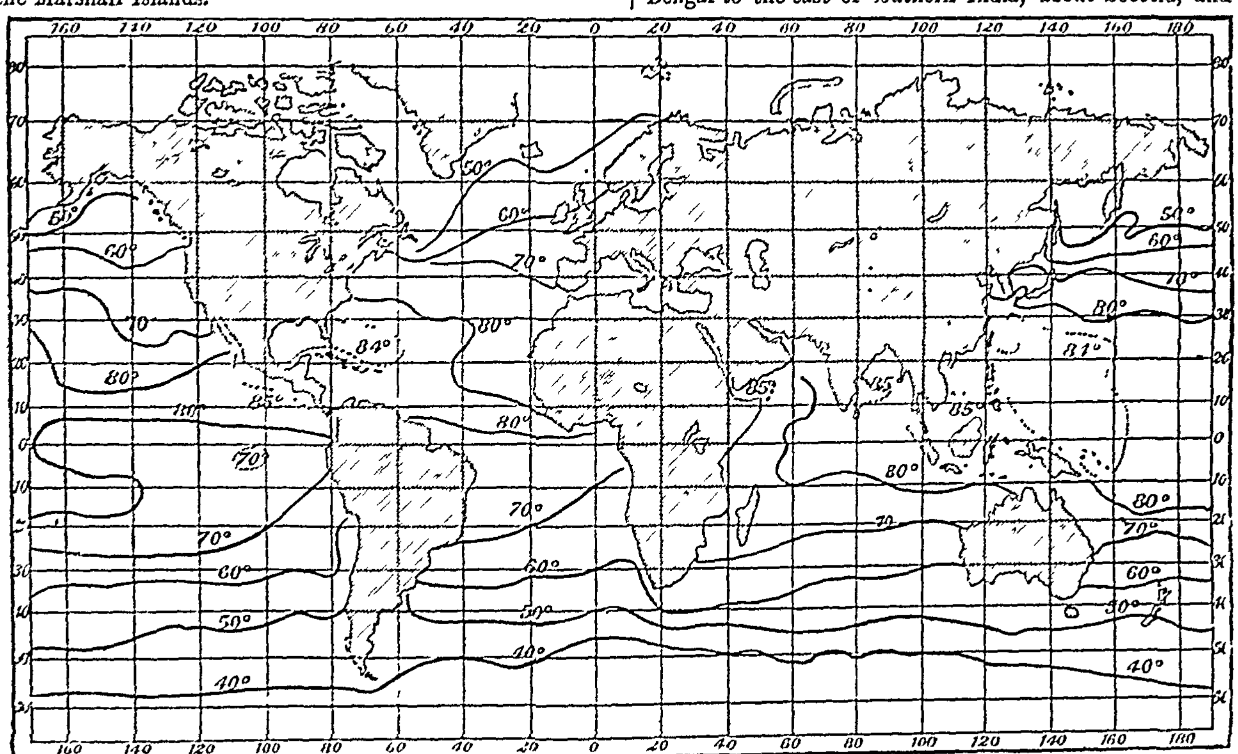

Fig. 9.—Isothermals of the Surface of the Sea for August.

west of Central America. But the most extensive regions of high temperature are in the west of the Pacific between long. 165° E. and the Philippines northward nearly to Japan and southward to New Guinea, and the Gulf of Mexico and the adjoining part of the Atlantic as far east as long. 57° W. A patch of remarkably low temperature occurs in the Pacific a little to the west of Galapagos, where the mean is only 70°, being 10° lower than what occurs anywhere else near the equator at this season.

The influence of currents is strongly expressed in the temperature of all the oceans. In the south of Asia the monsoons are S.W., S., and S.E. Under the impulse of these monsoonal winds an extensive surface drift of the waters of the equatorial regions is

carried northwards towards southern Asia, and consequently very high temperatures characterize these seas in summer. It is instructive to note the effect on the temperature of the sea resulting from the region of high atmospheric pressure in the North Atlantic at this season. Out of this anticyclonic region the winds blow in all directions, giving rise to surface currents flowing in the same directions. Thus to the west of Africa the winds and currents are from north to south; and hence the temperature of this part of the ocean is abnormally reduced. On the other hand, on the west side of this high pressure area, the prevailing winds and currents are from south to north; and it will be seen that the temperature of the whole of the region swept by the southerly winds is abnormally raised. On the north side of the area, the winds and currents are westerly as far as about long. 35° W., and over that space the isothermals follow the parallels of latitude. Farther to eastward and northward the prevailing winds become south-westerly, thus propelling northwards along the western shores of Europe, by oceanic surface drifts, the warmer waters of southern latitudes. Meanwhile the currents of cold water and ice drifts from the Arctic regions keep the temperature off America to the north of Newfoundland at a figure considerably lower than is observed in any other region in the same latitudes. In August similar relations exist as in January between the east and west coasts respectively of South Africa, South America, and Australia, all of which are readily explained by the charts of mean atmospheric pressure and the resulting prevalent winds.

One of the most striking facts of ocean temperature is that the temperature of the Southern Ocean from about 50° to 60° S. lat. is practically the same in January and August, a circumstance due chiefly to the magnificent icebergs of that ocean.

The Temperature of the Land.—In regions where the rainfall is distributed through all the months of the year, and where snow covers the ground for only a small part of the year, the mean temperature of the soil nearly equals that of the air. But when the year is divided into wet and dry seasons, and when snow lies during a considerable portion of the year, the mean annual temperature of the soil may be above or below that of the air. The greatest difference between the temperature of the soil and that of the air occurs where the surface of the ground is covered during several months with snow. Snow is a bad conductor of heat, and thus obstructs the free propagation of the cold produced by radiation downwards into the soil, and the escape of heat from the soil into the air. In this way, over a considerable portion of the Russian empire, the temperature of the soil is considerably in excess of that of the air. Thus at a place 120 miles south of Archangel the temperature of the soil is 10° higher than that of the air; and at Semipalatinsk it is 9° higher.

The daily changes of temperature only affect the soil to depths of about 4 feet. The precise depth varies with the degree of the sun-heat and with the nature of the soil. Similarly the heat of summer and the cold of winter give rise to a larger annual wave of heat propagated downwards, the amplitude of which diminishes with the depth till it ceases to be perceptible. Principal Forbes showed from observations on the Calton Hill, Edinburgh, that the annual variation is not appreciable lower than 40 feet below the surface, and that under 25 feet the change of temperature through the year is small. The depth at which the annual variation ceases, or where the temperature remains constant, is a variable depending on the conductivity and specific heat of the soil or rock, but particularly on the difference between the summer and winter temperatures. The rate at which the annual wave of temperature is propagated downwards is so slow that at Edinburgh, at a depth of 24 feet, the highest annual temperature does not occur till January 4, and the lowest till about July 13, thus reversing the seasons at this depth. At Greenwich, at a depth of 25½ feet, these phases of the annual temperature occur on November 30 and June 1.

Professor Everett in the *Report of the British Association* for 1879 has summarized the results of the observations of underground temperature. The temperature of the surface of the ground is not sensibly influenced by the flow of heat from below upwards, but is determined by atmospheric and astronomical conditions. The temperature gradient is defined as the rate of increase of the temperature downwards, and it may be taken as averaging one degree Fahrenheit for every 50 or 60 feet, the exact rate in particular cases being very variable. Thus the temperature gradient of the soil is about five times steeper than the temperature gradient of the air. The temperature gradient is steepest beneath gorges and least steep beneath ridges; and hence the underground annual isothermals are flatter than the uneven surfaces above them. This is the case even with the uppermost isothermal of the soil, and the flattening increases as we pass downwards until at a considerable depth they become horizontal. Where the surface of the ground and the isothermal surfaces beneath it are horizontal, the flow of heat is vertical, and the same quantity of heat flows across all sections which lie in the same vertical. In this case the flow across a horizontal area of unit size is equal to the product of the temperature gradient by the conductivity, if the latter term be used in an extended sense, so that it includes convection by the percolation of water, as well as conduction proper; and hence, in comparing different strata in the same vertical, the gradient varies in the inverse ratio of the conductivity.

Since the effects of the cold generated by nocturnal radiation mostly accumulate on the surface of the earth, but the effects of solar radiation are spread to some height by ascending currents from the heated ground, it might be expected that the annual temperature of the surface layer of the soil would be lower than that of the air resting over them. Observations prove that such is the case. Springs which have their sources at greater depths than that to which the annual variation penetrates have a constant temperature throughout the year, and if they do come from a depth considerably greater than this they may be regarded as giving a very close approximation to the mean annual temperature of the place. The temperature of cellars is also very near the mean annual temperature of the locality; at any rate this temperature may be secured for cellars anywhere.

Distribution of Temperature in the Atmosphere.—Of the larger problems of meteorology, the distribution of temperature in the atmosphere over the land surfaces of the globe was the first that received an approximate solution (by Humboldt). But as regards the ocean, which comprises three-fourths of the earth's surface, the question of the monthly and annual distribution of temperature in the atmosphere over it can scarcely yet be said to have been seriously looked at. The isothermals of the temperature of the atmosphere which cross the oceans continue still to be drawn essentially from observations made on the islands and along the coasts of these oceans. The first step towards the solution of this vital problem in climatology and other branches of meteorology is the construction of charts of mean monthly temperature of the surface water of the sea over all parts of the ocean from which observations for the purpose are available. In prosecuting this line of inquiry, excellent work has been done by the Meteorological Office as regards parts of the Atlantic between the tropics and the ocean to the south of Africa, and also by the Dutch, French, and German meteorologists. With such charts it would not be difficult, by a careful comparison during the same intervals of time between the temperature of the surface of the sea and that of the air resting over it, to construct monthly charts of the temperature of the atmosphere over the oceans of the globe.

In this connexion the whole of the observations of the temperatures of the air and sea made on board the "Challenger" have been examined, and sorted into one hundred and seventy-four groups according to geographical position, and the differences entered on a chart of the route of the expedition. In the Southern Ocean between latitudes 45° and 60° the temperature of the sea was lower than that of the air, the mean difference being 1°·4. The temperature of the air is here higher owing to the prevailing W.N.W. winds, and that of the sea lower owing to the numerous icebergs. To south of lat. 60° S. the sea was nearly 2°·0 warmer than the air, the result in this case being due to the open sea, which keeps up a higher surface temperature, and to an increased prevalence in these higher latitudes of southerly winds, thus lowering the temperature of the air.

The period during which the temperature of the sea exceeded that of the air was from June 1874 to March 1875, or during that part of the cruise from Sydney to New Zealand, and through the East India Islands to Hong Kong and thence to the Admiralty Islands. During the whole of this time, except when passing the north of Australia, the sea was much warmer than the air, the

general excess being from 2° to 3°, rising even near Tongatabu to upwards of 4°. The climate of the southern part of this extensive region at the seasons visited has a large rainfall, much cloud, and consequently a comparatively small evaporation and sunshine. In June, when the "Challenger" passed the north of Australia, the climate was very dry, the sunshine strong, and the evaporation large, and there the sea was slightly colder than the air. In the Atlantic between lat. 20° N. and 20° S. the sea was everywhere warmer, the mean excess being about a degree; and in the Pacific between lat. 30° N. and 30° S. the sea was also warmer, the mean excess being a degree and a half.

On the other hand, in the Atlantic from lat. 40° to 20° N. the sea was, on the mean, half a degree colder than the air. This region is remarkable for the high pressure which overspreads it, for the winds and currents which flow out in all directions, for its clear skies, strong sunshine, and consequently large evaporation, by which the temperature of the surface of the sea is lowered, and that of the air resting on it, being open to the heating influence of the sun, is raised. Similarly in the North Pacific from lat. 40° to 30° the temperature of the surface of the sea was half a degree lower than that of the air.

These remarks apply only to the observations made strictly on the open sea. Near land very great differences were observed which varied with season. Thus at Hong Kong during the latter half of November 1874 the sea was 3°·7 warmer than the air, the low temperature of the air at this season being caused by the lower temperature of the land and the northerly winds which then prevail; on the other hand, at Valparaiso in November and December of the following year the sea was 5°·8 colder than the air during the three weeks the "Challenger" was there, the difference being due to the cold oceanic current which sweeps northwards past that coast, and the rapid increase in the temperature of the air at that time of the year. These results will help us in gaining some knowledge of the temperature of the air over the oceans of the globe in February and August, taken in connexion with a careful examination of the sea temperature of these months represented in figs. 8 and 9.

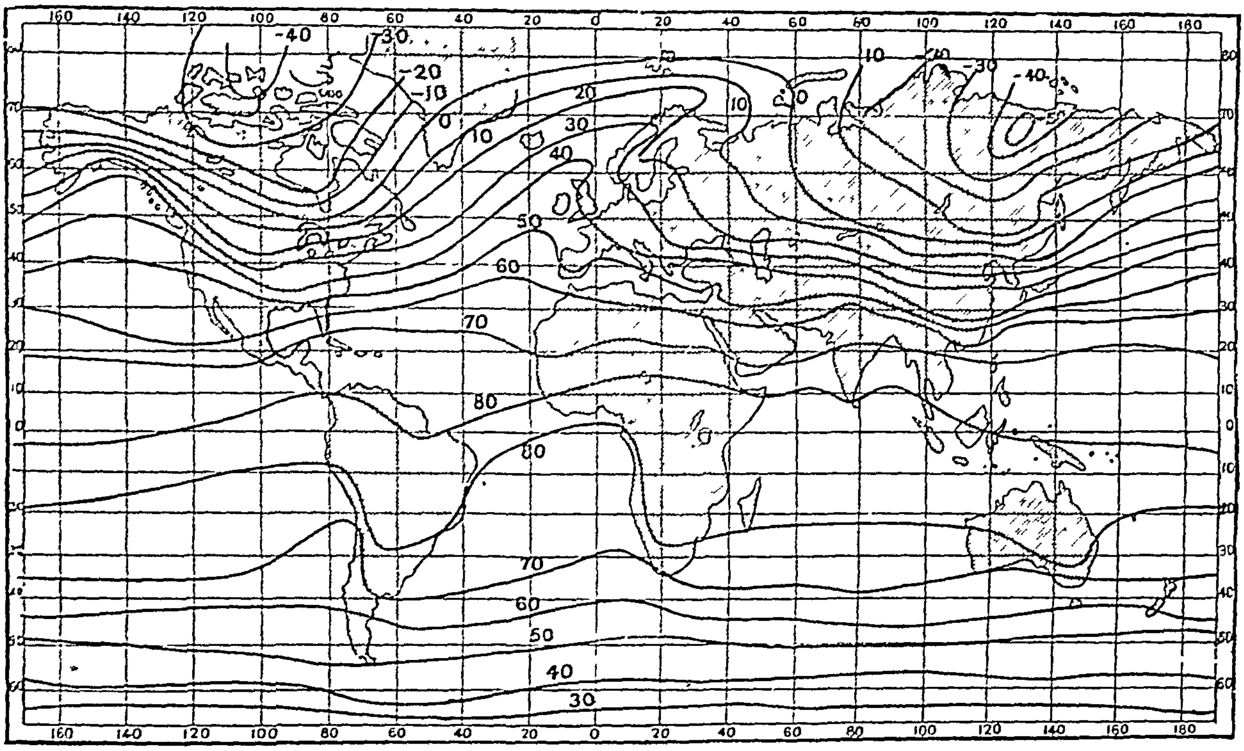

Fig. 10.—January Isothermals of the Surface of the Globe.

The distribution of temperature over the surface of the globe is shown by figs. 10 and 11, which represent the temperature of the two extreme months January and July for the eleven years 1870 to 1880. The region of highest temperature, which may be regarded as comprised between the north and south isothermals of 80°, forms an irregularly shaped zone, lying in tropical and partly in subtropical countries. On each side of this warm zone the temperature diminishes towards the poles, and the lines showing successively the gradual lowering of the temperature are, roughly speaking, arranged parallel to the equator, thus showing in an unmistakable manner the predominating influence of the sun as the source of terrestrial heat. While this decrease of temperature corresponds in a general way to what may be called the solar climate, there are great deviations brought about by disturbing causes.

Among these disturbing causes the unequal distribution of land and water holds a prominent place. In January the earth presents to the perpendicular rays of the sun the most uniform surface, or the largest water surface, and in July the most diversified surface, or the greatest extent of land. Hence the zone of the earth's surface comprised between the isothermals of 80° is less irregular, and also spreads over an area more restricted, in January than in July. In July the areas enclosed by the isothermals of 80° and 90° are much larger in the Old World than in the New, it being the former which presents the larger land surface to the perpendicular rays of the sun; and in January, the summer of the southern hemisphere, the most extensive area of high temperature occurs in Africa and the least in Australia, the high-temperature area of South America being intermediate. In contrast to this the belt of temperature exceeding 80° is of least breadth where it crosses the Pacific and Atlantic Oceans, the absolute minimum breadth being in July in the Pacific, the largest ocean, where the disturbing influence of the land is least.

During the cold months of the year, when the sun's heat is least and the effects of terrestrial radiation attain the maximum, the greatest cold is over the largest land surfaces which slant most to the sun. Thus the lowest mean temperature that occurs anywhere or at any season on the globe is −55°·8 at Werchojansk (lat. 67° 34′ N., long. 133° 51′ E.) in north-eastern Siberia. In Arctic America the lowest isothermal is −40°·0. During the winter the ocean everywhere maintains a higher temperature in all regions open to its influence, as is seen, not only in the higher latitudes to which the isothermals push their way as they cross the Atlantic and Pacific, but also in their irregular courses over and near the Mediterranean, Black, Caspian, and Baltic Seas, Hudson's Bay, the mouth of the St Lawrence, the American lakes, and all other large sheets of salt and fresh water. The disturbing influence of sheets of water on the temperature in all seasons is very strikingly shown when the isothermals are drawn for every

degree, these marking out the prominent features of local climates, a knowledge of which is of so great importance to the agriculturist, the horticulturist, and the invalid. Figs. 12 and 13 represent charts of temperature of this description for the British Islands for 1870–1880 from the *Jour. of Scot. Meteor. Soc.*, vol. vi. In the winter of the

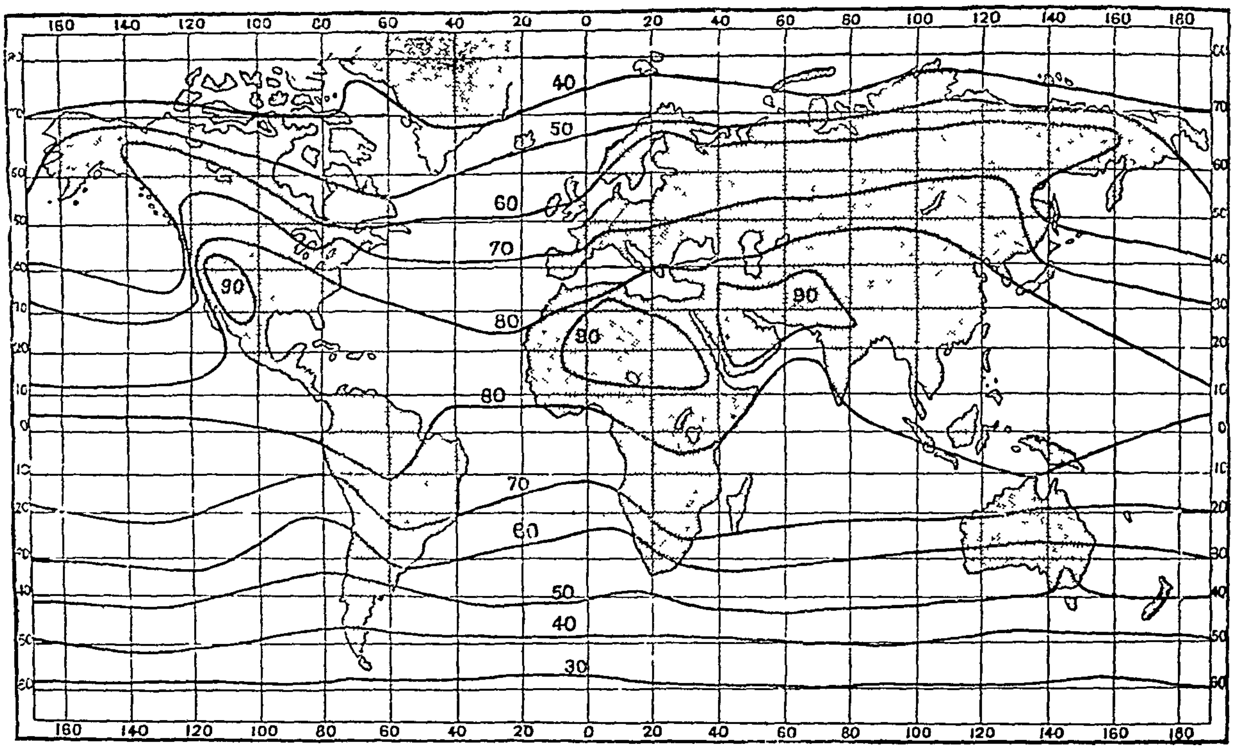

FIG. 11.—July Isothermals of the Surface of the Globe.

southern hemisphere the depressing influence of the land on the temperature is but slightly felt, owing to the small

FIG. 12.—Mean Temperature of the British Islands in January.

extent of the land surfaces and the comparatively low latitudes to which they extend southwards. In the south-east of Australia and in the basin of the La Plata, a lower temperature prevails in the interior.

Another prominent disturbing cause operating on the

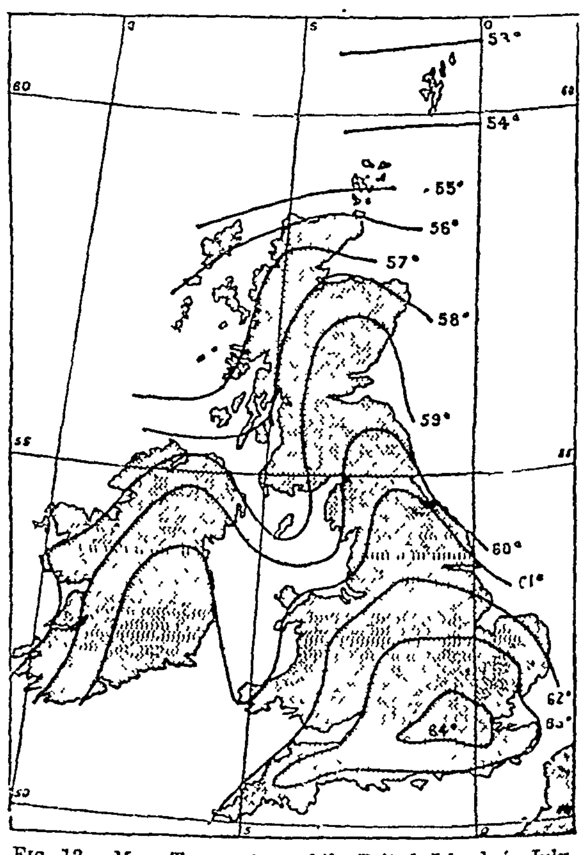

FIG. 13.—Mean Temperature of the British Islands in July.

mean temperature is to be found in the seasonal areas of low and high mean pressure in their connexion with the prevailing winds. Of these the most marked is the system of

narrow limits, as regards their temperature. The deflexions of the isothermals near the Baltic, Mediterranean, Black, and Caspian Seas and the freshwater lakes of America all point to the disturbing influence of these sheets of water on the temperature.

The height and direction of mountain ranges is an important element in determining climate. If the ranges are perpendicular to the prevailing winds and of a considerable height, they drain the winds of much of their moisture, thus causing to places to leeward colder winters and hotter summers, by partially removing their protecting screen of vapour, and exposing them more completely to solar and terrestrial radiation. Of this Norway and Sweden and the British Islands form excellent illustrations. It is this that makes the most important distinctions among climates in regions near each other, as respects both animal and vegetable life. With regard to the decrease of temperature with height, very much yet remains to be done before an approximation to the law of decrease can be stated. During the five months observations were made on Ben Nevis in the summer of 1881 the difference between the mean temperature at sea-level adjoining and at the top of the Ben, 4406 feet above the sea, was 15°·7, which shows a mean decrease of 1° Fahr. for every 280 feet of elevation. The actual differences from day to day varied from 1°·4 to 23°·2. As Ben Nevis forms a peak, and is in the very middle of the strong winds from the Atlantic, it is highly probable that this rate of decrease is a close approximation to the true decrease of the temperature of the air during the summer months in that part of the British Islands. When observations are made on elevated plateaus of some extent, the rate of decrease deduced from the observations will be less than the true rate in the free atmosphere in summer and greater in winter. The rate is thus a variable quantity, varying with latitude, situation, dampness or dryness of the air, calm or windy weather, and particularly with the season of the year. One degree Fahrenheit for every 300 is the rate of decrease generally assumed.

Amount of Aqueous Vapour.—It is scarcely possible to overestimate the importance of a knowledge of the horizontal and vertical distribution in the atmosphere of its aqueous vapour, for it may be truly said that it forms one of the prime factors in all the larger problems of atmospheric physics. A first rough approximation to the geographical distribution of the vapour of the atmosphere was published by Mohn in 1875 in his *Grundzüge der Meteorologie*, p. 84, in which vapour-pressure curves are drawn for the globe for January and July. These leave much still to be done, not only in a further discussion of observations already made, but also in improvement of the methods of observation and in the tables for their reduction. The chief point of interest in Mohn's vapour curves is their striking resemblance to the isothermals of the same months, and they also suggest that this line of inquiry is yet destined to make large contributions to our knowledge of the unceasing changes which occur in the pressure, temperature, cloud, rain, and movements of the atmosphere.

Still less is known of the vertical distribution of aqueous vapour. It decreases, like temperature, with the height, and if the statement generally made be at all correct, that half of the whole vapour of the atmosphere is contained in the lowest 6000 feet, and that at 20,000 feet high there is only about a tenth of what is at the earth's surface, the rate of decrease with height proceeds at a greatly more rapid rate than is consistent with the supposition that it forms an independent vapour atmosphere existing under its own pressure. The establishment of an increased number of high-level stations, and a more systematic inquiry than has yet been attempted into the upper currents of the atmosphere, are much needed in the further development of this branch of meteorology. In carrying out the inquiry, invaluable assistance will be obtained from observations of the diurnal range of the barometer and from well-devised methods of observing the effects of solar radiation at the earth's surface.

Amount of Cloud.—In Scotland, which lies completely within the region swept by the south-westerly winds from the Atlantic, and presents a well-defined mountain range lying across the track of these winds, the clouds have a distinct annual period. In the west, at places quite open to these westerly breezes, the amounts of cloud in spring, summer, autumn, and winter are respectively 67, 69, 71, and 74, and the annual mean 70.[1] In the east, in such districts as East and Mid Lothian, which have extensive ranges of hills between them and the Atlantic, the proportions are 59, 63, 62, and 60, and the annual mean 61. Thus about a tenth more of the sky is covered with cloud at the western as compared with the eastern situations, and the distribution of cloud differs materially in western and eastern climates. In the west winter is the cloudiest season, but in the east it is summer, and these are respectively the months when most rain falls in the several climates. Everywhere spring is the season when the sky is clearest. In England, owing to the protection afforded by Ireland and Wales to the west and the comparative absence of ranges of hills, the amount of cloud is less than in Scotland, and it is more equally distributed over the country. The minimum amount occurs in spring, and the maximum in winter and autumn.

Some of the best illustrations of the seasonal variation in the distribution of cloud are afforded by the Old Continent. These variations are the simple consequence of the systems of wind caused by the high winter and low summer pressures of that continent. In eastern Siberia the prevailing winds in winter are N.W. or continental, and in summer S.E. or oceanic; and accordingly at Ajan, Nertchinsk, and Blagoweshtchensk the mean amounts of cloud in these two seasons are 18 and 44. On the other hand, in western Siberia and eastern Europe the prevailing winds in winter are S.W., or from lower to higher latitudes, and in summer N.W., or from higher to lower latitudes. Kazan may be taken as fairly representing this extensive region, and there the amounts of cloud for the four seasons beginning with winter are 71, 48, 44, and 62. As the N.W. winds of summer rise over the Ural mountains in their course, condensation of the aqueous vapour is increased, and hence over this region the cloud in winter and summer is nearly the same, the mean amounts at Bogoslovsk, Ekaterinburg, and Zlatoust being respectively 53 and 52. At Tiflis and Kutais, situated on the high ground which lies between the Black Sea and the south of the Caspian Sea, the means for winter and summer are 53 and 55. On the eastern coast of the Black Sea the westerly winds of summer are accompanied with the annual maximum cloud, the winter and summer amounts at Redut-Kale being 59 and 69. In Central Siberia, to which the S.W. winds of winter do not extend, and to the north of latitude 55°, the amount of cloud is much diminished, and the cloudiness of summer is nearly the same as that of winter.

In India, in all regions which lie open to the summer monsoon, the minimum amount of cloud occurs during the winter and the maximum in summer,—the mean amounts being 19 and 74 at Calcutta, 16 and 86 at Bombay, 48 and 71 at Colombo, and 25 and 90 at Rangoon. At Trincomalee, on the east coast of Ceylon, and thus exposed to the rains of the N.E. monsoon of winter, and largely protected from the rains of the S.W. monsoon of summer, the amounts of cloud in these seasons are 52 and 59. At Darjiling (6912 feet) and Chakrata (7022 feet high), both on the Himalayas, whither the summer monsoon penetrates, the mean amounts are respectively 53 and 86, and 43 and 73. At Leh, in Kashmir, the amounts are 59 and 51, the excess being thus in winter. In the Punjab and to westwards, or those regions in southern Asia to which the summer monsoon does not extend, the cloud in winter is everywhere greater than in summer. Thus the amounts are 24 and 18 at Mooltan, 38 and 25 at Peshawar, 27 and 19 at Jacobabad, and at Quetta, in Baluchistan, 5500 feet high, 42 and 14. Similar relations as to cloud obtain in Australia and the other continents where high pressures rule in the interior during

[1] In this section the amount of cloud is stated in percentages of the sky covered with cloud.

the cold months and low pressures during the warm months of the year. The maximum cloud occurs with winds from the sea and winds advancing into the colder regions of higher latitudes, and the minimum with winds which have traversed an extensive track of land and winds advancing into the warmer regions of lower latitudes. As the subject, however, is essentially one with rainfall, it is not necessary to prosecute it further.

The other atmospheric movements on which the amount of cloud depends are the ascending and descending currents of the atmosphere,—the ascending currents with clouded skies occurring in the belt of calms and over cyclonic areas and regions, and the descending currents with comparatively clear skies over anticyclonic regions. The region of maximum vapour and densest cloud-screen on the globe is the equatorial belt of calms between the trades, which has an annual movement northward and southward with the sun as already explained. To ascensional movements is to be ascribed part of the cloudiness of the southern and eastern sides of the winter cyclonic regions of the North Atlantic and North Pacific, and of the cyclonic regions of low summer pressure in the interior of Asia and other continents. On the other hand the comparatively small amount of cloud in the anticyclonic regions of the Atlantic and Pacific Oceans, and in the high-pressure regions of the interior of Asia and other continents during the cold months of the year, is due to the vast down-currents which occupy the centres of the anticyclones, and which become relatively drier as they descend owing to the increasing pressure to which the air is subjected.

Distribution of Atmospheric Pressure.—The importance of a knowledge of the distribution of atmospheric pressure, or of the mass of the atmosphere, over the globe in its varying amounts from month to month is self-evident. Observations teach us that winds are simply the movements of the atmosphere that set in from where there is a surplus towards where there is a deficiency of air; and observations also teach that isobaric maps (*i.e.*, maps showing the relative distribution of mean pressure) and maps showing the prevailing winds are in accordance with each other. Since prevailing winds to a large extent determine the temperature and rainfall of the regions they traverse, isobaric maps may be considered as furnishing the key to the more important questions of meteoro-

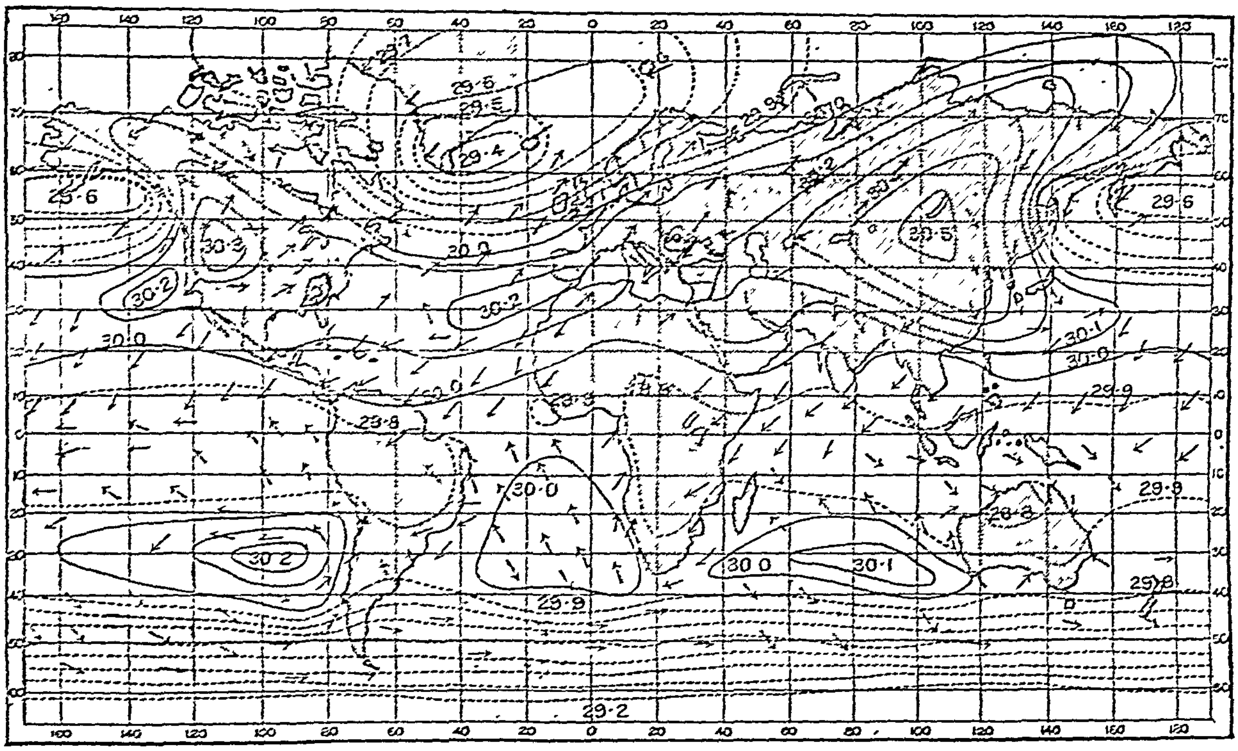

FIG. 14.—January Isobars of the Globe and Prevailing Winds.

logical inquiry. At the time of the first publication of isobaric maps of the globe in 1868, it was impossible to do more than present the subject in its broad general features, owing to the scantiness and quality of the materials then existing. But since then meteorological stations have been largely multiplied in all parts of the civilized world, and the general adoption of the issue of storm warnings has necessitated the use of more accurate barometers and uniform methods of observing. Since there is thus now the means of a more exact representation of this fundamental datum of meteorology, we have prepared a new set of isobaric maps, showing the distribution of the earth's atmosphere and the prevailing winds for January (fig. 14), July (fig. 17), and the year. They have been constructed from mean values calculated for the same eleven years (1870–80 inclusive) as the isothermal maps figs. 10 to 13, pressure of 30·0 inches and upwards being represented by solid lines, and of 29·9 inches and under by dotted lines, while the arrows show the directions of the prevailing winds at the localities indicated by the respective arrow-points.

Mean Atmospheric Pressure in January (fig. 14).—In this month, when the influence of the sun on the northern hemisphere falls to the minimum, the greatest pressures are massed over the continents of that hemisphere, and the least pressures over the northern parts of the Atlantic and Pacific Oceans, over the Antarctic Ocean and southern hemisphere generally. In the southern hemisphere there are three patches where pressure rises to 30 inches, viz., in the Atlantic between South America and Africa, south of the Indian Ocean, and in the Pacific between Australia and South America.

In the northern hemisphere, on the other hand, pressure rises in Central Asia to upwards of 30·5 inches, the mean pressure for January being at least 30·4 inches at Peking, Semipalatinsk, and Yenisei, and fully 30·5 inches at Irkutsk and Nertchinsk, in the upper basin of the Amur. This is the region where the normal atmospheric pressure attains to a maximum which is much higher than is reached in any other region or at any other time of the year. It will be observed that this region of highest pressure occupies a position near the centre of the largest continent. The area of high barometer is continued westward through Europe, through the horse latitudes of the Atlantic to Carolina, and thence through the United States to California, whence it crosses the Pacific to Asia. This belt of high pressure thus completely encircles the globe, broadening as it passes the land and contracting as it crosses the ocean. Its greatest breadth is over Asia and its least over the Pacific, or where land and ocean attain respectively their maximum dimensions.

Pressures greatly under the average cover the northern portions of the Pacific and Atlantic and also the greater part of the Arctic regions. In the north of the Pacific the normal pressure falls to about 29·6 inches between Kamchatka and Alaska. In the north of the Atlantic, however, a still lower mean pressure obtains over a narrow belt stretching from Iceland to the south of Greenland, the normal at Stykkisholm in the north-west of Iceland being 29·385 inches, and at Ivigtut in Greenland 29·361 inches. This low average for Ivigtut is the lowest normal known to occur anywhere and at any season in the northern hemisphere, and it is significant that the place is immediately to the north of that part of the Atlantic where a considerable number of the storms which sweep over Europe have their origin, and where not a few of the storms which cross the Atlantic from America develop intensity.

It has been seen that the highest mean pressure occurs near the centre of the largest extent of land; but as regards the two oceans the lowest pressure is met with in the northern division of the Atlantic, which is the lesser ocean. An inspection of fig. 14 shows, however, that the low-pressure area of the Atlantic is bounded to southward by systems of much higher pressures than are to be found in the Pacific. The result of this arrangement is that much stronger winds blow northward over the Atlantic and round upon Iceland; and, as these more quickly advance into colder latitudes, there is thus a greater and more frequent concentration of vapour and lowering of the barometer in the north of the Atlantic. The heavy rainfall of north-western Europe may be referred to as confirming this view.

A belt of low pressure passes through the equatorial regions quite round the globe. This marks the well-known region of calms towards which on either hand the trade winds blow. In the Atlantic it lies quite north of the equator even in January, when the sun's course is farthest to southward, and it lies nearly parallel with the equator. On the other hand, in the Indian Ocean the position of the line of lowest pressure is to the south of the equator and not parallel with it, but taking a slanting course from near the north of Madagascar towards Sumatra, thence towards the low pressure which prevails at this season in Australia; its course is then a little to northwards, and crosses the Pacific to the central regions of South America. Its path is thus a devious one, being north of the equator only in the eastern part of the Pacific and in the Atlantic, but elsewhere to the south of it, being drawn farthest southward when under the influence of the regions of low pressure which now occupy central Australia, central and southern Africa, and central South America. In this trough of barometric depression nearly all the tropical storms of the Indian Ocean have their origin.

There are several important modifications of the isobaric lines as originally published. In 1868 the region of lowest pressure in the northern hemisphere in winter was represented as extending from Iceland to north-eastward; now the area of lowest pressure is seen to extend from Iceland south-westward to Greenland. In connexion with this point Captain Hoffmeyer discussed the weather of the North Atlantic during several winter months, and published the results in 1878, which conclusively showed that the meteorology of Greenland and Iceland exerts on the distribution of atmospheric pressure a powerful influence not before properly recognized, resulting in the mean minimum of pressure being localized distinctly to the south-west of Iceland, and that in addition to this minimum there are two subordinate minima, one in Davis Straits and the other in the Arctic Ocean midway between Jan Mayen and the Lofoten Isles. The investigation further established the fact that, when any particular one of these three minima plays an important part, the other two either do not appear at all or occupy quite a subordinate place, and that according as one or other of these minima of pressure predominates so is the character of the weather, as regards mildness or severity, of the winter of north-western Europe and regions surrounding the North Atlantic. As regards the British Islands, the displacement of the minima to westward of the position shown in fig. 14 means milder winter weather, whereas a position more in the direction of the north of Norway means severer winter weather.

Another change implying important consequences is seen in the United States, where, instead of one, two distinct centres of maximum pressure occur, or rather the high pressure of the western and central States is separated from that of the south-eastern States by a region of lower pressure occupying the region of the Mississippi States. Professor Loomis first drew attention to this peculiarity in 1879 in an inquiry into the distribution of pressure over the United States, and established the fact that there are two distinct areas of high pressure, the larger having its centre in Utah, and the less overspreading the greater portion of the south-eastern and southern States, and that these two areas of high pressure are clearly separated from each other by a broad extensive region of lower pressure stretching in a south-western direction from the region of the great lakes to western Texas. The reason assigned by Professor Loomis is undoubtedly correct, that the relatively low normal pressure of the Mississippi States is due to the fact that the path usually taken by the barometric minima of American storms in the earlier part of their course is from Texas to the lakes. Since, on the other hand, the centres of comparatively few storms, with their low barometer readings, cross the southern and south-eastern States, the normal winter pressure is higher there than it is along the Mississippi.

Another important modification occurs in India, where the isobar of 30 inches is deflected to the south-east toward Madras and thence towards the north-east to near Akyab in Arakan. This remarkable deflexion well shows the important influence exerted on the course of the isobar by large well-defined sheets of water and extensive tracts of land. The distribution of pressure here indicated, by which south of lat. 22° the normal pressure is considerably higher in the east than in the west of India, has, through the agency of the winds resulting from it, the most intimate and vital bearings on the distribution of the winter rains and temperature over considerable portions of India; and the same relations hold, but in a degree still more striking, in the meteorology of Ceylon.

The remarkable effect in interrupting or changing the course of the isobars is particularly well illustrated by the lines in the region of the Aral, Caspian, and Black Seas. As the point is of no small importance in meteorology, and is best illustrated by the Mediter-

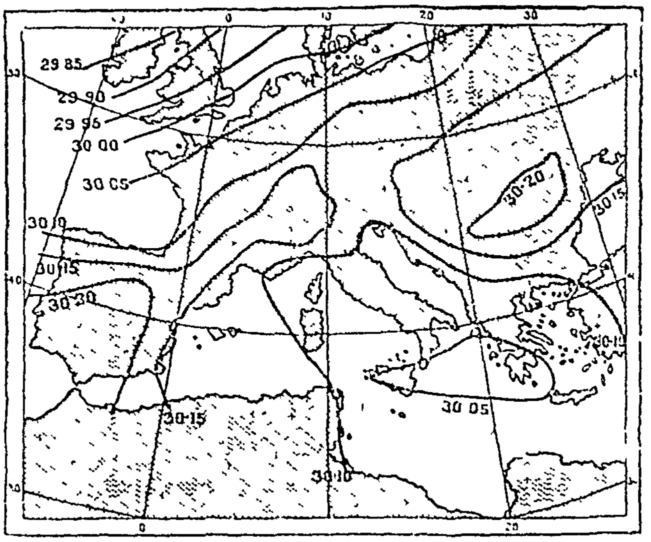

Fig. 15.—Isobars of Europe for January.

ranean and the countries to the north of it, we subjoin a map of this part of Europe (fig. 15), showing the normal pressure with greater distinctness and fulness than could be shown on fig. 14, the isobars being drawn for every half-tenth of an inch.

Here we see two distinct areas of high pressure, the one in Hungary and the other in the Peninsula, where the normal pressure exceeds 30·20 inches. The latter is the larger of the two, and may be regarded as the prolongation of the region of high pressure which characterizes the Atlantic immediately to the south-west at this season. The high-pressure area included within the isobar 30·15 inches is of peculiar interest. In the Peninsula it covers a pretty broad area, but to the north-east it contracts to a narrow neck between the Bay of Biscay and the Gulf of Lyons, and again expands to north-eastward covering the distance from Carlsruhe to Modena, its prolongation eastward being there somewhat suddenly interrupted. At some distance to the eastward the second region of high pressure is met with, which is properly a part of the high pressure that overspreads the interior of the Old Continent in the winter months, its western limit being the isobar of 30·15 inches, which passes round by Pinsk, Cracow, Vienna, Laibach and the upper southern slopes of the basin of the Danube, Sebastopol, and thence southward in the direction of Cyprus.

The position of the latter of these regions of high pressure is approximately midway between the south coasts of Asia Minor and the Baltic. In other words, its position occupies the interior of this part of the Old Continent; and it is instructive to note that the position of the Black Sea and the Greek archipelago in the south portion of this region pushes the isobar of 30·15 inches a good deal to northward. The position of the region of high pressure in the Peninsula, France, and Switzerland is also decidedly inland. It does not, however, exactly occupy the middle space of the land lying between the Mediterranean and the North Sea, owing no doubt to the circumstance that the very steep barometric gradient from France to Iceland greatly lowers the pressure over the whole of the northern half of France. It follows that the abnormally high pressure which so remarkably characterizes the interior of the Old Continent during the cold months of winter is represented, though in a greatly reduced form, westwards through the central districts of that continent.

These two regions of high pressure are separated from each other

by a large area of comparatively low pressure overspreading the greater portion of the Mediterranean Sea,—marked off in fig. 15 by the isobar of 30·10 inches, within which pressure is everywhere less than 30·10 inches. This region includes an area of still lower pressure within the isobar of 30·05 inches, bounded by Sicily, Corfu, Athens, and Crete. Hence the singularly low pressure which characterizes the northern part of the Atlantic at this season has its analogue in the south of Europe, which is unquestionably due to the higher temperature and larger humidity of the climates of southern Europe which they owe to the Mediterranean.

It is deserving of special notice that, while the increase of the normal pressure of January from Genoa to Geneva is 0·081 inch, it is only 0·021 inch from Trieste to Riva, and that to the north of the Adriatic as far as latitude 50° pressure is considerably lower than obtains to the west and east of that region. An examination of the daily weather maps of Europe shows that not unfrequently the storms of north-western Europe on advancing as far to eastward as Denmark seem to connect themselves in some degree with Mediterranean storms prevailing at the time through a north and south prolongation of a system of low pressures. The comparative frequency with which this occurs is probably occasioned by the general drift to eastward of the atmosphere of Europe, considered as a whole, taken in connexion with the high mountainous ridge which bounds the Adriatic on its eastern side, from which it follows that the air overspreading the deep basin of the Adriatic is often highly saturated with vapour, and this highly saturated air is drawn northwards through central Europe when north-western storms of Europe with low barometric depression centres pass across Denmark and the Baltic. Thus the low normal pressure to the north of the Adriatic, separating the two regions of high pressure to the east and west of it, is in some respects analogous to the low normal pressure of the Mississippi valley, which separates the higher normal pressures of the Rocky Mountains and of the south-eastern of the United States.

The influence of land and water respectively in the cold season of the year is well shown in fig. 16, which represents for every 0·020 inch the normal pressure over the British Islands in January, drawn from means calculated for two hundred and ninety-five stations.[1]

It is in the winter months that the isobars of the British Islands crowd most closely together, and in accordance therewith strong winds are then most prevalent. The crowding of the isobars reaches the maximum in January, forming what is probably the steepest mean monthly barometric gradient that occurs at any season anywhere on the globe. The point, however, to which attention is here drawn is the remarkable influence of St George's Channel and the Irish Sea in diminishing the pressures as they cross these seas, and of the land in increasing the pressure, which is seen in the curves occupying approximately the central districts of Great Britain from the Isle of Wight to Cape Wrath. This shows on a comparatively small scale the influence of the land in

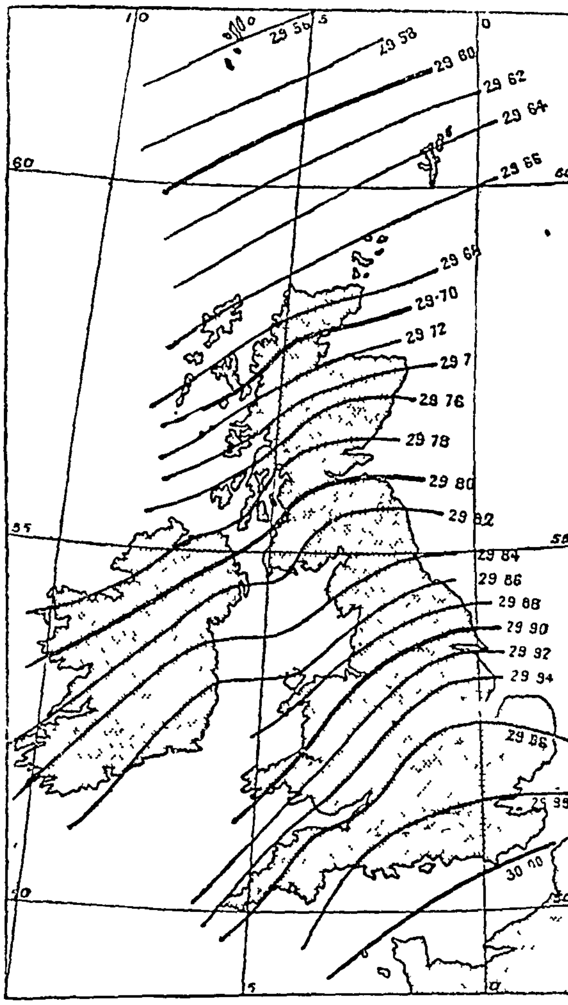

FIG. 16 —Isobars of the British Islands for January.

raising the normal pressure, and of the sea in lowering it, during the

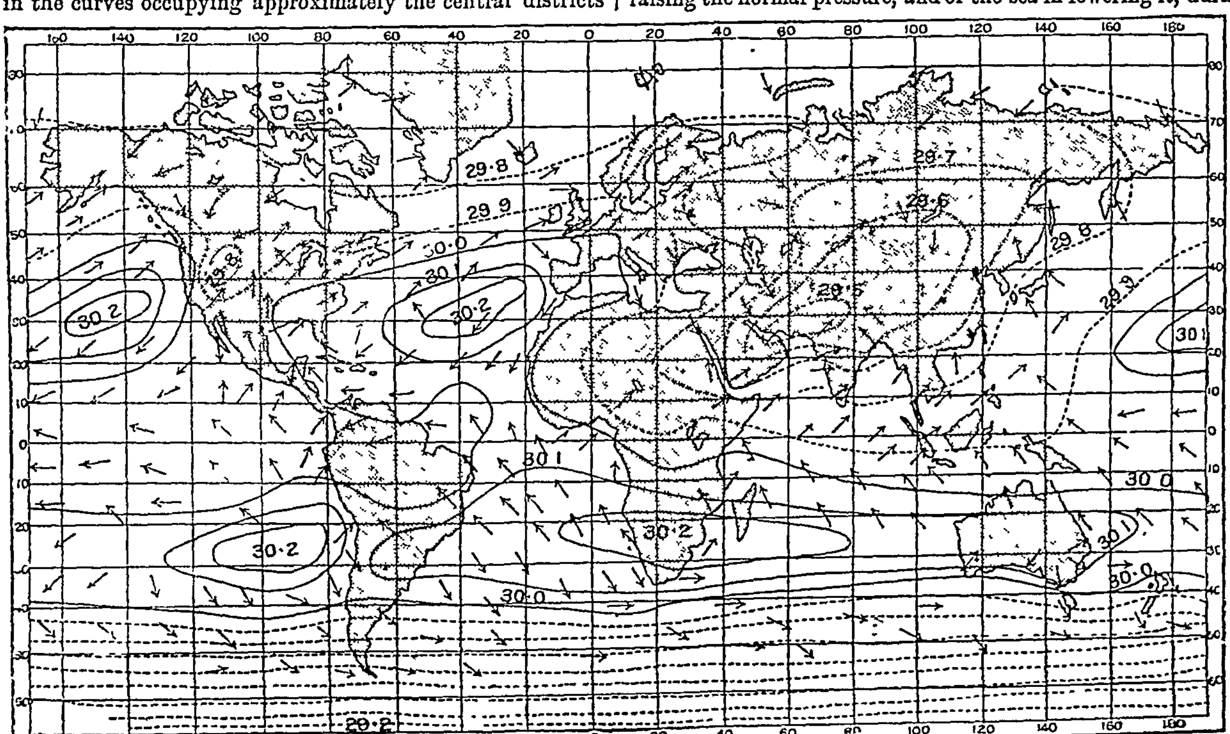

FIG. 17.—July Isobars of the Globe and Prevailing Winds.

cold months of the year, just as is seen on the grand scale in central Siberia and the north of the Atlantic.

Mean Atmospheric Pressure in July (fig. 17).—In this month the physical conditions are the reverse of what obtains in January, the effects of the influence of the sun on the temperature and humidity of the atmosphere rising to the maximum in the northern and fall-

[1] See *Journal of Scot. Meteorological Society*, vol. vi. pp. 4–21.

ing to the minimum in the southern hemisphere. With the solar conditions reversed, a comparison of figs. 14 and 17 shows that the distribution of atmospheric pressure in July is, considered in a broad sense, the reverse of what takes place in January.

In the southern hemisphere atmospheric pressure during the winter season is above the general average of 30 inches between lat. 10° and 40° S. This belt of high pressure encircles the globe, and embraces four regions where pressure rises considerably above this general high average. These regions are in South Africa, about lat. 20°, where it rises to a little above 30·20 inches; in Australia, where it rises on the Murray river very nearly to 30·20 inches; in South America, where in the basin of the La Plata, about lat. 30°, it rises to 30·13 inches; and in the ocean to westwards, where it reaches 30·02 inches. The point to be noted with respect to the position of these centres of high pressure at this season is that they occur over surfaces between latitudes 20° and 36°. As compared with January, pressure in July over nearly the whole of this broad belt of the southern hemisphere is about two-tenths of an inch higher, which is the simple result of season. A comparison of January and July shows that this large accession to the pressure of the southern hemisphere is accompanied by an extraordinary diminution of pressure over the continents of the northern hemisphere.

Now, just as the greatest excess of pressure during the winter of the northern hemisphere occurs in the continent of Asia, so the greatest diminution of pressure in the summer months takes place in the same continent. The position, however, of these two extremes is far from being in the same region or even near each other. In the Old Continent the maximum occurs in the valley of the upper Amur, where, at Nertchinsk, the normal pressure in January is about 30·500 inches; whereas the lowest normal pressure in July is 29·412 inches, and occurs, so far as observation enables us to locate it, at Jacobabad on the west side of the basin of the Indus. The difference of these two normals is 1·188 inch; and over no inconsiderable portion of central Asia the normal pressure of July is an inch less than that of January. In other words, the influence of the sun in summer as exerted on the temperature and aqueous vapour of the atmosphere and atmospheric movements resulting therefrom is so powerful as to remove a thirtieth part of the whole mass of the air from this extensive region.

The large extension in recent years of good meteorological stations over the Russian and Indian empires enables us to lay down with much greater precision than formerly the lines of pressure. Of the changes indicated by the new isobars, the most important perhaps is the position of the region of minimum pressure in Asia, which is now seen to occupy the basin of the Indus, and thence stretches over a somewhat broad region to westward nearly as far as the head of the Persian Gulf. The point is of no small importance in atmospheric physics, inasmuch as it places the region of least normal pressure in July as close geographically to the region where at the time terrestrial temperature is highest as the region of highest normal pressure in January is situated with respect to the region where in that month terrestrial temperature is lowest in Asia.

The July isobars of India are of singular interest, and imply consequences of the utmost practical advantage to the empire. From Cutch southward the normal pressure is everywhere higher, and considerably so, along the whole of the west than it is in the east in the same latitudes, the difference being approximately half a tenth of an inch. This is represented on the map by the slanting of the isobars from north-west to south-east as they cross this part of India; and it is to be noted that the east and west coasts of Ceylon show the same manner of distribution of the pressure. The consequence of this peculiarity in the distribution of the pressure is that the summer monsoon blows more directly from the ocean over western and southern India than would have been the case if the isobars had lain due east and west, and thus probably precipitates in its course a more abundant rainfall over this part of the empire. But a more important consequence follows from the geographical distribution of the pressure over the valley of the Ganges. If the normal pressure there had diminished in the manner it does over India to the south of the Gangetic valley, the winds would have been south-westerly and the summer climate practically rainless. This, however, is not the case, but the normal pressure diminishes westwards along the valley of the Ganges, as the following mean July pressures will show:—Calcutta, 29·576 inches; Patna, 29·535 inches; Lucknow, 29·522 inches; Roorkee, 29·505 inches; and in crossing westward into the Punjab pressure falls still lower—to 29·439 inches at Mooltan and 29·412 inches at Jacobabad. Indeed pressure in July is 0·220 inches lower at Jacobabad than at Sibsagar on the Brahmaputra, nearly in the same latitude. It necessarily follows from this distribution of the pressure that the summer monsoon, which blows northward over the Bay of Bengal, is deflected into an E.S.E. wind which fills the whole valley of the Ganges, distributing on its way a most generous rainfall over that magnificent region.

The influence of the land in lowering the pressure in summer is well illustrated by the course of the isobars over western Siberia and Russia, where pressure is seen to fall relatively lowest along the middle line of the Old Continent. In this connexion it is interesting to note the course of the isobar of 29·90 inches over that part of Europe where the breadth of the land is considerably increased—between the Baltic and Constantinople. In contradistinction to this the influence of the Aral, Caspian, and Black Seas in maintaining a higher pressure appears in the remarkable prolongation eastward of the isobars of higher pressure over the region of these seas, being in striking contrast to the lower pressures which prevail to the north and south.

The lowering of the normal pressure is very decided in the inland regions of Spain, North Italy, and Scandinavia. The effect is most strongly seen in Spain, the largest and compactest of these regions. Thus, while the normal pressure diminishes between Lisbon and Barcelona from 30·086 to 30·018 inches, the sea-level pressure at Madrid falls nearly to 30·000, and the pressure at Saragossa and Valladolid is nearly as low. This lowering of the pressure over the interior influences materially its summer climate. As remarkable an illustration of the principle as can be pointed to anywhere is seen in the north of Italy; for, while the normal pressure at Moncalieri is 29·941 inches, at Genoa on the coast the relatively high normal of 29·992 inches is maintained, the distance of the two places being about 40 miles. To the east pressure rises to 29·970 inches at Venice, and to westward to 30·023 inches at Geneva. Over Scandinavia, along the west coast from the Arctic circle southward, the normal pressure equals or exceeds 29·80 inches, the variation being comparatively small; and along the coast from the head of the Gulf of Bothnia to the south-east of Sweden pressure also exceeds 29·80 inches, and the increase from north to south proceeds at a slow rate. In, however, the strictly inland districts to the north-east of Christiania, which lie immediately to the east of the Scandinavian mountains, and sheltered by that lofty range from the winds of the Atlantic, pressure is considerably lower than it is along the east and west coasts of the peninsula. Owing to this peculiar distribution of the pressure, the winds which necessarily result from it give a much finer summer climate to the south-east of Norway and to the strictly inland part of Sweden than would otherwise be the case.

The remarkable curving northward of the isobar of 29·80 inches so as to include Lapland within it points probably to the influence of the White Sea and the wonderful lake system of Lapland in maintaining a higher summer pressure over that country, by which the northerly winds that blow towards the low-pressure region of Central Asia, to the serious deterioration of the summer climate of northern Siberia, do not extend so far to westward as Lapland.

The distribution of the normal pressure over North America is quite analogous to what prevails over Asia, but, the continent being less, the diminution of pressure in the interior is also correspondingly less. The highest normal pressure, 30·077 inches, is found in the south-east in Florida, and the lowest, 29·780 inches, in Utah, the difference being thus 0·297 inch. Another region of relatively high pressure is in the north-western States and British Columbia to the north; the maximum, near the mouth of the Columbia river, reaches 30·062 inches, being thus nearly as high as what occurs in Florida. These two regions are merely extensions of important high-pressure areas which at this season are highly characteristic features of the meteorology of the North Pacific and North Atlantic respectively.

Of these two regions of high pressure the one overspreading the Atlantic between the United States and Africa is the more striking, being not only the region where pressure is highest anywhere on the globe during the months of June, July, and August, but where the normal pressure reaches the highest point attained at any season over the ocean. The highest point reached by the normal pressure over the land at any season occurs, as has been pointed out, near the centre of Asia, or approximately in the middle region of the largest continuous land surface on the globe during the coldest months of the year. On the other hand, the highest pressure over the ocean occurs during the warmest months of the year, and not over the largest water surface, but in the middle regions of the North Atlantic, where the breadth is only about half that of the water surface of the North Pacific.

From the essential differences between these two sets of phenomena it may be inferred that the extraordinarily high pressure which is so marked a feature of the meteorology of Central Asia during the cold months of the year is a direct consequence of the lowering of the temperature of the land of Asia and of the atmosphere resting on it during the time of the year when the effects of solar radiation are at the annual minimum, and of terrestrial radiation at the annual maximum. But the determination of the place and time of highest pressure over the ocean must be regarded as indirectly brought about. The physical conditions under which it occurs are these:—it happens (1) at the time of the year when the earth presents the largest surface of land to the sun, and (2) over that part of the ocean which is most completely surrounded by these highly heated land surfaces. This high summer pressure of the Atlantic has its origin in the upper currents of the atmosphere.

Mean Atmospheric Pressure for the Year.—The distribution of the annual atmospheric pressure may be considered as representing

the sums of the influences directly and indirectly at work throughout the year in increasing or diminishing the pressure of the atmosphere. There are two regions of high pressure, the one north and the other south of the equator, which pass completely round the globe as broad belts of high pressure. The belt of high pressure in the southern hemisphere lies nearly parallel to the equator, and is of nearly uniform breadth throughout; but the belt north of the equator has a very irregular outline, and shows great differences in its breadth and its inclination to the equator. These irregularities wholly depend on the peculiar distribution of land and water which obtains in the northern hemisphere.

These two zones of high pressure enclose between them the comparatively low pressure of the tropics, through the centre of which runs a narrower belt of still lower pressure, towards which the trade-winds on either hand blow. Considered in a broad sense, there are only three regions of low pressure, the equatorial one just referred to, and one round each pole bounded by or contained within the zones of high pressure just described. The most remarkable of these, so far as it is known, is the region of low pressure about the south pole, which remains low throughout the year, playing the principal rôle in the wind systems of the Antarctic zone, in its heavy snowfall and rainfall, and in the enormous ice-bergs which form so striking a feature of the water of the Southern Ocean.

The depression around the north pole contains within its area two distinct centres of still lower pressure, the one filling the northern part of the Atlantic and the other that of the Pacific. Of these two the low-pressure area round Iceland is the deeper, and is probably occasioned by the steeper barometric gradients and stronger winds which prevail over the North Atlantic. The broad equatorial zone of low pressure also contains two distinct regions characterized by still lower pressures. The larger of the two stretches across southern Asia from Assam to the head of the Persian Gulf, and is entirely due to the very low pressures which form so marked a feature in the summer meteorology of that part of Asia. The regions of the middle Indus and upper Ganges occupy the centre of this low-pressure area, where normal pressure falls short of 29·80 inches. The second area of lowest equatorial pressure is in the centre of Africa.

It may be here pointed out that the whole of these areas of low mean annual pressure possess the common characteristic of an excessive amount of moisture in the atmosphere. The Arctic and Antarctic zones of low pressure, and the equatorial low-pressure zone generally, may be regarded as all but wholly occasioned by the comparatively large amount of vapour in their atmosphere. As regards the region of low pressure of southern Asia in summer, it is remarkable that, while the eastern half which overspreads the valley of the Ganges is characterized by a moist atmosphere and large rainfall, the western half of it is singularly dry and practically rainless, and that the central portion of this remarkable depression occupies a region where at the time the climate is one of the driest and hottest anywhere to be found on the globe. Hence, while the vapour is the more important of the disturbing influences at work in the atmosphere, the temperature also plays no inconspicuous part directly in destroying atmospheric equilibrium, from which result winds, storms, and many other atmospheric changes.

The Prevailing Winds of the Globe.—If atmospheric pressure were equal in all parts of the earth we should have the physical conditions of a stagnant atmosphere. Such, however, is not the case. Let there be produced a concentration of aqueous vapour over a particular region, or let one region show a higher temperature than what prevails around it, then from the different densities, and consequently different pressures thereby produced, the equilibrium of the atmosphere is destroyed, and, as might be expected from the laws of aerial fluids, movements of the air, or winds, set in to restore the equilibrium. Now every one of the isobaric maps we have given, as well as every isobaric map which has been made from recorded observations, indicates very considerable disturbance of the equilibrium at the surface of the earth. All observation shows that the prevailing winds of any region at any season of the year are simply the expression of the atmospheric movements which result from the disturbance of the equilibrium of the atmosphere indicated by the isobaric maps for that season and region.

All winds may be regarded as caused directly by differences of atmospheric pressure, just as the flow of rivers is caused by differences of level, the motion of the air and the motion of the water being both referable to gravitation. The wind blows from a region of higher towards a region of lower pressure,—in other words from where there is a surplus to where there is a deficiency of air; and this takes place whether the differences of pressure be measurable by the barometer, as is generally the case, or not readily measurable, as in the case of sea breezes, squalls, and sudden gusts of wind which are of short duration.

So far as is known, differences of atmospheric pressure, and consequently all winds, originate in changes occurring either in the temperature or the humidity of the air over restricted regions. Thus, if two regions contiguous to each other come to be of unequal temperature, the air of the warmer region, being specifically lighter, will ascend, and the heavier air of the colder region will flow in below to take its place. Of this class of winds the sea and land breezes are the best examples. Again, if the air of one region comes to be more highly charged with aqueous vapour than the air of surrounding regions, the air of the more humid region being lighter will ascend, while the heavier air of the drier regions will flow in below and take its place. Since part of the vapour will be condensed into cloud or rain as it ascends, heat is thereby disengaged, and the equilibrium still further disturbed. In this way originate gales, storms, tempests, hurricanes, and all the more violent commotions of the atmosphere, except some of the forms of the whirlwind, such as dust storms, in the production of which very great differences of temperature are more immediately and exclusively concerned.

The Trade-Winds.—From fig. 14, giving the isobarics for January, it is seen that atmospheric pressure in the Atlantic is lower near the equator than it is to north and south of it; and the arrows indicate that to the north of the tract of lowest pressure N.E. winds prevail and to the south of it S.E. winds. These are the well-known N.E. and S.E. trade-winds, which thus blow from regions of high pressure towards the tract of lower pressure situated midway between them. The trade-winds do not blow directly to where the lowest pressure is, but in a slanting direction at an angle of about half a degree. The deviation from the direct course is due to the influence of the rotation of the earth on its axis from west to east,—an influence to which all winds and all currents of the ocean are subject.

In virtue of this rotation, objects on the earth's surface at the equator are carried round towards the east at the rate of about 17 miles a minute. On receding from the equator, however, this rate of velocity is being continually diminished, so that at 60° N. lat. it is only about $8\frac{1}{2}$ miles a minute, and at the poles nothing. From this it follows that a wind blowing along the earth's surface in the direction of the equator is constantly arriving at places which have a greater eastward velocity than itself. As the wind thus lags behind, these places come up, as it were, against it, the result being an east wind. Since, therefore, the wind north of the equator is under the influence of two forces—one, the low pressure near the equator, drawing it southwards, and the other, the rotation of the earth, deflecting it eastwards—it will, by the law of the composition of forces, take an intermediate direction, and blow from north-east. For the same reason, south of the equator the south is deflected into a south-east wind.

In the Atlantic the north trades prevail between latitudes 7° and 30° N., and the south trades between latitudes 3° N. and 25° S. These limits are not stationary, but follow the sun, being farthest to the south in February and to the north in August. The tract of low pressure between these wind systems is named the region of calms, owing to the calm weather which often prevails there, and it is also characterized by the frequent occurrence of heavy rains. This region of calms varies its position with that of the sun, reaching its most northern limit, lat. 11° N.,

in August, and its most southern, lat. 1° N., in February. Its breadth varies from 3° to 8°, and it lies generally parallel to the equator. It is to be noted that, in the Atlantic, the region of calms is at all seasons north of the equator.

North and south trades also prevail in the Pacific Ocean, separated by a region of calms, which would appear, however, to be of less breadth and to be less clearly defined than is the region of calms in the Atlantic. In the eastern portion of the Pacific the region of calms lies at all seasons to the north of the equator, but in the western division it is considerably south of the equator during the summer months of the southern hemisphere, this southerly position being in all likelihood occasioned by the extraordinarily high pressure in Asia in its relations to the low pressure in the interior of Australia at this season. During the summer months of the northern hemisphere the region of calms wholly disappears from the Indian Ocean and from the western part of the Pacific Ocean, there being then an unbroken diminishing pressure from the latitude of Mauritius and Central Australia northwards as far as the low pressure of Central Asia.

Regions of light and variable winds and calms occur at the higher limits of the north and south trades. Except in the Pacific, where, owing to the greater breadth of that ocean, they spread over a considerable extent, these regions appear but in circumscribed patches, such as characterize the meteorology of the North and South Atlantic about latitudes 26° to 36°. Of these regions of calms the most important is that marked off by the high pressure in the North Atlantic, between the United States and Africa. This is the region of the Sargasso Sea, where the weather is characterized by calms and variable winds, and the ocean by its comparatively still waters. These are known to seamen as the "horse latitudes," and are essentially different from the equatorial region of calms. The latter, as has been stated, is the region of low pressure at the meeting of the north and south trades, where the climate is distinguished for its general sunlessness and heavy rainfall. On the other hand, the calm regions in the Atlantic and Pacific Oceans about the tropics have an atmospheric pressure abnormally high, clear skies, and the weather generally sunny and bright, with occasional squalls.

Numerous observations made in all parts of the globe establish the fact that, while the surface winds within the tropics are directed towards the equatorial region of calms in such a manner that the general intertropical movements of the atmosphere or prevailing winds are easterly, the prevailing winds of the north and south temperate zones are westerly. The westing of these great aerial currents is due to the same cause that gives easting to the trade-winds, viz., the rotation of the earth round its axis. For, as an aerial current advances into higher latitudes, it is constantly arriving at regions having a less rotatory velocity than itself; it thus outstrips them and leaves them behind; in other words, it blows over these places as a westerly wind.

While, however, the general prevalence of westerly winds has been established over the extratropical regions of Europe, Asia, Africa, America, and Australia, the directions which in different seasons and at different places are actually found to prevail often differ very widely from west. An examination of the winds at one hundred and fifteen places pretty well distributed over the northern hemisphere reveals the instructive fact that almost every place shows two maximum directions from which winds blow more frequently than from the other directions, and that one of these two directions shows a considerable excess over the other. Thus, for example, the following are, on a twenty years' average, the number of days at Greenwich each wind prevails during the year:—N., 41; N.E., 49; E., 23; S.E., 21; S., 34; S.W., 103; W., 38; N.W., 24; and calms, 32. Hence S.W. and N.E. winds are there more prevalent than winds from any other direction, and of these two winds the greater maximum direction is S.W. If the two maximum directions be sorted into groups, then the greater maximum direction occurs as follows:—

from S.S.W.	to	W.	at	47	places
,, W.N.W.	,,	N.	,,	33	,,
,, N.N.E.	,,	E.	,,	19	,,
,, E.S.E.	,,	S.	,,	16	,,

and the other maximum direction is

from S.S.W.	to	W.	at	20	places
,, W.N.W.	,,	N.	,,	22	,,
,, N.N.E.	,,	E.	,,	38	,,
,, E.S.E.	,,	S.	,,	32	,,

This result of observation, so different from what was long accepted as being in accordance with the generally received theory of the movements of the atmosphere, teaches the important lesson that the region towards which the extra-tropical winds of the northern hemisphere are directed is not the region of the north pole.

Prevailing Winds in January.—On examining fig. 14, which shows the distribution of atmospheric pressure in January, it is seen that pressure is abnormally low over the northern portion of the Atlantic—the lowest occurring between Iceland and South Greenland—from which it rises as we proceed in a S.W. direction towards America, in a S. direction over the Atlantic, and in a S.E. and E. direction over Europe and Asia. Now what influence has this remarkable atmospheric depression on the prevailing winds over this large and important part of the earth's surface? The arrows in the figure, which indicate the prevailing winds, and which have been laid down from observations, answer this question.

At stations on the east side of North America the arrows show a decided predominance of north-west winds; at the more northern places the general direction is more northerly, whereas farther south it is more westerly. In the Atlantic between America and Great Britain, in the south of England, in France and Belgium, the direction is nearly S.W. In Ireland and Scotland it is W.S.W.; in Denmark and the north-west of Russia S.S.W.; from St Petersburg to Tobolsk S.W.; on the west of Norway generally S.S.E.; and in Greenland, the north of Iceland, and about Spitzbergen N.E. Hence all the prevailing winds in January over this extensive portion of the globe may be regarded as the simple expression of the difference of atmospheric pressure which prevails over the different parts of the region. In truth the whole appears to flow vorticosely, or in an in-moving spiral course, towards the region of low pressure lying to the south-west of Iceland, and extending eastward over the Arctic Sea north of Russia. The only marked changes in these directions of the wind thus broadly sketched out are the deflexions caused by the various mountain systems which lie, so to speak, embedded in these vast aerial currents; of these the winds in the south of Norway afford excellent illustrations.

The influence which this peculiar distribution of the pressure over the north of the Atlantic exercises in absolutely determining the winter climates of the respective countries is most instructive. It is to this low pressure, which draws over the British Islands W.S.W. winds from the warm waters of the Atlantic, that the open, mild, and, it must be added, rainy winters of these islands are due. The same region of low pressure gives Russia and Western Siberia their severe winters; and it is the same consideration that fully explains the enormous deflexion of the isothermal lines from Norway eastwards and south-

eastwards over the Old Continent. Finally, the same low pressure draws over British America and the United States, by the N.W. winds which it induces, the intensely dry cold air-current of the Arctic regions. At Portland, Maine, which is swept by these cold north-westerly winds, the normal temperature in January is 23°·6, whereas at Corunna, on the coast of Spain, in nearly the same latitude, where south-westerly winds from the Atlantic prevail, the mean temperature of the month is 49°·1, or 25°·5 higher.

The region of low atmospheric pressure in the north of the Pacific is accompanied by prevailing winds over the region embraced by it and by climatic effects in all respects similar to the above. In Vancouver Island the prevailing winds in January are S.W., at Sitka E.S.E., on Great Bear Lake E.N.E., in Alaska N.E., in Kamchatka N.N.E., and in Japan N.W. In accordance with these winds the winter climate of Vancouver and adjoining regions is mild and humid, and that of the north-east of Asia dry and intensely cold.

On the other hand, abnormally high pressure rules over the continent of Asia at this season, and as regards this region of high pressure the arrows represent the winds as blowing outwards from it in all directions. Over the interior of Asia, where the highest normal pressures are, observations show a marked prevalence of calms and light winds, but around this central region the prevailing winds in January are—at Calcutta N., at Hong-Kong E.N.E., at Peking N.W., on the Amur W.N.W., S.E. at Nijnikolynisk and S.S.W. at Ustjansk (in the north of Siberia), and at Bogoslovsk S.W. Hence from this extensive region, where pressure is abnormally high, or where at this season there is a large surplus of air, the prevailing winds flow outwards in all directions towards the lower pressure which surrounds it. Owing to the excessive dryness of the air of Central Asia, terrestrial radiation is less obstructed there than anywhere else on the globe, and consequently the temperature falls very low, the mean of January at Werchojansk being – 55°·8, which is the lowest mean monthly temperature known to occur on the earth's surface. And, since the winds blow outwards from the dry cold climates of the interior, temperatures are low, even on the coasts. Of this China affords good illustrations. Thus the mean January temperature of Peking is 22°·7 and of Zi-ka-Wei, near Shanghai, 35°·4, whereas at Corfu and Alexandria the normal temperatures for January are respectively 50°·9 and 58°·0, or 28°·2 and 22°·6 higher than in corresponding latitudes on the coast of China.

The winds of the United States in winter, taken in connexion with the peculiar distribution of pressure already described, are very interesting. There are two regions of high pressure, one in the south-eastern States and the other and larger one in the region around Utah; and between these there is interposed a trough of lower pressure extending from Chicago to the south-west of Texas. On the western side of this depression the winds are north-westerly, but to the east of it they become W., W.S.W., and in some places S.W., and again on nearing the Atlantic seaboard they become north-westerly. In connexion with the region of higher pressure in the west, the prevailing winds are seen to flow outward from it. The normal pressure diminishes everywhere to southward of a line drawn from the Canaries to Bermuda, thence westward in nearly the same latitude to Texas, and then to west-north-west to San Francisco. The tract of lowest pressure stretches from the basin of the Amazon in the direction of the isthmus of Panama in about latitude 8° N., and thence is continued westward for a considerable distance into the Pacific in nearly the same latitude. It follows from this distribution of the pressure that the north trades in a more or less modified form prevail over South America to the north of the Amazon, and in the Pacific to the north of lat. 8° N., probably as far to westward as long. 150° W.

The low-pressure systems which prevail during the summer months in South America and South Africa have each its corresponding system of winds all round. It is, however, in Australia, as being the most compact and isolated continent, that the influence of the summer sun in lowering the pressure is best illustrated. In that continent the lowest pressure occurs in the region situated about midway between the north coast and the tropic of Capricorn, over which the normal pressure does not exceed 29·80 inches. Further, everywhere in Australia pressure diminishes from the coast on advancing upon the inland districts. It follows from this disposition of the pressure that all round the island the prevailing winds in summer blow from the sea towards the interior; and accordingly it is in these months that the greater part of the rain falls. From the low pressure of the interior southwards to Bass's Straits pressure rises continuously, the increase in the normal over this space being about 0·200 inch. To northward it also rises continuously to beyond the north of China, the increase on this side being about ¾ of an inch. In this case the greater part of the increase occurs over the continent, the rate of increase from the north of Australia to the Philippine Islands being only about the rate of increase which obtains southward towards Bass's Straits. It will be shown when the subject of the rainfall is examined that it is the relative excess of these high pressures, the one in the south of Australia and the other in the south-east of Asia, that determines the position of the area of low pressure in Australia in particular years, and with that position the degree and extent to which the whole of the northern portion of Australia is watered by the rainfall. Thus, when pressure is more than usually high in the south-east of Asia, and either low or not excessive in the south of Australia, then the low-pressure region is pushed farther southward into the interior, and with it the rainfall spreads inland over a wider area and to a greater depth.

Prevailing Winds in July.—In the winter of the southern hemisphere, the geographical distribution of pressure is exactly the reverse in Australia of what obtains during the summer months. Everywhere all round it increases on advancing from the coast into inland districts. The lowest pressure, about 30·00 inches, occurs on the north coast, and the highest over the basin of the Murray river and its affluents, where it rises generally to 30·18 inches. On the south coast it is generally about 30·12 inches, falling, however, at Gabo Island, in the extreme south-east, to 30·050 inches, and to 29·836 in the south of New Zealand. From the Murray river the diminution of pressure is continuous to the north, even to the low pressure of Central Asia. From this arrangement of the pressure, the prevailing winds blow from the interior towards the surrounding ocean all round Australia, with the single exception of the extreme south-west of the continent, where the prevailing winds are south-westerly, being here essentially an outflow of the high pressure which overspreads the Indian Ocean to the westward. As these S.W. winds are from the ocean, the rainfall at Perth in July is fully 6 inches, and it is high over south-western districts of West Australia. The prevailing winds round Australia are S.E. on the north coast, S.W. at Brisbane, W.N.W. at Sydney, N. at Melbourne, N.E. at Adelaide. These all represent an outflow from the high-pressure regions of the interior modified by the influence of the earth's rotation, and, in correspondence with the reversal of the distribution of the pressure, are directions the reverse of the prevailing winds of January.

In July the central and southern parts of Asia are

highly heated by the summer sun, and, besides, the rainfall over southern parts is excessive. Consequently atmospheric pressure is very low, being fully 0·40 inch lower in the Punjab than it is in the south of Ceylon. From the interior pressure rises continuously on advancing to the eastward, southward, westward, and northward, and from all these directions the prevailing winds of summer flow inwards upon the interior, and these bring rain or parching drought according to the vapour they bring from the ocean they have traversed, and according as they advance into warmer or colder regions. The prevailing summer winds of Asia, being an inflow inwards upon the interior, have, generally speaking, exactly the reverse direction of that prevailing in winter.

The winds of Europe are mainly determined by the extraordinarily high pressure of the Atlantic in its relations to the low-pressure systems of Central Asia and Central Africa at this time. The winds in the Spanish Peninsula are north-west; in the north of Africa they are northerly, and again north-westerly in Syria. The winds of the British Islands and western Europe have less southing and more northing than the prevailing winds of winter, and to the east of long. 40° E. they become decidedly north-west. It is to the Atlantic origin of these winds that the summer climates of these large and important regions owe the comparatively large rainfall of this season, it being at this time that the rainfall reaches the annual maximum. The bearing of the low-pressure areas and mountain systems of the north of Italy and Scandinavia on the climates of these countries will be afterwards referred to.

The centre of lowest pressure in North America is over the district about Utah, from which it rises all round, least to northward and most in south-easterly and north-westerly directions. In California N.W. winds necessarily blow inwards upon this central low-pressure area; and, as these winds pass successively over regions the temperature of which constantly increases, the summer climate is rainless. On the other hand, southerly and south-easterly winds from the Gulf of Mexico blow up the western side of the basin of the Mississippi inwards upon the low-pressure area of the centre, depositing in their course, in a rainfall more or less abundant, the moisture they have brought from the Gulf. To the north of lat 50°, and to westward of Hudson's Bay, the prevailing winds become easterly and north-easterly, distributing over Manitoba, Saskatchewan, and neighbouring regions, as they continue their westerly course towards the low-pressure area, the rainfall they have transported thither from the wide expanse of Hudson's Bay. An attentive examination of the arrows of fig. 17 shows that the prevailing winds over all the States to the east of the Mississippi river are rather to be regarded as an outflow from the region of very high pressure over the Atlantic to south-eastward. Thus in Florida the winds are S.E., in the southern States S., and in the lake region, in the New England States, and on the Atlantic seaboard S.W. Since the origin of these winds is thus essentially oceanic, and since in their course northwards no mountain range crosses their path, the whole of this extensive region enjoys a large but by no means excessive rainfall, which, taken in connexion with the temperature, renders the summer climate of these States one of the best to be met with anywhere on the globe for the successful prosecution of agricultural industries.

The remarkable protrusion of high pressures from the southern hemisphere, where they are massed at this time of the year, northwards into the Atlantic is, as has already been referred to, one of the outstanding features of the meteorology of the summer months of the northern hemisphere. In the central area of this large region the climate is remarkable for its prevailing calms, light winds, occasional squalls, and clear skies. From this comparatively calm space the wind blows outwards in all directions towards and in upon the surrounding regions of low pressure. These winds, owing to the high temperature, clear skies, and strong sunshine of the region from which they issue, carry with them a great amount of vapour near the surface, by which to a large extent the north of South America, the east of North America, the greater part of Europe, and a large portion of Africa are watered. The prevailing winds over this region are further interesting, not merely from the striking illustration they give of the intimate relation of the winds to the distribution of the pressure, but as being of no small importance in determining the best routes to be taken over this great highway of commerce, and the more so inasmuch as the currents of the ocean are coincident with these prevailing winds.

In the Antarctic regions, or rather to the south of lat. 45° S., the normal atmospheric pressure is low at all seasons, there being a gradual diminution of pressure to 29·20 inches about lat. 60° S. Pressure is probably even still lower nearer to the south pole, as seems to be indicated by the observations made by Sir James C. Ross, and in the "Challenger" and other expeditions. Over this zone the prevailing winds are W.N.W. and N.W. This is the region of the "brave west winds," the "roaring forties" of sailors, which play such an important part in navigation, and which determine that the outward voyage to Australia be round the Cape of Good Hope and thence eastward, and the homeward voyage eastward round Cape Horn, the globe being thus circumnavigated by the double voyage. That the general drift of these winds is inwards upon the south pole is strongly attested by the existence of the enormously thick wall of ice which engirdles these regions, from which are constantly breaking away the innumerable icebergs that cover the Southern Ocean, none of which is ever seen of a calculated thickness less than 1400 feet. The snow and rainfall which must take place in the south polar regions for the formation of icebergs of such a thickness must be peculiarly heavy, but not heavier than might be expected from the strength and degree of saturation of the "roaring forties" which unceasingly precipitate their moisture over these regions.

To sum up:—so far as the prevailing winds are concerned, it has been shown that where pressure is high, that is to say, where there exists a surplus of air, out of such a region winds blow in all directions; and, on the other hand, where pressure is low, or where there is a deficiency of air, towards such a region winds blow from all directions in an in-moving spiral course. This outflow of air-currents from a region of high pressure upon a region of low pressure is reducible to a single principle, viz., the principle of gravitation. Given as observed facts the differences of pressure, it is easy to state with a close approximation to accuracy what are the prevailing winds, before calculating the averages from the wind observations. Indeed so predominating is the influence of gravitation where differences of pressure, however produced, exist that it may practically be regarded as the sole force immediately concerned in causing the movements of the atmosphere. If there be any other force or forces that set the winds in motion independently of the force called into play by differences of mass or pressure, their influence must be altogether insignificant as compared with gravitation.

It has been abundantly proved that the wind does not blow directly from the region of high towards that of low pressure, but that, in the northern hemisphere, the region of lowest pressure is to the left of the direction towards which the wind blows, and in the southern hemisphere to the right of it. This direction of the prevailing wind with reference to the pressure is in strict accordance with Buys

Ballot's Law of the Winds, which may be thus expressed:—the wind neither blows round the centre of lowest pressure in circles, or as tangents to the concentric isobaric curves of storms or cyclones, nor does it blow directly towards the centre; but it takes a direction intermediate, approaching, however, more nearly to the direction and course of the circular curves than of the radii to the centre. The angle formed by a line drawn to the centre of lowest pressure from the observer's position and a line drawn in the direction of the wind is not a right angle, but an angle of from 60° to 80°.

From its importance in practical meteorology Buys Ballot's law may be stated in these two convenient forms. (1) Stand with your back to the wind, and the centre of the depression or the place where the barometer is lowest will be to your left in the northern hemisphere, and to your right in the southern hemisphere. This is the rule for sailors by which they are guided to steer with reference to storms. (2) Stand with the high barometer to your right and the low barometer to your left, and the wind will blow on your back, these positions in the southern hemisphere being reversed. It is in this form that the prevailing winds of any part of the globe may be worked out from the isobaric charts (figs. 14 and 17).

From the all-important consequences which flow from the geographical distribution of the pressure it is evident that the regions of low and of high normal pressure must be regarded as the true poles of the prevailing winds on the earth's surface, towards which and from which the great movements of the atmosphere proceed. From the unequal distribution of land and water, and their different relations to solar and terrestrial radiation, it follows that the poles of pressure and of atmospheric movements are, just as happens with respect to the poles of temperature, very far from being coincident with the north pole. Thus during the winter months the regions to which the origin of the great prevailing winds of the northern hemisphere are to be referred are Central Asia, the region of the Rocky Mountains, and the horse latitudes of the Atlantic, and the regions towards and in upon which they flow are the low-pressure systems in the north of the Atlantic and Pacific Oceans, and the tract of low pressure within the tropics towards which the trade-winds blow. In the summer months the reversed conditions of pressure-distribution then observed are attended with corresponding changes in the prevailing winds; and, generally speaking, if the south polar region be excepted, the poles of highest and lowest pressure and atmospheric movements are at no time coincident with the north pole. It is this consideration which affords the true explanation why prevailing winds at so large a proportion of stations in the northern hemisphere do not blow in the directions in which true equatorial and polar winds should blow.

The causes which bring about an unequal distribution of the mass of the earth's atmosphere are mainly these two—the temperature and the moisture of the atmosphere considered with respect to the geographical distribution of land and water. Owing to the very different relations of land and water to temperature, as already stated, the summer temperature of continents greatly exceeds that of the ocean in the same latitudes. Hence the abnormally high temperature which prevails in the interior of Asia, Africa, America, and Australia during their respective summers, in consequence of which the air, becoming specifically lighter, ascends in enormous columns thousands of miles in diameter. On arriving at the higher regions of the atmosphere it flows over neighbouring regions where the surface temperature is lower, and thus the atmospheric pressure of the highly heated regions is diminished.

Surface winds set in all round to take the place of the air removed from the continents by these ascending currents, and since these necessarily are chiefly winds from the ocean they are highly charged with aqueous vapour, by the presence of which, and by the condensation of the vapour into cloud and rain, the pressure over continents at this season is still further and very largely diminished. Air charged with vapour is specifically lighter than when without the vapour; in other words, the more vapour any given quantity of atmospheric air has in it the less is its specific gravity; and, further, the condensation of vapour in ascending air is the chief cause of the cooling effect being so much less than that which would be experienced by dry air. From these two principles, which were established by Dalton, Joule, and Sir William Thomson, it follows that the pressure of vapour in the air, and its condensation, exercise a powerful influence in diminishing the pressure. The great disturbing influences at work in the atmosphere are the forces called into play by its aqueous vapour; and it is to these, co-operating with the forces called into play by the differences of temperature directly, that the low normal pressure of the continents during the summer is to be ascribed. The degree to which the lowering of the pressure takes place is, as was to have been expected, greatest in Asia, the largest continent, and least in Australia, the smallest continent, while in America it is intermediate.

The influence of the aqueous vapour in diminishing the pressure is well seen in the belt of calms in the tropics between the north and the south trade-winds. Since these winds import into the belt of calms the vapour they have taken up from the sea on their way thither, the climate is characterized by a highly saturated atmosphere and heavy rains. Again the air in regions near the Atlantic contains much more vapour and is of a higher temperature during winter than is observed at places in the interior of continents in the same latitudes. It follows thus that the air over the north of the Atlantic and the regions adjoining is specifically lighter than in the regions which surround them. We have here therefore the physical conditions of an ascending current; and it is plain that the strength of this current will not merely be kept up but increased by the condensations of the vapour into cloud and rain which take place within it, by which a higher temperature and a greater specific lightness are maintained at the surface of the earth and at various heights in the atmosphere than exist over surrounding regions at the same heights. Accordingly it is seen from the winter isobars that an enormous diminution of pressure occurs over these regions, and also over the north of the Pacific and the Antarctic, as compared with the continents.

Since, on the other hand, dry and cold air is specifically heavy, the winter isobars show that where temperature is low and the air very dry pressure is high. Of this Asia and North America are striking examples during December, January, and February, and Australia, South Africa, and South America during June, July, and August.

Since vast volumes of air are thus poured into the region where pressure is low without increasing that pressure, and vast volumes flow out of the region where pressure is high without diminishing that pressure, it necessarily follows that the volumes of air poured into the region of low normal pressure do not accumulate over that region, but must somehow escape away into other regions, and that the volumes of air which flow out from the region of high normal pressure must have their place supplied by fresh accessions of air poured in from above. That the same law of relation observed between sea-level pressures and surface winds obtains between pressures at different heights and winds at the same heights is simply a necessary inference. We are therefore justified in expecting that

ascending currents will continue their ascent till a height is attained at which the pressure of the air composing the currents equals or just falls short of the pressure over the surrounding regions at that high level. On reaching this height the air, no longer buoyed up by a greater specific levity than that of the surrounding air, will cease to ascend, and expanding horizontally will thenceforth flow over as an upper current towards those regions which offer the least resistance to its course; that is to say, it will flow over upon those regions where, at that height, pressure happens at the time to be least. Now from the known densities of air of different temperatures and humidities it is evident that the overflow of the upper current will take place towards and over that region or regions the air of which in the lower strata of the atmosphere happens to be colder and drier than that of the other surrounding regions,—because, being denser, a greater mass of air is condensed or gathered together in the lower strata of the atmosphere, thus leaving a less mass of air, or a diminished pressure, in the higher region of the upper current.

If this be so, then the extraordinarily high pressure of Central Asia during winter is to be ascribed to these two causes:—(1) the low temperature and excessive dryness of the air of this extensive region; and (2) its relative proximity to the low pressure of the Atlantic to the north-west, the low pressure of the Pacific to the north-east, and the low pressure of the belt of calms to the south. Similarly, since in summer the temperature of air resting over the Atlantic between Africa and the United States is much lower than that of the land, the ascending currents which arise from the heated lands of Africa, Europe, and North and South America, as well as from the region of calms immediately to the south, all of which are remarkable for a low normal pressure, will on reaching the upper regions of the atmosphere flow towards this part of the Atlantic, because there, the temperature being lower and the density of the air composing the lower strata being greater, pressure in the upper regions is less. And, since the surface winds are constantly flowing outwards from this region of abnormally high pressure, thus draining away the air poured down upon it by the upper currents which converge upon it, extreme saturation does not take place, and the air consequently is relatively dry and cool. That this view generally represents the movements of the upper currents has been strongly confirmed within the last few years by Professor Hildebrandsson and Clement Ley in their researches into the upper currents of the atmosphere based on observations of the cirrus cloud.

From these considerations it may be concluded that the winds which prevail near the earth's surface are known from the isobaric lines, the direction of the wind being from regions where pressure is high towards regions where it is low, in accordance with Buys Ballot's law; and that the upper currents may be inferred from the isobaric lines taken reversely, together with the isothermal lines taken directly. In other words, the regions of lowest pressure, with their ascending currents and relatively higher pressure at great heights as compared with surrounding regions, point out the sources or fountains from which the upper currents flow; and the isothermals, by showing where on account of the relatively low temperatures the greater mass of the air is condensed in the lower strata of the atmosphere and sea-level pressure consequently is high, thus diminishing the pressure of the upper regions, point out the regions towards and upon which these upper currents of the atmosphere flow. The facts of the diurnal oscillations of the barometer in the different regions already discussed afford the strongest corroboration of these views.

The term "monsoon" has long been applied to the prevailing winds in southern Asia which blow approximately from S.W. from April to October, and from N.E. from November to April. The term is now, however, generally applied to those winds connected with continents which are of seasonal occurrence, or which occur regularly with the periodical return of the season. Since they are caused immediately by the different temperatures and pressures which form marked features of the climates of continents in winter and summer respectively, they are most fully developed round the coast of Asia, owing to the great extent of that continent. The monsoons of different parts of the coasts of Asia differ widely in direction from each other. Thus in winter and summer respectively they are W.N.W. and E.N.E. at the mouth of the Amur, N. and S.S.E. at Shanghai, N.E. and S.W. at Rangoon, N. and W.S.W. at Bombay, N.W. and S.W. at Jerusalem, and S.S.W. and N.N.E. at Archangel. The Indian winter monsoon generally begins to break up in March, but it is not till about the middle of May, when the normal pressure has been decidedly diminished over the heated interior, that the summer monsoon acquires its full strength and the heavy monsoonal rains fairly set in. In October, when the temperature has fallen considerably and with the falling temperature the pressure of the interior has risen, the summer monsoon begins to break up, and this season is marked by variable winds, calms, and destructive hurricanes. As the temperature continues to fall and pressure to rise, the winter monsoon again resumes its sway. Monsoons, equally with the trade-winds, play a most important part in the economy of the globe. The relatively great force and steadiness in the direction in which they blow, and the periodical change in their direction, give facility of intercourse between different countries; and, besides, by the rainfall they bring they spread fertility over extensive regions which otherwise would be barren wastes.

The winds of Australia are also strictly monsoonal, but owing to the small extent of that continent, and consequently the smaller differences there are between the normal pressure of the interior and that of the surrounding coasts in summer and winter respectively, they are less strongly marked than are the monsoons of southern Asia; and particularly they neither blow with the same force nor so steadily from the same point of the compass. For the same reason the Australian climates are characterized by the occurrence of more frequent droughts than are the climates of southern Asia, and the same remark applies to the climates of southern Africa.

Since the Malay archipelago lies during the summer of the northern hemisphere between the high pressure of central Australia and the low pressure of Asia, and during the winter between the high pressure of Asia and the low pressure of central Australia, it follows that the winds of these islands are eminently monsoonal in their character, being in summer southerly and in winter northerly. The result of this peculiar wind system of the archipelago is to give to these islands a singular diversity of climates, which will be more particularly referred to under rainfall.

At Zanzibar the prevailing wind in July is S.E., but in January, when the low pressure of the interior is situated much farther to southward, it is N.E.; and the same influence is felt, though in a greatly modified degree, as far as Mauritius, where the S.E. trade changes nearly into E. during the summer. On the other side of Africa the S.E. trade of the South Atlantic is changed into a S.W. monsoon on the coast of the Gulf of Guinea.

In the southern, central, western, and northern regions of North America the prevailing winds have a well-marked monsoonal character. The prevailing winds of winter and summer respectively are N.E. and S.S.E. at New Orleans,

N.W. and S.W. in Utah, N. and S. at Fort Yuma (California), E.S.E. and N.W. at Portland (Oregon), and S. and E.N.E. at Fort York, Hudson Bay. These winds are readily accounted for by the distribution of pressure over the continent in winter and summer. On the Atlantic seaboard of the United States the prevailing winds of winter vary from N.W. in the New England States to W. in South Carolina; whereas in summer they vary generally from S.S.W. in South Carolina to S.W. in the New England States. Hence over the eastern States the summer winds are not directed towards the low-pressure region of the interior of the continent, but are determined by the relations of their pressure to the high pressure of the Atlantic to the eastward, and to the lower pressure overspreading the Atlantic to the N.E. This influence of the Atlantic may be considered as felt westward through the States as far as the Mississippi.

Though not so decidedly marked, the winds of Europe, except the extreme south, are also monsoonal. In winter they flow from the land towards the region of low pressure in the north of the Atlantic; but in summer the arrows, representing the prevailing winds, show that all but the extreme south of Europe is swept by westerly winds, which flow in a vast continuous stream from the Atlantic towards the central regions of the Old Continent, and which deposit in their course the rains they have brought from the ocean.

Similarly, monsoons prevail on the coasts of Brazil, Peru, North Africa, and many other regions which happen to lie between other regions whose temperatures, and therefore pressures, differ markedly from each other at different times of the year.

These are the chief prevailing winds of the globe when the differences of the normal atmospheric pressure are such as to cause a decided and steady movement of the atmosphere over a large portion of the earth's surface, resulting in well-marked prevailing winds. But there are other winds which are greatly influenced by local causes, such as the nature of the ground, whether covered with vegetation or bare; the physical configuration of the surface, whether level or mountainous; and the vicinity of extensive sheets of fresh or salt water. An important characteristic of winds in their practical relations to climate is their quality,—they being warm or cold, dry or moist, according to their direction and the nature of the earth's surface over which they have just passed. Thus in the northern hemisphere southerly winds are warm and moist, while northerly winds are cold and dry. In Europe southwesterly winds are moist and easterly winds dry, while in the New England States and Canada north-easterly winds are cold and raw and north-westerly winds cold and dry.

In particular regions certain meteorological conditions occur at stated seasons intensifying these effects, resulting in excessive drought, heavy rains, intense or great heat, thus giving rise to the following among other well-known winds. The east winds of the British Islands occur chiefly in spring, but also in a less degree in November, being in the latter case often accompanied with fog. The winds here referred to are dry and parching, and their deleterious influence on the health is seen, not merely in the discomfort and uneasiness they impart to the less robust of the population, but also in the largely increased mortality which they cause from consumption and all other diseases more or less connected with the nervous system. In the countries bordering on the north of the Atlantic, atmospheric pressure reaches the annual maximum in May, and it is above the average during the other two spring months. In these months the normal pressure approaches nearer to what obtains farther south, and an examination of daily weather maps shows that this is due to the repeated occurrence in spring of very high pressures in the north of Europe while pressures much lower prevail to southward. Now these east winds are simply the outflow from these regions of high pressure to northward. Northerly and even westerly winds which are truly outflows from what may be styled Arctic anticyclonic areas bring with them qualities as noxious as those of the east wind itself, and prove as injurious to health and vegetation. The cold dry wind of April 29, 1868, which blasted and shrivelled up vegetation in Scotland, particularly in the western counties, as effectually as if a scorching fire had passed across them, was a west wind.

In the south of Europe, during the winter and early spring, peculiarly dry, cold, and violent northerly winds are of occasional occurrence. Of these winds the "mistral" is one of the most notorious, which is a steady, violent, and cold north-west wind blowing from central and eastern France down on the Gulf of Lyons. It is particularly trying while it lasts to invalids who are spending the winter at the various popular sanataria which are scattered along this part of the Mediterranean coast. The great cold that took place in the north of Italy and south of France in the beginning of 1868 was a good example of the mistral. The meteorological conditions under which it occurred were unusually low pressure over the Mediterranean to southward (29·450 inches), whilst at the same time pressure rose steadily and rapidly on proceeding northward to 30·905 inches in the north of Russia. From this geographical distribution of the pressure, northerly winds swept southwards over Europe, carrying with them the low temperatures of the higher latitudes, and became still colder and drier on crossing the Alps before they made the descent on the shores of the Mediterranean. The cold tempestuous winds which descend from the Julian Alps and sweep over the Adriatic, and the dreaded "gregale" of Malta, which is a dry cold north-east wind, are in their character and origin quite analogous to the mistral.

The "northers," or "nortes," are peculiarly dry cold strong winds which repeatedly occur from September to March in the States bordering on the Gulf of Mexico, and are perfectly analogous to the mistral. The conditions under which they occur are a pressure lower than usual to the south or south-east over the Gulf of Mexico, together with a pressure even higher than the high normal which is so marked a feature of the meteorology of the Rocky Mountains during the colder months. When, as most frequently happens, they occur in the wake of a storm, their disagreeable qualities of extreme dryness, cold, and violence are all intensified. From a temperature of upwards of 80° experienced as the storm comes up the thermometer rapidly falls to 18° or even lower; and, as the low temperature often occurs with a wind blowing with great violence, the northers prove most deleterious. A violent wind with a temperature of 18° is altogether unknown in the British Islands.

The "pampero" is a strong, dry, cold wind which blows across the pampas of the River Plate of South America, occurring at all seasons, but most frequently during the spring and summer from October to January. They are preceded by easterly winds, a falling pressure, a rising temperature, and increased moisture. A pampero is described by Dr D. Christison, and its appearance figured, in the *Journal of the Scottish Meteorological Society*, vol. v. p. 342, as seen advancing on the morning of November 28, 1867, in central Uruguay. In the early morning the wind blew rather strongly from north-east, and by and by clouds were seen moving very slowly from the west, throwing out long streamers eastwards. As they advanced, two dense and perfectly regular cloud-masses appeared in front, one behind the other, in close contact yet not intermingling,—the one being of a uniform leaden grey, while the other was as black as the smoke of a steamer. On arriving overhead, the front, though slightly wavy in appearance, was seen to be quite straight in its general direction, and the bands were of uniform breadth. They rushed forward at great speed under the other clouds without uniting with them, preserving their forms unbroken, being borne onward by an apparently irresistible force, as if composed of some solid material rather than vapour. They extended probably 50 miles in length, but as they took only a few minutes to pass their breadth was not great, and they appeared to diminish to mere lines in the distant horizon. At the instant the first cloud-band arrived overhead, the wind chopped round from north-east to north and then to south-west; a strong cold blast at the same time seemed to fall from the leaden cloud, and continued to blow till both bands had passed. No rain or thunder occurred at this time, but in the confused rabble of clouds which followed low thunder continued to roll, and in a quarter of an hour rain fell, and for some hours thereafter wind, rain, and thunder continued, but only to a moderate degree. The low temperature and rising barometer and change of wind are the constant and most striking characteristics of the pampero. On one occasion the temperature fell 44° in fourteen hours, and on another occasion the fall was only 4°. Rain is a usual accompaniment, but on rare occasions the pampero passes off and no rain falls.

Rainfall.—Whatever tends to lower the temperature of the air below the dew-point is a cause of rain. It is therefore to the winds we must chiefly look for an explanation of the rainfall, and the broad principles of the connexion may be stated to be these five:—(1) when the winds have previously traversed a considerable extent of ocean, the rainfall is moderately large; (2) if the winds advance at the same time into colder regions, the rainfall is largely increased, because the temperature is sooner reduced below the point of saturation; (3) if the winds, though arriving from the ocean, have not traversed a considerable extent of it, the rainfall is not large; (4) if the winds, even though having traversed a large extent of ocean, yet on arriving at the land proceed into lower latitudes or regions markedly warmer, the rainfall is small or nil; (5) if a range of mountains lies across the onward path of the winds, the rainfall is largely increased on the side facing the winds, and reduced over the regions on the other side of the range. The reason here is that, the air on the windward side of the ridge being suddenly raised to a greater height in crossing the range, the temperature is further reduced by mere expansion, and a more copious precipitation is the result; whereas on the leeward side as the air descends to lower levels it becomes gradually drier, and accordingly the rainfall rapidly diminishes with the descent.

We have drawn attention to the diminished velocity of the wind over land as compared with the open sea (p. 125). From this it follows that an envelope of stiller air or air of less velocity than that of the prevailing wind broods over the land, and by its presence forces the prevailing wind to a greater height, thus tending to increase the rainfall. If the foreshore rises within a few miles to a height of 200 or 300 feet, the result is very striking when the wind from the sea blows straight upon it. Thus at Spittal, near Berwick, on September 1877, a N.E. wind blew straight ashore at an estimated velocity of 25 miles an hour. To eastward the sky was singularly clear down to the horizon, but to westward all the country beyond a mile from the shore was enveloped in what appeared a dense mist or fog. About 15° to eastward of the zenith of an observer on the shore, the thinnest rack of cloudlets was seen emerging without intermission from the deep stainless blue of the sky, which as they drifted landward increased so rapidly in volume and density that the zenith was three-fourths covered with clouds. A similar phenomenon was seen in September 1879 on board the Orkney steamer at the magnificent cliff of Hoy Island, Orkney. A heavy storm had just cleared away, and a strong W.N.W. wind was blowing right against the cliff. The sky was absolutely cloudless all round, except the upper 300 feet of Hoy Hill, 1570 feet high, which was enveloped in a thick mist that stretched away to windward, some distance to westward of the steamer's course, which was about 2 miles from land. The western termination of the cloud was the thinnest rack of cloud, which emerged unceasingly from the blue sky at a distance not less than 4 miles to windward of the cliff. The constituent parts of the cloud itself were in rapid motion eastward, but, owing to the fresh accessions it was constantly receiving, the cloud itself appeared stationary. Thus the wind was forced upward into the atmosphere for some considerable distance to windward of the ridge lying across its path.

It is this dragging effect of the land on the wind, and the consequences which result from it, that explain how it is that during storms of wind and rain from the north-east the rainfall over the foreshores of the Firth of Forth, the Moray Firth, and the Pentland Firth looking to the north-east is so much in excess as compared with the rest of Scotland. The same principle explains the heavy rainfall in plains at some distance from the range of hills lying across the wind's path and on the side of the rain-bringing winds.

For short intervals of time the heaviest rainfalls occur with tornadoes, waterspouts, and some other forms of the whirlwind, the reason being that not only is there rapid expansion due to the rapid ascent of the air, but also great rarefaction is produced by the extreme velocity of the aerial gyrations round the axis of the tornado. On August 1, 1846, 3·12 inches of rain fell at Camberwell, London, in two hours and seventeen minutes. Of heavy falls may be mentioned 4·60 inches in London, April 13, 1878; 6·00 inches at Tongue, September 7, 1870; 5·36 inches in Monmouthshire, July 14, 1875; 6·62 inches at Seathwaite, Cumberland, November 27, 1848; and 7·12 inches at Drishaig, Argyllshire, December 7 to 8, 1863. But it is in lower latitudes that the heaviest single showers have been recorded. The following are among the most remarkable:—at Joyeuse, France, 31·17 inches in twenty-two hours; at Genoa, 30·00 inches in twenty-four hours; at Gibraltar, 33·00 inches in twenty-six hours; on the hills above Bombay, 24·00 inches in one night; and on the Khasi Hills, India, 30·00 inches on each of five successive days.

As regards the ocean, there are no available data from which an estimate could be formed as to the amount of the rainfall, since the rainfall statistics of the ocean must be regarded as giving hardly anything more than the comparative frequency of the fall. It is, however, certain that the equatorial belt of calms in the Atlantic and Pacific between the trades is the region where the ocean rainfall reaches the maximum, and the parts of these oceans are the rainiest which are the longest within the belt of calms as it shifts its position northward and southward with season. While the cloud-screen is undoubtedly dense, and the rainfall frequent and heavy, the careful observations of the "Challenger" and "Novara" show that the statements generally made as to these points are greatly exaggerated.

In the regions of the trades the rainfall is everywhere small over the open sea, seeing that the trade-winds are essentially an outflow from anticyclonic regions, and their original dryness is to a large extent maintained because their course is directed into regions which become constantly warmer. Thus at Ascension, lat. 8° 45′ S., which is throughout the whole year within the S.E. trades, the mean rainfall for the two years 1854–55 was only 8·85 inches. At St Helena, which lies constantly within the same trades, five years give a mean rainfall of 5·36 inches on the coast; but in the same island at a height of 1763 feet the annual amount rises to 23·98 inches. Malden Island and some other islands in the Pacific, about long. 150° W., and for some distance on each side of the equator, have been pointed to by Scott as practically almost rainless, as is shown by their containing extensive guano deposits. These islands are situated somewhat similarly to Ascension with respect to the zone of calms. In Mauritius the annual rainfall on a mean of four years was 30 inches at Gros Cailloux, but at Cluny, only 16 miles distant, for the same four years it was 146 inches; in regard to which Meldrum remarks that at Cluny, which is in the vicinity of mountains and forests, in the south-east of the island, and thus directly exposed to the trade-wind as it arrives from the sea, the rainfall in almost any month is from four to six times greater than at Gros Cailloux on the north-west coast, where neither mountain nor forest exists, and where the S.E. trade arrives considerably drained of its moisture.

From what has been said it is evident that the heaviest rains will be brought by the winds which have traversed the greatest extent of ocean within the tropics, and which accordingly of all ocean winds have the highest temperature and humidity. These conditions are most completely fulfilled during the summer months of the northern hemisphere by the winds which, commencing from near lat. 30° S., blow home on southern Asia as the well-known S.W. monsoon of these regions. Accordingly it is by the winds of this monsoon that a larger rainfall is distributed over a larger portion of the earth's surface than occurs anywhere else in any season; and this large rainfall is in many regions still farther greatly increased by the mountain ranges which lie across the path of the rain-bringing winds.

It is on these winds that the rainfall of India chiefly depends. Along the whole of the west coast from the

Gulf of Cambay southward, and on the Western Ghats, the rainfall is excessive. The following are some of the more interesting annual means in inches beginning with Bombay and proceeding southwards:—Bombay, 74; Matheram, 247; Mahabaleshwar, 252; Ratnagiri, 104; Baura, 255; Goa, 102; Karwar, 115; Honawar, 139; Mangalore, 134; Cannanore, 132; Calicut, 116; and Cochin, 114. In the west of Ceylon the rainfall is also heavy, being at Colombo 87, at Galle 91, and at Ratnapura, at some distance inland among the hills, 149. Since the S.W. monsoon is drained of much of its moisture in crossing these mountains, a greatly diminished rainfall is distributed over the interior and east side of India, and on the eastern slopes of Ceylon.

If now we cross to the eastern shores of the Bay of Bengal, we again encounter an excessive rainfall along these coasts and up the slopes of the mountains looking down on them. Thus from south northward the following are among the more characteristic rainfalls in inches:—Nancowry, 102; Port Blair, 116; Mergui, 152; Tavoy, 196; Maulmain, 189; Rangoon, 100; Bassein, 98; Sandoway, 212; Akyab, 198; and Chittagong 104. On the other hand, at Thyetmio, inland on the Irawadi, the annual rainfall is only 48 inches.

We have shown how, in accordance with the peculiar distribution of pressure in India in summer, the monsoon is diverted up the valley of the Ganges as an E.S.E. wind, distributing on its way, even to the head of the valley, in a generous rainfall the moisture it has brought from the Indian Ocean and the Bay of Bengal. The rainfall does not extend farther westward than the basin of the Ganges, and the precipitation is most copious along the lower Himalayas, the largest falls being recorded at heights about 4000 feet,—being, as pointed out by Hill, near the level at which the summer monsoon is cooled just below its dew-point. The following are some of the larger rainfalls in inches, beginning with the more western:—Mussooree, 95; Naini Tal, 92; Khatmandu, 57; Darjiling, 121; Kurseong, 154; Buxa, 219; Kuch Behar, 131.

The rainfall is very large in the north-east angle of the Bay of Bengal and thence northwards towards Bhutan, or at the angle where the summer monsoon from the bay curves round to a westerly course on its way up the Ganges. Thus at Noakhally, on the coast, it amounts in inches to 109; at Tura, on the Brahmaputra, immediately to west of the Garo Hills, 129; at Silchar and Sylhet to eastward, 117 and 155; whilst at Cherrapunji, on the Khasi Hills, it rises to 493·19 inches on a mean of twenty-four years. This last rainfall is the largest known on the globe, the causes of which are the highly saturated state of the monsoon on its arrival at the lower Ganges, the high mountain range of Burmah to eastward of Bengal, which turns the monsoon to the north, and the protrusion westwards of the Khasi and Garo Hills so as to lie in the line of that branch of the monsoon which passes from the lower Ganges into the basin of the Brahmaputra above Goalpara. The consequence is that the highly saturated air of the monsoon in its passage across the Khasi Hills is suddenly raised to a height of about 6000 feet, and being thereby reduced far below the point of saturation the superabundant moisture is precipitated in unequalled deluges of rain. The amount of the annual rainfall at all these places is determined, essentially if not altogether, by the rains of the summer monsoon, the relative intensity of which over India may be taken to be fairly represented by the rainfall of July.

The rains which accompany the N.E. monsoon of the winter months may be represented by the rainfall for January. These are heaviest in Ceylon, especially on its east slopes, and in southern India, or where the N.E. monsoon arrives after having traversed a large extent of ocean. The fall for the month exceeds 6 inches over a large portion of the east coast, whilst at Colombo in the west the rainfall is only half that amount, and farther north at Pattalum the January rainfall is only 1·82 inches. In southern India the amount varies from about 1 to 2 inches. Blanford pointed out in 1873 (*Phil. Trans.*, vol. clxiv. p. 618) that, while the surface winds of northern India in winter are northerly, on the Himalayas, especially the north-west portion, southerly winds prevail during the cold months. It is these upper southerly winds which bring the winter rains to the Punjab, Upper India, and the highlands of Assam. It is further to be noted that winter rains also occur in Central India, where the prevailing surface winds are from east and north-east. The mean rainfall of January at Mussooree is 2·00 inches and at Naini Tal 2·86 inches, and in Assam, at Sibsagar, 1·13 inch. Over a large tract of the east side of southern India from Nellore southward, including Ceylon, the maximum rainfall for the year occurs in the months of October and November.

Rainfall of the Malay Archipelago and Australia.—Under the direction of the late Dr Bergsma, systematic observations of the rainfall of the Malay archipelago were begun in 1879, the number of stations being 150. The results of the first three years show that the mean annual rainfall over the archipelago varies from about 60 inches in Timor to upwards of 200 inches at some spots among the western slopes of Sumatra. But the most important feature in the rainfall in its relations to climate is not the absolute amount that falls annually, but rather the manner of its distribution through the months of the year. Over the greater number of the islands rain falls copiously every month; but as regards some of the islands the year is divided into dry and wet seasons as marked as are seen in the climates of India. The key to this essential difference among the climates is the distribution of atmospheric pressure during the months of the year from south-eastern Asia to Australia, with the resulting prevailing winds. During the winter months atmospheric pressure is high in south-eastern Asia and low in the interior of Australia, the difference being about three-quarters of an inch. Since between these two regions the fall in the mean pressure is practically uninterrupted, the Malay archipelago lying between them is swept by northerly winds (fig. 14). As these winds have traversed a great breadth of ocean in their course, they arrive in a highly saturated state, and consequently deposit a copious rainfall, particularly on the northern slopes of the higher islands. Hence in these months the rainfall over the islands without exception is large, the mean monthly amount being in many cases more than 30 inches. These winds continue their course to southward towards the low-pressure region in the interior of Australia, and deposit along the north coasts of that continent a monthly rainfall rising generally to from 14 to 20 inches. On advancing into the interior, the mean amount gradually diminishes at the successive telegraphic stations to 3·50 inches at Alice Springs near the tropic of Capricorn. The amount of the rainfall for any particular year, and the distance from the coast to which the rains penetrate inland, depend essentially on the height of the winter pressure of south-eastern Asia as compared with the low mean pressure of central Australia, by which the strength of the northerly monsoon is regulated.

On the other hand, during the summer of the northern hemisphere pressure is high in the interior of Australia and low in China, the mean difference being about half an inch. Between the two regions the fall in the mean pressure is continuous and uninterrupted, and as a consequence southerly winds prevail over the intervening archipelago. These winds, as they advance from the continent into lower latitudes, are absolutely rainless in the north of Australia, and over Timor and the other Malay islands which are separated from Australia only by a comparatively narrow belt of sea. During the three years no rain whatever fell in Timor in July and August, and the fall in June, September, and October was small. As, however, the winds pursue their course to northward, they eagerly lick up moisture from the sea, so that by the time they arrive at Amboyna they have become so saturated that the monthly rainfall there rises to nearly 30 inches. Again at some distance to the west of Timor rain falls more or less regularly every month, the amount increasing in proportion to the extent of ocean traversed by the S.E. winds, which advance towards these islands from the direction of Australia. These marked differences among the climates of the Malay archipelago, which, since they really depend on the geographical distribution of land and sea of this part of the globe, must be regarded as permanent differences, have played no inconspicuous part in the singular distribution of animal and vegetable life which characterizes the archipelago.

In July the prevailing wind in West Australia is N.W., and the rainfall reaches the maximum for the year, whereas in January the wind is S.E., and the rainfall is the minimum. Similarly in January since the winds of the southern half of South Australia and Victoria are from the south, and thus blow towards warmer regions, the rainfall is either at the annual minimum, or it is small. But on rounding the coast and proceeding northward, the wind becomes E., then N.E., and ultimately N. in the north of Queensland. With this prevalence of oceanic and equatorial winds, the rainfall at this time of the year rapidly rises over the whole of the eastern slopes, till at Cape York it is about 20 inches. In the basins of the Murray and Darling rivers, which are shut off from the east by the mountain ranges of New South Wales, the rainfall is only about an inch and a half. On the other hand, to south of the latitude of Sydney, including Tasmania, the maximum rainfall occurs in winter over those regions which slope south towards the sea. On crossing the mountain range of Victoria into the basin of the Murray river, the rainfall rapidly diminishes. In the north of New Zealand the winter rainfall is the heaviest; but farther south, where westerly winds prevail with some steadiness through the year, the rainfall is more equally distributed through the months; and, as the prevailing winds are westerly, the heaviest rainfall is in the west of the islands. Thus at Hokitika in the west near sea-level, and not far from a lofty range of mountains to the east, the annual amount reaches 120 inches, and at Bealey inland at a height of 2104 feet it is 106 inches. At Wellington the annual rainfall is 52 inches, at Southland 46, at Dunedin 34, and at Christchurch 25, thus showing, in the rainfall of the two sides of the island, extremes nearly as great as in Scotland.

Rainfall of Europe.—As regards rainfall, Europe may be conveniently divided into two distinct regions,—western and northern Europe, extending in a modified degree through the interior of the continent into Siberia, and the countries bordering on the Mediterranean. A vast ocean on the one hand, a great continent on the other, and a predominance of westerly winds are the determining circumstances in the distribution of the rainfall over western Europe. Hence the rainiest regions are to be found in the west, where mountain ranges stretch north and south. The annual rainfall exceeds 80 inches over a considerable district, including the greater part of Skye and portions of the counties of Inverness and Argyll to the south-east, in the lake district of England, and in the more mountainous parts of North Wales,—these three districts being the wettest in Europe. As Ireland presents no continuous range of mountains opposing the westerly winds of the Atlantic, no Irish rain-gauge shows a mean rainfall of 80 inches. A point of some interest is suggested by the rainfall of the counties of Kirkcudbright and Dumfries in Scotland. These counties offer to the westerly winds a series of valleys sloping south to the Solway Firth, which show successively a diminished rainfall on advancing eastward till at several places in Nithsdale and Annandale it does not exceed 40 inches. But in Eskdale, farther to the east, the rainfall instead of falling increases to about 60 inches. The reason is that the westerly winds are obstructed in their onward course by the range of hills by which Eskdale is bounded on the east, in surmounting which the winds are much reduced in temperature, and their superabundant moisture falls in copious rains immediately to westward of the ridge. The cause of the larger rainfall of Eskdale is thus analogous to that of the large rainfall of the coast in the north-east of the Bay of Bengal immediately under the Assam range of mountains. In England the largest annual rainfall is 146 inches at Seathwaite in the Lake district, in Scotland 128 inches at Glencroe in Argyll, whilst in Ireland the largest is only 76 inches. The driest part of the British Islands is an extensive district to south-south-west of the Wash, with a rainfall of about 21 inches. A large extent of England, and all the more important agricultural districts in Scotland, have a rainfall under 30 inches: the greater part of England, and nearly the half of Scotland, have a rainfall not exceeding 40 inches; but in Ireland it is isolated patches only that show a rainfall less than 40 inches.

In the west of Norway the rainfall in inches is 72 at Bergen, 51 at Aalesund, 46 at the Naze and in the Lofoten Isles, falling to 10 at the North Cape. At Christiania, Upsala, and a large part of the east of Scandinavia the rainfall is about 21 inches, falling to 16 inches on the north coast of the Gulf of Bothnia. In Russia and Siberia it rises only at a few places to 20 inches, several districts of this extensive region having an annual rainfall of 10, 5, 3, or even 2 inches. The rainfall of Spain presents great extremes—from 68 inches at Santiago to 13 inches at Saragossa. In France and the plains of Germany the average varies from 35 to 20 inches, but in mountainous regions these figures are greatly exceeded, rising through all gradations to upwards of 100 inches at some points in the Alps.

An important distinction between the manner of distribution of the rainfall in the west of Europe and at more inland places is that the greater part of the annual quantity of the west falls in winter, whilst in the interior the amount in summer is greater than in winter. The rainfall of January and July shows this in a very forcible manner. The summer climates of the extreme south of Europe and North Africa are rainless, and over extensive regions in the south of Europe adjoining the July rainfall does not amount to an inch. Over these dry regions the prevailing winds of summer are northerly, and hence the drought which characterizes them. On the other hand, the rainfall in the interior of the continent is large. In January the maximum rainfall occurs on the mountains and high grounds overlooking the Atlantic, and the minimum on the plains of Russia.

Owing to the way in which Europe is broken up by the seas which diversify its surface, the time of the year when the rain attains the maximum differs greatly in different regions. This phase of the rainfall occurs, indeed, according to locality, in all months except February, March, and April. The month of occurrence of the annual maximum rainfall over Europe is shown by fig. 18. A similar map

FIG. 18.—Showing Month of Maximum Rainfall in Europe.

representing the month of least rainfall shows still greater uniformity in a regular succession of the months in passing from region to region. Thus the month of least rainfall is January on the lower Volga, February in western Russia and the greater part of central Europe, March in the north of France and south of Great Britain, April farther to the north,

May in Scotland north of the Grampians, June in Orkney, Shetland, Iceland, the west of Ireland, and the north-west of France, and July over the whole of the south of Europe. The driest month occurs nowhere in Europe in any of the five months from August to December.

Rainfall of North America.—West of the Rocky Mountains the rainfall is very unequally distributed, the annual amounts varying from 86 inches at Astoria, near the mouth of the Columbia river, to 8 inches at San Diego on the coast, and 3 inches at the head of the Gulf of California. Over the whole of the region between the Cascade and Rocky Mountains the rainfall at all seasons is extremely small, this being indeed that feature in the climate to which the formation of the cañons of that region is chiefly to be referred. On the other hand, in the United States and Canada to east of long. 100° W. the distinguishing feature of the rainfall is the comparative equableness of its distribution, an annual rainfall exceeding 50 inches occurring only over restricted districts, and a rainfall as low as 20 inches being scarcely met with anywhere. The regions where the rainfall exceeds 50 inches are Florida, the lower basin of the Mississippi, and the Atlantic seaboards of Nova Scotia and Newfoundland.

In January the annual maximum rainfall occurs over the whole of the west coast from Sitka to lower California; but in the interior between long. 120° and 95° W. the amount is everywhere small, and over a considerable part in the south-west of this region no rain falls. The region of largest rainfall extends from Louisiana to West Virginia, where the mean varies from 4 to 6 inches. Over nearly the whole of the Dominion of Canada, by much the greater part of the winter precipitation is in the form of snow, which has been carefully measured and recorded by the Meteorological Service. The average snowfall for January exceeds 30 inches at St John's, Newfoundland, in Anticosti, Prince Edward Island, and in many other regions.

In July the rainfall is everywhere small in the west, a large part of this extensive region being absolutely rainless. The remarkable dryness of the climate at this season is due to the N.W. winds that set in towards the low pressure of the interior, which thus blow towards warmer regions. The rainfall to the east of the Rocky Mountains is distributed by the winds which are connected with the low-pressure region of the interior and with the high-pressure region of the Atlantic. The result is two regions of larger rainfall, the one in the south-east of the States and the other to the west of the lakes. The summer winds of the south-eastern coasts are southerly, and as they are anticyclonic in their origin and have in their course traversed some extent of ocean, they arrive well- but not super-saturated, and pour down a rainfall in July of 6 inches and upwards along the coasts and for some distance inland from Louisiana to Chesapeake Bay. Further, since in July these winds attain their maximum force and persistency, the rainfall at the same time reaches the maximum along the whole coast from Boston to some distance west of New Orleans. Since the summer winds blow in the line of the Alleghany mountains and not across them, the rainfall diminishes in ascending their slopes. The comparative equableness of the rainfall over the eastern States is the necessary result of the winds' passing into higher latitudes, and, therefore, cooler regions. A broad region where the rainfall is less than on each side of it, extends from Michigan to the south-west as far as Canadian River. To the west of the lakes the rainfall rises above 4 inches, and, since over this region the winds become somewhat easterly as they flow towards the low-pressure area, it is probable that the larger rainfall of this prairie region has its origin in no small degree in the evaporation of the lakes. On ascending the higher reaches of the Mississippi, the amount diminishes, but scarcely falls lower than 2 inches, being thus analogous to the summer rains of the Upper Ganges. On crossing the water-parting into the basin which drains into Hudson Bay, we encounter E. and N.E. winds laden with vapour licked up in their passage over Hudson's Bay, which they distribute in a generous rainfall of probably 3 to 5 inches over the rising colonies of Manitoba and Saskatchewan. An important point in the climate of the States is that over nearly the whole of the extensive region stretching between Alleghanies and Rocky Mountains, except the south coast already referred to, the annual maximum rainfall does not occur in summer but in spring, the month of largest rainfall in the great majority of cases being May. In the basin of Hudson's Bay July is the month of largest rainfall.

Rainfall of Central and South America.—The following are, in inches, the larger and more interesting annual rainfalls round the coasts:—Vera Cruz, 182; Belize, 75; Maracaibo, 163; Carácas, 155; Georgetown, 95; Paramaribo, 142; Cayenne, 140; Para, 71; Pernambuco, 109; Buenos Ayres, 34; Bahia Blanca, 19; Puerto Montt, 102; Valdivia, 109; Valparaiso, 100; Serena, 93; Lima, 9; and a large part of Peru, nil. A remarkable feature of the rainfall of South America is the large amounts that fall in the basins of the Orinoco and Amazon; the fall is 91 inches in the upper basin of the Madeira, and 112 inches at Yquitos (lat. 3° 40′ S., long. 72° 57′ W.). The reason is that this immense region, where pressure appears to be almost constantly low, is open to the highly saturated winds that blow from the equatorial Atlantic. Quite different is the distribution of the rainfall over the La Plata basin. The annual falls, in inches, are 92 at Joinville, 58 at Corrientes, 44 at Monte Video, 36 at Parana, 24 at Santiago, 22 at San Luis, and only 6 at Mendoza. The fall rapidly rises in ascending the eastern slopes of the Brazil mountains facing the South Atlantic; thus, while the amount at Rio Janeiro is 45 inches, on the hills to northward it is 116 inches.

In January northerly winds prevail on the south coasts of the Gulf of Mexico and the Caribbean Sea, and as they have their origin in the high pressure of the American continent, and in crossing the sea pass into lower latitudes, the January rainfall of these coasts is comparatively small. In July, however, the prevailing winds are easterly, and as they have traversed a large extent of the equatorial waters of the Atlantic they are highly saturated, and consequently the July rainfall of these coasts is everywhere very large. The following are, in inches, the January and July rainfalls:—Carácas, 1·00 and 14·04; Guatemala, 0·28 and 10·79; Vera Cruz, 5·10 and 35·90. The seasonal distribution of the rainfall in the basin of the Amazon is the reverse of this. In January the position of the belt of calms is about lat. 3° N., and as pressure is relatively low over the basin of the Amazon, especially its southern slopes, the trades and the west portion of the region of calms unitedly spread their highly saturated air over the whole region as far as the Andes, resulting in one of the most widespread heavy rainfalls anywhere to be met with. On the other hand, since in July the belt of calms is about lat. 10° N., the saturated atmosphere of the tropical regions no longer flows up the Amazon, but is carried westward into the Caribbean Sea and Gulf of Mexico. Hence at this season the rainfall of the Amazon valley is small. The following are, in inches, the January and July falls:—Para, 6·51 and 3·26; Manaos, 7·33 and 1·82; upper Madeira, 15·90 and 0·30; and Yquitos, 10·24 and 4·26. On the La Plata in January pressure is low, and as winds consequently blow from the ocean in upon the region of low pressure the rainfall is large; but as pressure is high in the interior in July the rainfall in that month is small. The following are, in inches, the January and July rainfalls:—Buenos Ayres, 2·37 and 1·70; Parana, 4·63 and 1·32; Corrientes, 5·24 and 2·67; Joinville, 14·26 and 3·55; and San Luis, 2·63 and 0·00.

Rainfall of Africa.—As regards the rainfall, Africa presents the greatest diversity in its climates. The following are the annual amounts in inches at various points on or near the coast:—Port Said, 2; Alexandria, 8; Tunis, 12; Algiers 31; Oran, 17; Mogador, 50; mouth of the Senegal, 17; Goree, 21; Sierra Leone, 126; Christiansborg, 23; St Thomas, 40; Gaboon, 106; Loanda, 11; Cape Town, 23; Mossel Bay, 12; Port Elizabeth, 24; Durban, 43; Zanzibar, 58; and mouth of the Zambezi, 61. In the north of the continent, the rainfall rapidly diminishes inland, and over the great desert of Sahara practically none falls. In the interior of Algiers it diminishes, the amount at Laghouat being 17 inches, and at Biskra 9. In Egypt the rainfall is limited to a narrow strip along the coast; at Cairo the annual fall scarcely amounts to an inch. The January and July rainfalls are, in inches, as follows:—Port Said, 0·46 and 0·00; Alexandria, 1·95 and 0·20; Algiers, 4·43 and 0·04; Biskra, 0·56 and 0·03; St Louis (Senegal), 0·28 and 3·00; Goree, 0·00 and 4·06; Sierra Leone, 0·69 and 24·20; Christiansborg, 0·50 and 2·00; Katunga, 0·11 and 4·76; Gaboon, 9·35 and 0·48; Cape Town, 0·28 and 3·83; Durban, 5·00 and 1·70; Pretoria, 6·07 and 0·71; and Zanzibar, 2·02 and 2·35. At Zanzibar the heaviest rains occur about the equinoxes, the mean for April being 14·55 inches, and for October 6·80 inches.

In the case of this, as the other continents, the explanation of the different amounts is to be had in the seasonal changes of wind. In the north the winter rains are to a very large extent the accompaniment of the Mediterranean storms of that season, but in summer pressure is diminished in the interior and increased in the Atlantic to the north-west, resulting in strong steady northerly winds, which as they advance into hotter regions are unaccompanied with rain. The heavy summer rains from Senegambia to the Gold Coast are due to the strong monsoonal winds which set in towards the interior, thus drawing over these coasts the highly saturated air of the belt of calms and of the trades immediately to the north and south of it. Since in winter the belt of calms is removed 8° of latitude farther to the south, and the temperature of the interior is greatly reduced, it follows that the winds blowing on these coasts from the sea are drier and less strong, and consequently the rainfall is small. At Sierre Leone the absolutely driest month is February, 0·31 inch, and the wettest September, 29·15 inches. On the other hand, at Gaboon (lat. 0° 25′ N.) the dry season is from June to August, when the belt of calms is farthest to the north; and the absolutely rainiest about the equinoxes, the mean of March being 14·70 inches and October 19·52 inches. At Loanda (lat. 8° 49′ S.) the annual amount is only a tenth of what falls at Gaboon, and it

falls wholly during the summer months of the southern hemisphere. In South Africa pressure in January is lowest in the interior, towards which prevailing winds from the ocean blow, and as these advance into regions becoming rapidly hotter the rainfall all round the coast and for some distance inland falls to the annual minimum. But in more strictly inland districts which are at a considerable elevation the rainfall reaches the maximum at the same season. Thus the amounts in inches for January and July are—for Pretoria, 6·07 and 0·71; Maritzburg, 4·23 and 0·21; Graham's Town, 2·89 and 1·51; Lower Nel's Poort, 1·33 and 0·49; and Aliwal North, 1·55 and 0·00. In the winter months pressure in the interior is high, and the rainfall consequently small. Though on the coast winds from the arid interior frequently prevail, yet the storms that sweep eastward past South Africa precipitate over large portions of the southern slopes of this part of the globe what must in the main be regarded as a generous rainfall. It follows that the climates of these important colonies range themselves into two perfectly distinct classes,—the climates of the inland regions and the Natal coast, where the rains occur during the hottest months, and the climates of the other regions, where the annual rains occur during the coldest months. Little is accurately known regarding the rainfall of the interior of Africa. It is certain, however, that it is small, or nil, over the extensive region of the Sahara, and that it is large from about 15° N. lat. to some distance south of the equator. Probably the rainiest part of Africa is the region extending from the Victoria Nyanza northwards to and including the gathering grounds of the two great tributaries of the Nile.

Snow.—Snow takes the place of rain when the temperature is sufficiently low to freeze the condensed moisture in the atmosphere. Snow is composed of crystals, either six-pointed stars or hexagonal plates, which exhibit the greatest variety of beautiful forms, one thousand different kinds having been observed. These numerous forms Scoresby reduced to five principal varieties:—(1) thin plates, comprising several hundred forms of the most exquisite beauty; (2) a nucleus or plane figure, studded with needle-shaped crystals; (3) six-sided, more rarely three-sided, crystals; (4) pyramids of six sides; (5) prismatic crystals, having at the ends and middle thin plates perpendicular to their length. In the same snowfall the forms of the crystals are generally similar. The flakes vary from 0·07 inch to an inch in diameter, the smallest occurring with low temperatures and the largest when the temperature approaches 32°. If the temperature is a little higher, the snow-flakes are partially thawed in falling through it, and fall as sleet. The white colour of snow is caused by the combination of the different prismatic colours of the minute snow-crystals. The density of snow is far from uniform; it is generally from ten to twelve times lighter than an equal bulk of water, but varies from eight to sixteen times lighter than water.

The limit of the fall of snow near sea-level coincides roughly with the winter isothermal of 52°, since in places where the mean winter temperature is no higher than 52° that of the air falls occasionally to 32° or lower during the winter months. As regards Europe, the southern limit is about Gibraltar; in North America it is Savannah, New Orleans, the mouth of the Rio Grande, the head of the Gulf of California, and San Francisco. In Europe, north of lat. 60°, snow falls generally on an average of from 80 to 110 days in the year. At Upsala the number of days is 61, at Warsaw 45, Aberdeen 42, Oxford 18, Ostend 15, Brussels 27, Tarum (in the south-west of Jutland) 12, Copenhagen 23, Vienna 33, Odessa 19, Sebastopol 12, Milan 11, Trieste 6, Saragossa 5, Madrid 3, and Lisbon 1. In Greenland the number of days exceeds 80, and this figure is nearly reached in Newfoundland and the north-east seaboard of Nova Scotia. At Quebec the mean days of snow are 66, Halifax 64, Winnipeg 54, Detroit 34, Cape Henry 13, St Louis 11, mouth of the Columbia River 7, and Charleston, S.C., 2. In Russia the time of the year when snow falls most frequently is December and January, except in the south of the empire, where February is the month of the most frequent occurrence of snow. But to the north of a line drawn from the entrance of the Gulf of Finland through Warsaw, Cracow, Salzburg, and Santiago March is the month of maximum occurrence in the great majority of instances; while to the south of this line it is January and in several cases December.

The largest falls of snow occur in the Antarctic regions, as is well attested by the magnificent icebergs of solidified snow which break off all round from the lofty walls of ice that engirdle the Southern Ocean. Excepting perhaps in the Dominion of Canada, no data have been anywhere collected from which even a rough estimate could be formed as to the mean annual amount of snow that falls in different parts of the globe.

Snow-Line.—The snow-line marks the height below which all the snow that falls annually melts during summer. No general rule can be stated for this height in different climates owing to the many causes determining it. These are the exposure of mountain slope to the sun (and hence, other things being the same, it is higher on the south than on the north sides of mountains), exposure to the rain-bringing winds, the steepness of the mountains, and the degree of dryness of the air. Hence the position of the snow-line can be known by observation only. It falls only little on either side of the equator to lat. 20°; from lat. 20° to 70° it falls equably, but from lat. 70° to 78° much more rapidly. To this general rule there are many exceptions. It is 4000 feet higher on the north than the south side of the Himalayas, owing to the larger snowfall on the south, and the greater dryness of the climate of the north side, and therefore the greater evaporation from the snow there. It is higher in the interior of continents than near the coasts, because the precipitation is less and summer heat greater. In the Caucasus it is 11,063 feet high, but only 8950 in the Pyrenees. In South America it rises from the equator to lat. 18°, and more on the west than on the east slopes of the Cordilleras, owing to the large precipitation on the east and small precipitation and arid climate of the west side of that chain of mountains. It is as high in lat. 33° S. as in 19° N., but south of that latitude it rapidly sinks owing to the heavy rains brought by the moist N.W. winds of these regions. In the south of Chili it is 3000 feet lower than in the same latitudes in Europe, and 6000 feet lower than in the extremely arid climates of the Rocky Mountains.

Storms.—If weather charts representing a large part of the northern hemisphere be examined, two distinct systems of pressure are seen which change their forms and positions on the earth's surface from day to day. The one set are systems of low pressure marked off by concentric isobars enclosing pressures successively lower till the centre is approached; and the other systems of high pressure marked off by concentric isobars enclosing pressures becoming successively higher towards the centre. The former of these are called cyclones, and the latter anticyclones. These areas of low pressure are the distinguishing characteristics of the hurricanes and typhoons of tropical regions, and of the ordinary storms of higher latitudes, and they may all be conveniently grouped under the general name of cyclones. Fig. 19 shows a storm which was passing across north-western Europe on the morning of November 2, 1863, and it may be taken as fairly representing the general features of cyclones. In the figure the arrows fly with the wind, and the force of the wind is indicated by the number of feathers on the arrows.

It will be seen that the winds indicate, not a circular movement round the centre of lowest pressure, but a vorticose motion inwards upon that centre, the motion being opposite to that of watch-hands. In other words, the wind follows Buys Ballot's law, already explained. The winds are strongest where the isobars are closest together; or they are generally proportioned to the "baro-

metric gradient,"—a term introduced by Stevenson in 1867. Cyclones have diameters seldom less than 600, and they occasionally exceed 3000 miles; the cyclone of fig. 19 had a diameter of about 1200 miles. The cyclones of the Mediterranean are usually of smaller dimensions than those of north-western Europe and America. The rates at which cyclones advance over the earth's surface vary greatly, the average in America being 24 miles an hour, in the Atlantic 20 miles, and in Europe 26 miles. A rate as high as 70 miles an hour has occurred in the British Islands; sometimes they remain stationary, and more rarely their course is for a time retrograde. The temperature and humidity increase at those places towards and over which the front part of the storm is advancing, and fall at those places over which the front part of the storm has already passed. In other words, the temperature and humidity rise as pressure falls and fall as pressure rises. This is the important climatic significance of cyclones. Thus a succession of low pressures passing eastwards in courses lying to northward of the British Islands are the essential conditions of open winters; whereas, if the cyclones follow courses lying to southward, the winters are severe. In a cyclone the broadest feature of weather is an area of rain about or rather somewhat in front of the centre, surrounded by a ring of cloud, outside which the sky is clear. The precise form and position of these areas have been shown by Abercrombie to vary with the type of pressure distribution, with the intensity of the cyclone, and with the rate of its progress, and they are also influenced by local, diurnal, and seasonal variations.

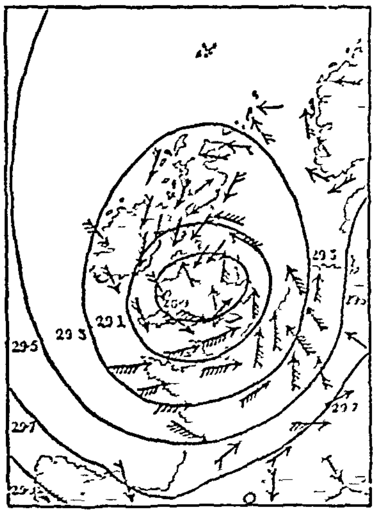

Fig. 19.

The chief point of difference between American and European storms is essentially the result of the mean winter pressures to the west and north-west of their respective storm-tracks. Owing to the high winter pressure in the interior of America, the barometer rises in the wake of the storms of the United States more rapidly, the wind veers round more quickly and more uniformly to N.W., N.N.W., and N. and keeps longer in these directions, and the temperature and humidity fall to a greater degree, than happens in Europe. In the New England States and Canada the easterly winds of the storms, coming as they do from the Atlantic, are disagreeably cold, damp, and misty in a degree and with a frequency much greater than occurs with the same winds in the British Islands.

The chief points of difference between the hurricanes and typhoons of the tropics and the cyclones of higher latitudes are these:—tropical cyclones are of smaller dimensions, show steeper barometric gradients and therefore stronger winds, and advance at a slower rate over the earth's surface. Another point of difference is that a large number of the hurricanes of the West Indies and the typhoons of eastern Asia first pursue a westerly course, which gradually becomes north-westerly, and on arriving at about lat. 30° they recurve and thereafter pursue a course to north-eastwards. The tropical cyclones of the Indian Ocean south of the equator also first pursue a westerly course, which gradually changes to south-west, and often on arriving about lat. 30° recurve to the south-east. Many of the cyclones of India have their origin to westwards of the Nicobar Islands, pursue a course to north-westward, and die out in the valley of the Ganges; and, similarly, a considerable number of the cyclones of the West Indies pursue a westerly course through the Gulf of Mexico, and several die out in the States.

The most dreadful attendant on tropical cyclones is the storm-wave, caused by the in-blowing winds and the low pressure of the centre of the storm. When this wave is unusually high and is hurled forward on a low-lying coast at high water it becomes one of the most destructive agents known. The Bakarganj cyclone of October 31, 1876, was accompanied by a wave which flooded the low grounds to the east of the delta of the Ganges to heights varying from 10 to 45 feet, by which more than 100,000 human beings perished.

Tracks of Cyclones of North America, Atlantic, and Europe.—In the *Physical Atlas of the Atlantic Ocean*, issued under the direction of Dr Neumayer of the Deutsche Seewarte, plate 28 shows by shadings the mean positions of the centres of cyclones and by lines their mean tracks. The following are the regions where the lowest barometer of storms has been most frequently found:—the region to west-south-west of the lakes of the United States; the Gulf of St Lawrence; mid-Atlantic about lat. 35° long. 52°; to the south-west of Greenland; to the south-west of Iceland, which is by far the most important of the whole; to the south-west of the Lofoten Isles; the region embracing Denmark, the south of Scandinavia, and Finland; and, as secondary centres of frequency, the south of the British Islands, Corsica and part of Italy adjoining, and the north-east of the Adriatic. The great importance of these centres, where the lowest barometers are most frequently found, consists in the indication they give of the precise regions either where many storms originate or where they are either retarded or arrested in their course. As regards the origin of storms, the centre west of the Mississippi is the region where most of the United States storms originate, the centre in the Gulf of St Lawrence is where many of the great Atlantic storms have their origin, and the centres in mid-Atlantic and to the south-west of Iceland are the regions where the storms of north-western Europe chiefly originate. The centres on the south-west of Greenland, the Lofoten Isles, Denmark, and the south of the British Islands, all appear to suggest that storms are retarded in their onward courses on coming up against large masses of land,—which may, in part at least, be occasioned by the heavy rainfalls that mark these parts of their courses.

Of all storm tracks the most frequently taken is that by the storms of the United States, which pursue an easterly course through the lakes to the Gulf of St Lawrence. A considerable number of storms follow a course from Nova Scotia to Davis Straits; but the larger number take a north-easterly course through the Atlantic towards Iceland and thence past the north of Norway. Among the less frequent but important tracks are these:—from near New Orleans along the east coast of the States towards Nova Scotia; from mid-Atlantic to south of Ireland and thence through France to the north of the Mediterranean; and from the Atlantic about lat. 42° long. 40° in a north-easterly course quite outside but at no great distance from the British Islands, and thence towards the North Cape. Of the tracks more immediately affecting British weather are one from Iceland in a south-easterly direction through the North Sea and Germany, and four tracks which start from near Scilly:—(1) to the south-east as already described; (2) eastward through the north of Germany; (3) north-east to Christiania; and (4) north through Ireland and the Hebrides. These are the storm tracks which chiefly give the United Kingdom its easterly and northerly winds.

The Inclination of Winds to the Isobars.—The vorticose motion of the winds in a cyclone towards and in upon the centre has been already pointed out. One of the more important practical problems of meteorology is the determination of the angle of inclination of the winds to the isobars in the different segments of the cyclone, not only from the application of the results of the inquiry to the theory of storms but also to practical navigation. The first real contribution to the subject, based on accurate measurements, was made by Clement Ley in 1873.[1] From the observations made at fifteen places in north-west Europe examined by him he showed that the winds incline from districts of higher towards those of lower pressure at a mean angle of 20° 51′; that the inclination is much greater at inland than at well-exposed stations on the coast, the respective angles being 28° 53′ and 12° 49′; and that the greatest inclinations are with S.E. winds. Then follow S.W., N.E., and N.W. winds, the last showing the least inclination. Whipple has recently compared the winds at Kew with the barometric gradients for the five years ending 1879, with the result that the greatest inclination is 63° with S.E. winds, the least 35° with N.E. winds, and the mean for all winds 52°.

As regards the open sea, Captain Toynbee has shown, from a careful investigation of the great Atlantic storm of August 24, 1873, that the mean angle of inclination calculated from one hundred and eight observations was 29°, the mean at the three selected epochs examined varying from 25° to 31°.

Barometric Gradient and Velocity of the Wind.—In inquiring into the relation of the velocity of the wind to the barometric gradient, it is necessary to have some definite information as to the increase of the velocity with height above the ground. Stevenson recently made observations on this point on winds varying from 2 to 44 miles an hour from the surface up to a height of 50 feet, from which he has drawn the following conclusions:—(1) the spaces passed over in the same time by the wind increase with height above the ground; (2) the curves traced out by these variations of velocity from 15 to 50 feet high coincide most nearly with parabolas (fig. 20)

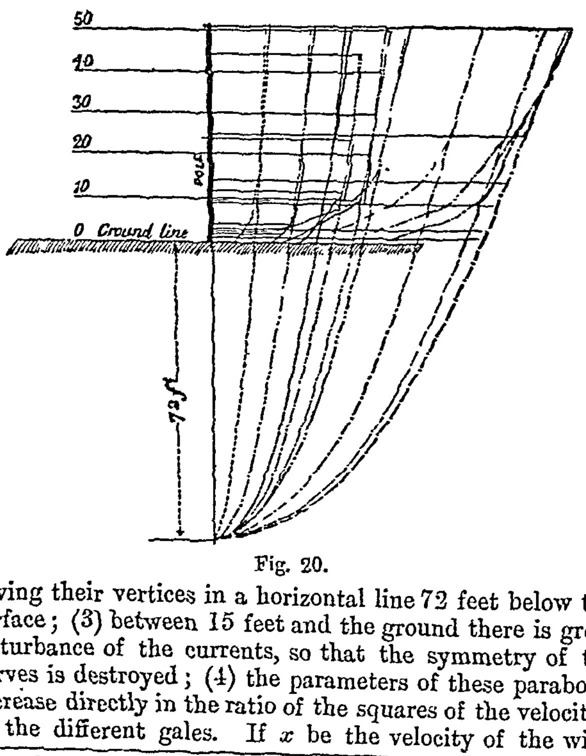

Fig. 20.

having their vertices in a horizontal line 72 feet below the surface; (3) between 15 feet and the ground there is great disturbance of the currents, so that the symmetry of the curves is destroyed; (4) the parameters of these parabolas increase directly in the ratio of the squares of the velocities of the different gales. If x be the velocity of the wind at height H above the ground, the parameter of the corresponding parabola is $x^2/(H+72)$; and as x varies the parameter will vary as x^2 or as the square of the velocity of the gale. It follows that, to render wind observations comparable, it is necessary that anemometers be placed at one uniform height above the ground, and that standard height not lower than 15 feet above the surface. It is very desirable that the inquiry were prosecuted up to a height of 100 feet; and it is of the utmost importance that the variation in the diurnal velocity be at the same time determined at different heights from 15 feet upwards.

Stevenson also made wind observations on the Calton Hill, Arthur's Seat, and the Pentland Hills, in the vicinity of Edinburgh, up to a height of 1600 feet above sea-level. It is from observations made at stations on knolls and peaks at different heights above the sea, and at different heights above the surfaces of their summits, that the problem of the variation of the wind's velocity at different heights with the same barometric gradient can be ascertained. In carrying the inquiry to considerable heights, the results cease to be comparable with those obtained at lower levels, unless in those cases where neighbouring heights are available for data from which the barometric gradient at the observed height can be calculated. The results of observations as to the velocity of atmospheric currents at very great elevations in the atmosphere deduced from the apparent movements of the higher clouds are altogether incomparable with the winds near the surface of the earth, for these among other reasons:—the heights of the clouds can be at best but imperfectly ascertained; the motion of the clouds, particularly the higher clouds, may be only apparent, it being sometimes difficult to distinguish between the formation and dissolution of clouds and their motion; and above all, since the higher clouds are usually the accompaniments of the greater weather changes, their movements are the result of barometric gradients towards a knowledge of which we are absolutely powerless to take a single step.

As regards surface winds, Clement Ley in 1881, and Whipple more recently and with greater fulness, have calculated the mean wind velocities for twelve gradients,—the gradients being derived from the daily weather charts of the Meteorological Office for the five years 1875 to 1879 at 8 A.M., and the corresponding wind data being obtained from the hourly readings of the Kew anemograph. The barometric gradient is for 15 nautical miles, and the following are the velocities for the twelve gradients on the mean of the year:—

Gradient. inch.	Velocity. miles.	Gradient. inch.	Velocity. miles.
0·002	5·0	0·017	15·0
0·005	7·0	0·020	16·5
0·007	7·5	0·022	19·1
0·010	9·2	0·025	22·0
0·012	11·6	0·027	22·0
0·015	12·6	0·030	25·5

The influence of season is very strongly marked. The velocities for the same gradients in order are—October to December, 12·5 miles; July to September, 12·6 miles; January to March, 14·8 miles; and April to June, 17·2 miles. From those observations of Whipple it follows that during the six months when the temperature is falling the velocity for the same gradients is least, while the velocity is greatest during the six months when the temperature is rising, and absolutely greatest during the three months ending June, when the greater part of the annual increase of temperature occurs. It is evident that the observed increase in the velocity of the wind for the same gradients is to be referred to the same cause that brings about the diurnal increase in the wind's velocity, viz., the wind blowing over a warmer surface than itself.

[1] *Journal Scottish Meteorological Society*, vol. iv. p. 66.

Whipple has also sorted the winds according to the eight points of the compass, with results of the greatest interest. If N.W., N., N.E., and E. winds be grouped together as polar, and S.E., S., S.W., and W. winds as equatorial winds, the mean hourly velocity of the polar winds, for the same gradients, is 1·1 miles in excess of the equatorial winds. Now, since polar winds pass into lower latitudes, the surface of the earth over which they blow is warmer, whereas the surface is colder than the equatorial winds which blow over it. It follows that the increased velocity of polar winds is referable to the same conditions which result in the diurnal increase in the wind's velocity and the greater velocity for the same gradients of winds when the annual temperature is rising, since in all these cases the winds blow over a surface of a higher temperature than their own.

It is evident from these considerations that for the development of the law of the relation of the wind's velocity to the barometric gradient with an exactness sufficient to warrant us in expressing that relation in a general mathematical formula much yet remains to be done. In truth, as regards the various formulæ submitted by Ferrel, Mohn, Hann, Everett, and others, we have no choice but to allow the justness of Strachan's criticism (*Modern Meteorology*, p. 98) that the theoretical values furnished by the formulæ do not accord with the actual values, and that therefore a satisfactory formula is yet to be found. Ere such a formula need be looked for, the conditions must be fulfilled for the preliminary work of supplying the observational data required. The "Challenger" observations prove that, with gradients substantially the same, the velocity of the wind is greater on the open sea than near land; and we have seen that the velocity varies with the hour of the day, and generally is increased as the temperature of the surface rises above that of the air blowing over it, and diminished as the temperature of the surface falls below that of the air. It is evident that observations on the open sea will afford data for the simplest solution of the problem; but on land the diurnal, seasonal, and nonperiodic changes of temperature greatly complicate the problem, and render necessary for its solution observations specially designed for the purpose. It is not easy to see how these can be obtained but by carrying out the plan proposed in 1875 by Stevenson of establishing strings of well-equipped meteorological stations planted sufficiently close that the barometric gradients may be determined within the limits of accuracy required. Observations made twelve times daily for a year, at stations so arranged, would supply the observational data for the solution of this fundamental problem in meteorology. Till some such proposal be carried out, the problem remains unsolved, for barometric gradients based on the widely separated existing stations are too uncertain and rough and the wind observations are wanting in that comparability which alone can satisfy the inquiry.

Weather and Weather Maps.—Weather is the state of the air at any time as respects heat, moisture, wind, rain, cloud, and electricity; and a change of weather implies a change in one or more of these conditions. Of these changes the most important as regards human interests are those which refer to temperature, wind, and rain; and, as these are intimately bound up with the distribution of atmospheric pressure, the latter truly furnishes the key to weather changes.

These relations are well shown by the International Monthly Weather Maps issued by the United States Signal Service. Of these that for December 1878 is a striking example. This month was characterized over the globe by unusually abnormal weather. A line drawn from Texas to Newfoundland, across the Atlantic, the north of France, and Germany, thence round to south-east, through the Black Sea, the Caucasus, India, the East India Islands, and Australia to the South Island of New Zealand, passes through a broad and extended region where pressure was throughout considerably below the mean of December, and this low pressure was still further deepened in various regions along the line. Another line passing from Australia, through the Philippine Islands, Japan, Manchuria, Behring's Strait, and Alaska, also marks out an extensive region where pressure was uninterruptedly below the mean.

On the other hand, pressure was above the average, and generally largely so, over the United States to west of longitude 90°, over Greenland, Iceland, the Faroes, Shetland, and a large portion of the Old Continent bounded by a line drawn from Lapland round by Lake Balkhash, Canton, Peking, to the upper reaches of the Lena. Another area of high pressure extended from Syria, through Egypt and East Africa, to the Cape; and part of a third area of high pressure appeared in the North Island of New Zealand. As regards North America, the greatest excess of pressure, 0·196 inch above the mean, occurred in the Columbia Valley, from which it gradually fell on proceeding eastward to a defect from the average of 0·146 inch near Lake Champlain and to northward, rising again to near the mean on the north of Nova Scotia. To the north and north-east exceedingly high pressures for these regions and the season prevailed, being 0·635 inch above the mean in Iceland, 0·500 in the south of Greenland, and at the three stations in West Greenland, proceeding northward, 0·115, 0·102, and 0·316 inch.

West Greenland being thus on the west side of the region of high pressure which occupied the northern part of the Atlantic, and on the north-east side of the area of low pressure in the States and Canada, strong south winds set in over that coast, and the temperature at the four Greenland stations, proceeding from south to north, rose to 1°·1, 8°·8, 12°·1, and 11°·4 above the means. As the centre of lowest pressure was in the valley of the St Lawrence about Montreal, strong northerly and westerly winds predominated to westward and southward, where consequently temperature was below the average, the deficiency at Chicago and St Louis being 9°·5; and, winds being easterly and northerly in California, the temperature there was also under the mean. On the other hand, in the New England States, the greater part of the Dominion of Canada, and West Greenland temperature was above the average. Pressure was much higher at St Michael's, Alaska, than to south-westward at St Paul's, Behring's Strait, and hence, while temperature at St Paul's was 2°·9 below the normal, it was 12°·0 above it at St Michael's, where strongly southerly winds ruled. With these strong contrasts of pressure, America presented contrasts at least as striking in the distribution of the temperature. Along the south of Lake Michigan the November temperature was 13°·7 above the normal, whilst the December temperature was 9°·5 below it, the difference there between the two consecutive months being thus 23°·2.

As regards Europe, Iceland was on the east side of the patch of high pressure which overspread the north of the Atlantic, and hence northerly winds prevailed there and temperature fell 7°·2 below the mean, presenting thus a marked contrast to the high temperature of West Greenland at the time. In Europe, the area of lowest pressure occupied the southern shores of the North Sea, extending thence, though in a less pronounced form, to south-eastward. Hence over the whole of western Europe winds were N.E., N., and in the south-west of Europe W.; and hence everywhere from the North Cape to the north of Italy temperature was below the normal, in some places greatly so, the deficiency being 10°·4 in the south of Norway and 12°·2 in the south of Scotland. On the other hand, on the east side of this area of low pressure winds were southerly and temperature consequently high. In some localities in Russia the excess above the mean was 15°·0, and over a large proportion of European Russia the excess was not less than 9°·0. This region of high temperature extended eastward into Siberia as far as the Irtish, being coterminous with the western half of the anticyclonic region of high pressure which overspread central Siberia. But over the eastern portion of the anticyclone northerly winds prevailed, with the inevitable accompaniment of low temperatures over the whole of Eastern Asia, the deficiency at Nertchinsk on the upper Amur being 6°·8. Here again, just as in America, Greenland, and Iceland, places with atmospheric pressure equally high presented the strongest contrasts of temperature. Thus at Bogoslovsk, on the Ural Mountains, pressure was 0·211 inch and at Nertchinsk 0·154 inch above the normals, but Bogoslovsk on the west side of the high pressure area had a temperature 15°·0 above, whilst at Nertchinsk it was 6°·8 below the average.

At this time of the year the mean pressure falls to the minimum in Australia, but during December 1878 the usually low pressure was still further diminished. Pressure at this season also falls to the annual minimum in the North Pacific and North Atlantic, and it has been seen that the low pressure of these regions was likewise still further diminished. But in the case of the Atlantic it was attended with a most important difference. The centre of lowest pressure, usually located to the south-west of Iceland, was removed some hundreds of miles to the south-east, and an unwonted development of extraordinarily high pressure appeared to the north

ward, overspreading the extensive region of Baffin's Bay, Greenland, Iceland, Faroes, and Shetland. It was to this region of high pressure, particularly in its relations to the low-pressure region to the south-east of it, that *the extreme severity of the weather in the* British Islands at the time was due. Now this high-pressure region was intimately connected with, and doubtless occasioned directly by, upper atmospheric currents from the widely extended region of low pressure to southward, with its large centres of still lower pressure in the North Sea, mid-Atlantic, and United States, where pressures were respectively 0·307, 0·322, and 0·146 inch under the normals. Thus, with the single exception of the high-pressure area about Greenland, the meteorological peculiarities which render December 1878 so memorable over nearly the whole globe arose out of a distribution of the earth's atmosphere essentially the same that obtains at that time of the year, but the usual irregularities in the distribution of the pressure appeared in more pronounced characters.

Taking the all-important bearings of these areas of high and low pressure on weather and climate into consideration, along with the abnormal concentration of aqueous vapour over extensive regions which they imply, it is evident that, when the meteorologist will be in a position to forecast, on scientific grounds, the weather of the coming season for the British Islands, it is to the Atlantic he will require to look for the data on which the forecast is based.

These questions, which the International Weather Maps of the United States enable us to discuss, are of the first importance in meteorology, whether we consider the amplitude of the atmospheric changes they disclose (these being often so vast as to embrace four continents at one time, besides being profoundly interesting from their direct bearings on the food supplies and commercial intercourse of nations) or regard the larger problems they present, with hints towards their solution, which underlie physical geography, climatology, and other branches of atmospheric physics. The discussion presents the great atmospheric changes as influenced by oceans and continents, including the subordinate but important parts played by mountain ranges, extensive plateaus, and physically well-defined river basins in determining the development, course, and termination of these changes.

Weather Forecasts and Storm Warnings.—It is in tropical and subtropical countries that an isolated observer may, with a close approximation to certainty, predict the approach of gales and hurricanes. In these regions atmospheric pressure and the other meteorological conditions are so constant from day to day that any deviation, even a slight one, from the average of the hour and season in respect of pressure, the direction and strength of the wind, and the direction and amount of cloud, implies the presence of a storm at no great distance. Dr Meldrum has practically worked out this problem at Mauritius with great success. At the Royal Alfred Observatory there the mean pressure at sea-level in January at 9 A.M. is 29·966 inches, from which it falls to 29·904 inches at 4 P.M., then rises to 29·980 inches at 10 P.M., and again falls to 29·927 at 4 A.M. The mean direction of the wind and the diurnal variation, both as regards direction and force, have been stated (p. 125). Suppose then that the barometer is observed to fall after 9 A.M. more rapidly than is due to the usual daily barometric tide, that in the afternoon it does not indicate the second maximum or that it continues to fall instead of rising,—or suppose, in short, any deviation from the mean daily march,—then it is certain that there is somewhere an atmospherical disturbance near enough to Mauritius to influence the pressure. The direction in which the disturbance is from Mauritius is readily known from the wind, and the distance of the storm closely approximated to by noting the rate and amount of the fall of the barometer, in connexion with the changes of the wind and the clouds,—the rate and progressive motion of the storm being known chiefly from the veerings of the wind. For a good many years past notifications have been sent to the daily newspapers when observations show that a storm is not far from the island, stating its position and probable course from day to day. The scheme of storm warnings at Mauritius has been entirely successful, and the result is of great value, since it shows what may be done at an isolated station in the ocean, or what may be done in ships at sea. In this connexion it is not possible to overestimate the importance to seamen of a knowledge of the hourly variations of the barometer and its mean monthly heights over the ocean tracks of commerce.

In passing from Mauritius to the British Islands we pass from a region where the forecasting of storms and weather is simplest and easiest to the region where it is most complex and difficult, particularly for the western districts of these islands. The great difficulty lies in the fact that the British Islands are immediately bounded by the Atlantic to westwards; and, since practically every storm and nearly all weather changes come from that direction, no telegraphic communication of their approach can be received. The Meteorological Office in London has therefore no choice but to base the forecasts on such of the observations telegraphed to the office as experience has shown to be the precursors of storms and other weather changes. The more important of these observations are the falling and rising of the barometer taken in connexion with changes in the direction and force of the wind. Since on the north side of the track of the centre of the storm winds are northerly and easterly and temperature low, and on the south side winds are southerly and westerly and temperature high, one of the most important points to be ascertained is the probable path the centre of the coming storm will take. Though a good deal remains to be accomplished in the development of this phase of storms, yet much has recently been done in this direction by close examination of the changes of pressure in the region of the anticyclone contiguous to the advancing storm and by the changing positions of the rain area near the centre of the cyclone.

As regards Europe, the facility of forecasting storms increases as distance from the west coasts is increased. Thus to the middle and eastern districts of the British Islands, were a day and night watch established in the west, forecasts of almost every storm could be issued, the exceptions being those small cyclones or satellite cyclones, as they are called, originating within the British Islands themselves, which are frequently characterized at once by their severity and by the rapidity of their onward course. In the United States, the system of weather forecasting is perhaps the best in temperate regions,—a result due to the admirable system organized and developed under the direction of the late General Myer, and adequately subsidized by the Government, but above all to the facilities to detect and track the storms in the region where nearly all of them have their origin, to west of the Mississippi, before they advance upon the more thickly peopled States.

Meteorology sustained a heavy loss by the death in 1877 of Leverrier, who was not only the keenest-sighted of physicists but also the prince of organizers of systems of meteorological observation. His last great service to the science was the establishment of a system of observation, by which the propagation of rain, hail, and other weather phenomena could be followed and recorded from commune to commune over France. This scheme for the investigation of the vitally important bearing on the meteorology of a country of a comprehensive observation of its rainfall, hail, and thunderstorms, through numerous observers possessing sound local information, is not only eminently just in science, but is calculated to be attended with the greatest benefits to agricultural and other public interests. The practical advantages of the scheme, it need scarcely

be added, can only be reaped after a very large expenditure of labour and money in organizing a comprehensive parochial scheme of observation, systematically and persistently carried through and discussed.

Further details regarding meteorological phenomena will be found in the articles ATMOSPHERE, BAROMETER, CLIMATE, HYGROMETRY OZONE, RAINGAUGE, SEA, and THERMOMETER. (A. B.)

TERRESTRIAL MAGNETISM.

1. In the preceding portion of this article some account has been given of the influence which the sun and moon exert upon the air, the earth, and the ocean, their strictly tidal effects being left to be separately dealt with. The discussion of the influence of these bodies on what may be termed the movables of the earth will not be complete, however, without embracing an account of the changes which they produce in the earth's magnetism. An account of the earlier magnetic observations has already been given under the heading MAGNETISM, and our task will now be to give in the first place a description of the best and most recent instruments by which the magnetic state of the earth is determined, embracing therein observatory instruments, those adapted for travellers whether by land or by sea, and differential magnetometers. We shall next give a short account of the magnetic system of the earth and of its secular variation; and we shall then investigate the changes connected with terrestrial magnetism depending on the sun and moon. In performing this task we shall be led to conclude that the sun's power is variable, and we shall therefore examine whether this conclusion is likewise borne out by strictly meteorological observations. Finally, we shall venture on remarks embodying a provisional working hypothesis, and our object will be gained if this should be found to suggest certain lines of thought to those interested in the subject which may lead them to examine and discuss the very great mass of observations at present existing.

INSTRUMENTS FOR DETERMINING THE MAGNETIC STATE OF THE EARTH.

(α) *Observatory Instruments.*

2. *Declinometer.*—It is that end of the needle which points to the north magnetic pole of the earth of which the position is invariably noted even when the observation is made in the southern hemisphere. The difference of this position from true geographical north denotes what is called the variation or declination (east or west, of the needle. East is often reckoned negative and west positive. The instrument by which this information is obtained is called the declinometer. The unifilar magnetometer, which is the form of declinometer now used, is described and figured in MAGNETISM, vol. xv. p. 228.

3. *Dip Circle.*—The instrument by which the magnetic dip or inclination is observed contains a thin needle about 3 inches long, the centre of gravity of which coincides as accurately as possible with the axis of motion of the needle. The needle has two axles consisting of two very fine cylinders of hard steel standing at right angles to the plane of the needle, and great attention must be paid to keep these axles in a state of perfect polish and dryness. By means of these the needle can oscillate freely on two horizontal agate rounded edges, the one axle lying on the one edge and the other axle on the other. If the centre of gravity coincides exactly with the axis of motion, and if there be no adhesion or friction between the axles and the agate edges, the needle must settle into such a position that its magnetic axis lies in the true line of dip.

The position of the ends of the needle is read by means of two microscopes which move round on a cross piece carrying verniers. To view the position of the lower end of the needle we move round the lower microscope until the cross wire in its field of view (extending in the line between the two microscopes) symmetrically cuts the extremity of the needle. The lower vernier is then read. The same process is repeated for the upper vernier, and the mean of the two readings is taken. This mean will accurately denote the position of the needle if the circle is properly set.

The sources of error in a dip observation are—(1) a want of symmetry in mass, the centre of gravity of the needle not being coincident with the axis of motion; (2) the vertical circle being erroneously set; (3) a want of symmetry in magnetism, the magnetic axis not being coincident with the axis of figure; (4) eccentricity, the axis of rotation of the needle not passing through the centre of the circle; (5) friction and adhesion of the axles as they rest on their agate supports. This last source of error is guarded against by taking great care of the axles, and by inserting them gently into a piece of cork before each observation; the agate supports ought also to be rubbed with cork. Then, again, when the needle has assumed its position, before reading it is gently raised by means of a lifter, the handle for turning which is shown in the figure towards the right. It is then gently lowered, and this process is repeated until no apparent change of position is produced by the operation.

4. We shall now describe a complete dip observation. The first point is to make the needle to swing in the plane of the magnetic meridian. In order to accomplish this, after levelling the instrument, the verniers are set for 90°, that is, for a vertical position of the needle. The whole instrument is now turned round its horizontal circle until the extremities of the needle are bisected by the wires of the two microscopes, and the position of the vernier of the horizontal circle is then read. The needle is next reversed so that the microscope shall view its other flat side; it is made vertical as before, and the position of the horizontal circle read once more. Next the face of the instrument is turned round 180°, and the same two operations repeated. We have thus four readings of the horizontal circle, and if we take the mean of these we shall have ascertained with sufficient accuracy the position of that plane for which the needle is vertical. Now this plane must be removed 90° from the magnetic meridian, for in such a plane the horizontal magnetic force of the earth would have no resolved portion acting in the plane of the needle's motion, so that the needle would practically be under the sole influence of the vertical magnetic force, and would therefore point in a vertical direction. By this means therefore we obtain the magnetic meridian, and thus know the plane in which we ought to swing the needle. The needle must now be read in the following positions:—(α) face of instrument east—face of needle to face of instrument; (β) face of instrument west—face of needle to face of instrument; (γ) face of instrument west—back of needle to face of instrument; (δ) face of instrument east—back of needle to face of instrument. Finally, the poles of the needle must be reversed, by rubbing them with powerful bar magnets in a direction opposite to that in which they were previously rubbed, and four observations taken corresponding to the above. The mean of the eight observations so obtained will give us the true dip.

The turning round of the face of the instrument from east to west is made to counteract any error due to erroneous setting of the vertical circle. The reversal of the face of the needle is made to counteract any error due to the centre of gravity of the needle not being quite coincident in the direction of the needle's breadth with its axis of motion, and likewise any error due to want of symmetry of the magnetic axis. The correction for eccentricity is made by reading both ends of the needle. Finally, the reversing of the poles of the needle is intended to counteract any error due to the centre of gravity of the needle not being coincident in the direction of the needle's length with its axis of motion.

Dr Joule[1] has suggested a modification of the dip circle in which the needle is hung on fine threads on which it rolls instead of resting on agate supports.

5. *Horizontal Force Magnetometer.*—The theory of the instrument for determining the horizontal component of the earth's magnetic force has already been given in the article MAGNETISM, vol. xv. pp. 228 *sq.*, and the instrument is shown in two forms, *ibid.*, figs. 28 and 29. The corrections necessary for accurate results are explained in a paper by G. M. Whipple (*Proc. Roy. Soc.*, 1877).

(β) *Instruments adapted for Travellers by Land.*

6. *Declinometer.*—For travellers by land the unifilar instrument (§ 2), mounted on a tripod stand and duly levelled, is perhaps the most accurate kind of declinometer.

For this purpose it is furnished with a transit mirror by means of which an image of the sun may be thrown into the field of view of the telescope, and—the geographical position of the station as well as the apparent time of the observation being known—an azimuth thus determined. In order that such an observation may succeed, the following points must receive attention.

In the first place the axis of the mirror must be horizontal; the adjustment for this is made by means of a riding level. Secondly, the normal to the plane of the mirror must be perpendicular to the axis. The adjustment for this is made by a screw attached to the back of the mirror. Take some object sufficiently elevated and reflect it into the telescope, getting the object bisected by the wire of the telescope. Then reverse the mirror in its bearings. If the object remains still bisected by the wire no correction requires to be made, but if not the screw at the back of the mirror must be moved until the object is in precisely the same position in both observations. Thirdly, the line of collimation of the telescope must be perpendicular to the plane of the mirror. In order to obtain this there is a collimating eye-piece attached to the telescope by which the sun's light may be made to illuminate the cross wires. Now turn the transit mirror until the reflection of the illuminated cross wires coincides with the wires themselves, in which case the line of collimation of the telescope must be perpendicular to the plane of the mirror. When this correction has been once made, note the circle reading of a small vernier which moves with the mirror and always set the mirror so as to give this reading.

[1] *Proc. Lit. and Phil. Society, Manchester*, vol. viii. p. 171.

By these means an accurate reading of the sun's bearing may be made; and, the position of the place and the time of observation being known, there are tables which enable the azimuth to be at once determined.

7. *Lloyd's Method of Determining the Total Force.*—While the dip circle and the horizontal force magnetometer may be used by travellers in addition to their use as observatory instruments, the Rev. Dr Lloyd has devised a new method of determining the total force. The ordinary method of obtaining this is first to find the dip and the horizontal force, from which the total force can be at once determined by the equation,—total force = horizontal force × secant dip. This method is, however, open to objection in high magnetic latitudes where the horizontal force is very small and the dip approaches 90°. Now in Lloyd's method this objection is overcome. Another circumstance which renders his method peculiarly convenient for high magnetic latitudes, where a traveller's equipment must be kept as light as possible, is the fact that it only requires the addition of two needles to an ordinary dip circle in order to give the required determination. These needles must be carefully kept from contact with other magnets, and their poles never reversed.

Here as before we have two unknown quantities to determine, the one being the magnetic moment of the magnet and the other the total force of the earth. We must, therefore, obtain two results, the one embodying the product of the earth's total force into the magnetic moment of the needle, while the other gives the ratio between these two quantities.

8. In order to determine the former of these, let the needle have a grooved wheel of radius r attached to its axle as in fig. 21, and over this wheel let an accurately known weight W be

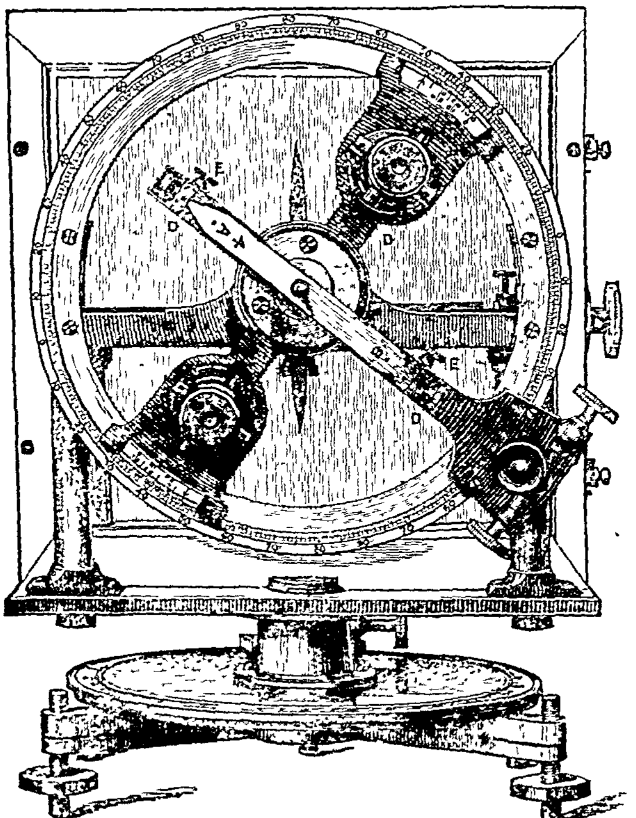

FIG. 21.—Dip Circle.

suspended by means of a very fine silk thread. The best way of doing this is to have a thread with two hooks of precisely equal weight at each end and then attach the preponderating weight W to one of these hooks. When this is done a new position of equilibrium will be taken by the needle. If we suppose that m denotes the magnetic moment of the needle, that i is the angle of dip at the place, and that η denotes the angle which the needle in its deflected tiposition makes with the horizon, the weighting being so made dellet η shall be less than i, then it is clear that the needle has been If we out of its position of equilibrium through an angle $i - \eta$. at the pl..ll this angle u and designate by R the total force we obtain the following equation of equilibrium:—

on the supposit $$m\mathrm{R}\sin u = \mathrm{W}r \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (1),$$

that W denotes a c (which is very nearly but not strictly correct) tant force at all latitudes.

9. Next, in order determine the ratio between this needle's force and that of the deflect another substitute th, let it be removed and employed to i its place.

When using it thus as a deflector it should be laid in a frame in an invariable position as in fig. 21. This frame is at right angles to the line between the two microscopes, and as both pieces move together the best plan is to turn the whole round until the deflected needle is visible in the centre of the field of the microscopes, in which position it is of course perpendicular to the deflecting needle. By always keeping to this arrangement we secure an invariable distance between the poles of the two needles. Suppose therefore that we have employed the needle as a deflector in the above manner, and that the deflected needle has thus been made to assume a position denoting an angle η' with the horizon. It has therefore been deflected from its position of equilibrium by an angle $i - \eta'$ (i denoting the dip as before); calling this angle of deflexion u', we obtain the following equation of equilibrium:—

$$\mathrm{R}\sin u' = m\mathrm{U} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (2),$$

U being a function depending upon the distance of the needles and on the distribution of free magnetism in them.

10. If we multiply together equations (1) and (2), we obtain

$$\mathrm{R}^2\sin u \sin u' = \mathrm{UW}r \quad . \quad . \quad . \quad . \quad . \quad . \quad (3),$$

in which u, u' are determined by observation, while W and r may be regarded as constants. U is, as we have said, a function depending upon the distance of the two needles and upon the distribution of free magnetism in them.

The magnetic moment of these needles is of course liable to alteration, but if they are carefully guarded from contact with magnets we may imagine that while their intensity alters, becoming weaker for instance, this nevertheless does not sensibly affect the distribution of the free magnetism within them, in which case the function U may be regarded as a constant quantity. The results obtained by this method of Lloyd's fully confirm this hypothesis regarding U; but it is essential that the two additional needles, the deflector and the deflected needle, should have their poles at no time either reversed or disturbed.

Assuming therefore the constancy of the quantity U, its value may be easily determined at any base station where the total force has been determined independently by the ordinary method.

11. Having thus determined the value of U, or at once of UWr (which we may call c), let us carry our instrument to a different station and make the requisite observations. We thus obtain

$$\mathrm{R} = \sqrt{\frac{c}{\sin u \sin u'}} \quad . \quad . \quad . \quad . \quad . \quad . \quad (4).$$

As this method is specially adapted for high latitudes, the dip circle employed (fig. 21) ought to be one for which the agate supports are horizontal, so as to admit of the needle being visible when the dip is nearly equal to 90°. It will also be noticed that, if the deflecting needle have the same temperature when it is used in equation (1) which it has when used in equation (2), then m in the one case is strictly equal to m in the other, and thus no temperature correction is rendered necessary.

12. A slight modification of the method now described is sometimes adopted. Instead of employing separate weights, which may be easily lost, two small holes are bored in the deflecting needle near each end. The one of these is filled with a suitably heavy brass peg when the observations are to be made in the higher magnetic latitudes of the northern hemisphere, and the other is filled in a similar manner when the observations are to be made near the southern pole. In this case therefore we must readjust the instrument as we pass from the one hemisphere to the other. A slight change must be made in the formula when this method is adopted, for it is clear that the weight will not now act always at the same constant leverage. If the weight be called W and its leverage when the needle is horizontal r, we shall have to modify equation (1) as follows:—

$$m\mathrm{R}\sin u = \mathrm{W}r\cos\eta \quad . \quad . \quad . \quad . \quad . \quad . \quad (5).$$

Equation (2) will, however, remain unaltered, and hence equation (3) will become

$$\mathrm{R}^2\sin u \sin u' = \mathrm{UW}r\cos\eta \quad . \quad . \quad . \quad . \quad . \quad (6).$$

If the quantity UWr be determined at the base station and called c', we shall have

$$\mathrm{R} = \sqrt{\frac{c'\cos\eta}{\sin u \sin u'}} \quad . \quad . \quad . \quad . \quad . \quad . \quad (7).$$

(γ) *Instruments adapted for Travellers by Sea.*

13. *Azimuth Compass.*—At sea the declination is generally observed by means of an azimuth compass invented by Kater. This is exhibited in fig. 22. It consists of a magnet with a graduated compass card attached to it. At the side of the instrument opposite the eye there is a frame which projects upwards from the plane of the instrument in a nearly vertical direction, and this frame contains a wide rectangular slit cut into two parts by a wire extending lengthwise. The eye-piece is opposite this frame, and the observer is supposed to point the instrument in such a

manner that the wire above mentioned shall bisect the sun's visible disk. There is a totally reflecting glass prism which throws into the eye-piece an image of the scale of the graduated card, so that the observer, having first bisected the sun's disk by the wire, must next read the division of the scale which is in the middle of the field of view. He thus obtains a reading of the sun's position; let us call this 100°. From this, knowing the geographical position of his station and the time of the observation, he may deduce an azimuth; let us imagine that this is 70° W. Thus a reading of 100° corresponds to a position 70° W. Suppose next that the instrument is so adjusted that when the magnetic axis of the magnet is between the eye-piece and the wire the reading is 0°. It is thus clear that the magnetic meridian is 100° removed from the position 70° W. Let us imagine that the instrument is so graduated that this denotes a position 30° E. We have thus obtained the magnetic declination. If the vessel be at rest the plan generally adopted is to take the reading of the sun when rising and also when setting; a mean between the two will give that which corresponds to a geographical meridian.

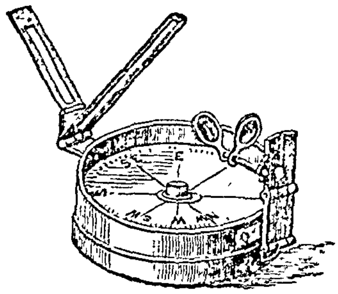

FIG. 22.—Azimuth Compass.

14. *Fox's Dip Circle.*—This instrument, contrived by Robert Were Fox, is more especially useful for observations at sea. In this case it must be placed on a gimball stand and duly levelled before commencing the observation. The following are the peculiarities of this instrument:—(1) the needles have two fine pivots or axles which are inserted into jewelled sockets; (2) in order to avoid parallax there are two graduated circles, the one farther from the eye than the other, and when reading the needle the eye is to be so placed that precisely the same reading shall be given by both circles,—the true position of the needle being thus obtained; (3) there is a rubber made of bone or ivory and roughened, the object of which is to rub a prolongation of the socket on the back of the instrument,—the friction which this rubbing causes enabling the needle to find its true position; (4) to avoid as much as possible all effects due to friction and adhesion, the entire socket arrangement may be turned round. The axles of the needle are thus compelled to be in contact with a different set of particles. Another way of varying the suspension is to use a magnetic deflecting arrangement attached to the back of the apparatus. Suppose that a reading of the position of the needle so deflected is now taken. Next reverse the position of the deflecting arrangement, which is done by turning a movable circle attached to this arrangement 180° round; let the position of the needle be again read. On the hypothesis that the needle is equally deflected on opposite sides of its true position in these two observations, the mean reading will give the true dip. The principle of the method of observing with this circle is precisely the same as that already described for observations on shore with an ordinary inclinometer.

15. *Fox's Intensity Arrangement* is merely a modification of that introduced by Lloyd, and already described in § 7.[1]

(δ) *Differential Magnetometers and Self-Recording Magnetographs.*

16. In addition to determinations at fixed intervals of time, it is a point of much interest and importance to keep a continuous record of all the magnetic changes which take place at a few selected stations. This is accomplished by means of differential magnetometers. It is, however, necessary to continue to use absolute instruments side by side with differential magnetometers, because the latter (with the exception of the declination instrument) are badly fitted for recording changes of long period, such as the secular changes of the horizontal and the vertical force. The reason of this will presently be seen.

17. Early in the history of such instruments it was found that hourly observations were exceedingly laborious, and attempts were made to construct a set of self-recording magnetometers. The first set of such instruments which were brought into systematic operation were those devised and constructed by the late Charles Brooke, which have been at continuous work in the Greenwich Observatory since 1848. In 1857 John Welsh devised a fresh set of self-recording instruments, and introduced them into the Kew Observatory. These, with certain slight modifications, have formed the type of instruments supplied to a large number of magnetic observatories all over the globe.

18. As we cannot conveniently record changes of dip by a differential instrument, changes of vertical force are measured instead by a balance or vertical force magnetometer. We have thus in a differential system, whether adapted to eye observation or to continuous photographic registration, three instruments, namely, the declination, the horizontal force, and the vertical force magnetometers or magnetographs as the case may be. The most recently constructed instruments are adapted both for photographic registration and for eye observation through a telescope. The advantage of eye observations is that we see what is taking place at the very moment of its occurrence, whereas we only obtain the photographic record some time after the changes to which it relates have actually happened.

We shall therefore describe—(α) the three instruments of the Kew pattern as adapted to eye observations; (β) these instruments as adapted to continuous registration by photography; (γ) the method of determining their scale coefficients; (δ) the method of determining the temperature coefficients of the force instruments.

19. *Kew Instruments—Eye Observations.*—Fig. 23 shows us these instruments arranged in the relative positions recommended by Lloyd so as magnetically to interfere with one another as little as possible. We are supposed to be viewing the whole from the south. No. 1 to the right is the declination instrument, No. 2 that for the horizontal force, and No. 3 in the distance behind the centre pillar (No. 4) the vertical force magnetometer. Figs. 24, 25, 26 give us the details of these three instruments in the same order as above. Connected with each instrument there is a circular mirror, or rather two semicircular mirrors, made of perfectly plane glass. One semicircular half of each mirror is attached to the magnet and moves with it, while the other half is firmly attached to the marble slab. Each magnet is enclosed in a gun-metal case with windows of perfectly plane glass; each gun-metal case is covered with a glass shade; and the whole is air-tight, and capable of exhaustion. Each magnet too is provided with a copper damper with the view of checking its oscillations. In fig. 23 will be seen two pillars of smaller size. The right-hand pillar carries a telescope, with a scale attached, to record the position of the declination magnet. The scale is reflected from the semicircular mirror moving with the magnet, and the position of this reflected scale as viewed in the telescope indicates the position of the magnet. The optical arrangement for the other instruments is similar, except that the vertical force mirror has a horizontal and not a vertical axis. The telescopes for viewing the force instruments are attached to the left-hand pillar of smaller size.

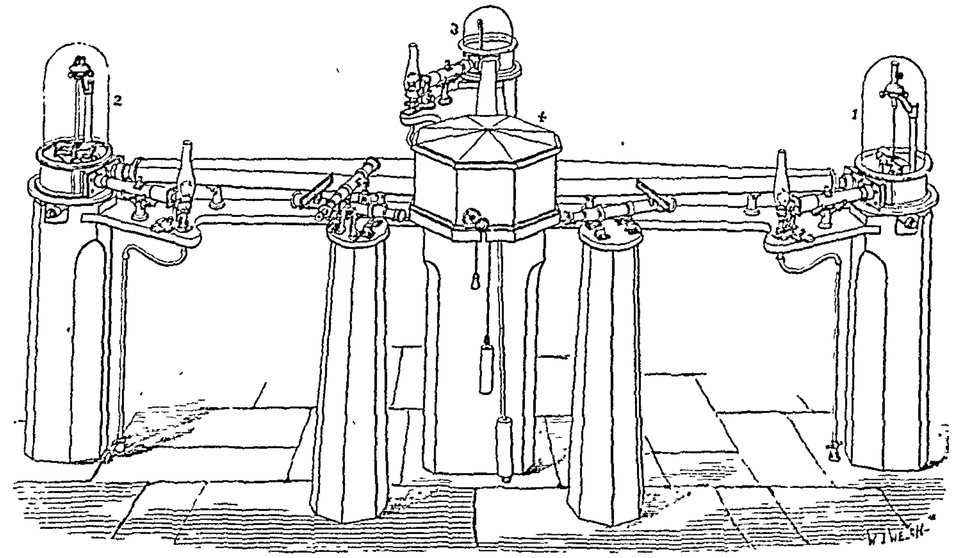

FIG. 23.—Kew Instruments.

20. The *Declinometer*[2] (fig. 24) consists of a magnet about 5 inches long suspended by a silk thread freed from torsion as completely as

[1] A great deal of detailed information regarding instruments for absolute determination and the methods of observing with them is to be found in the *Admiralty Manual of Scientific Inquiry* in an article on "Terrestrial Magnetism," by Sabine and Welsh. A treatise on *Terrestrial and Cosmical Magnetism*, by E. Walker, may likewise be consulted with much advantage.

[2] For a detailed account of the Kew magnetographs, see *British Association Reports*, 1859.

possible. To keep the state of the thread constant the glass shade should be rendered air-tight, and should contain some substance for absorbing moisture, such as chloride of calcium. It is clear that if the state of the thread remains the same, and if the position of the magnetic axis of the magnet does not change, this instrument should record faithfully the various changes of declination.

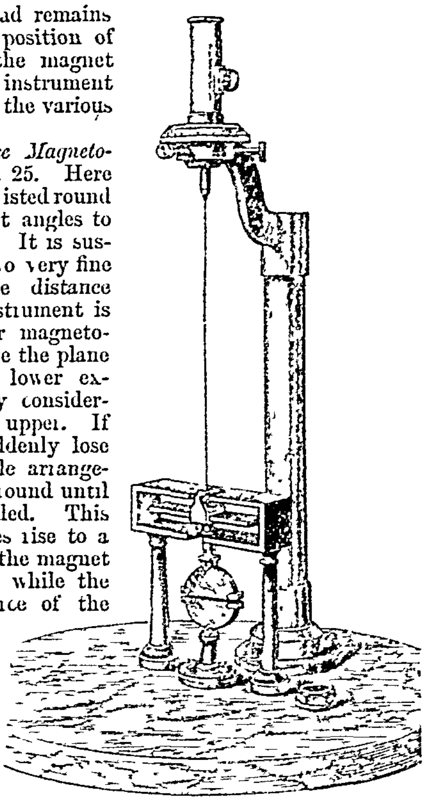

Fig. 24.—Declinometer.

The *Horizontal Force Magnetometer* is exhibited in fig. 25. Here the magnet[1] has been twisted round into a position at right angles to the magnetic meridian. It is suspended by means of two very fine steel wires some little distance apart, and thus the instrument is often called the bifilar magnetometer. These wires have the plane passing through their lower extremities differing very considerably from that of their upper. If the magnet should suddenly lose its magnetism the whole arrangement would be twisted round until the two planes coincided. This difference of plane gives rise to a couple tending to twist the magnet round in one direction while the horizontal magnetic force of the earth constitutes an equal and opposite couple, the two couples keeping the magnet in equilibrium. The couple depending upon the bifilar arrangement may for the present be regarded as constant, that depending on the horizontal force of the earth as variable. If the latter increase or diminish, the magnet will be slightly twisted round in one direction or the other.

In the *Vertical Force Magnetometer* (fig. 26), the magnet is balanced by means of a knife-edge resting on an agate plane. By means of two screws working horizontally and vertically the centre of gravity may be thrown to either side of the point of suspension, or it may be raised or lowered and the sensibility of the magnet when balanced thereby increased or diminished. These screws are so arranged that there is a preponderance of weight towards the south side of the magnet. This is neutralized partly by the magnetic force tending to pull the north end down and partly by a slip of brass standing out horizontally towards the north side. Let us suppose the system to be in equilibrium at a certain temperature; if the temperature rise (since brass expands more than steel), the leverage of the weight at the north side will increase more than that of the weight at the south. There will thus be a slight preponderance towards the north, and this may be arranged so as to neutralize to a great extent the decrease in the magnetic moment which an increase of temperature produces.

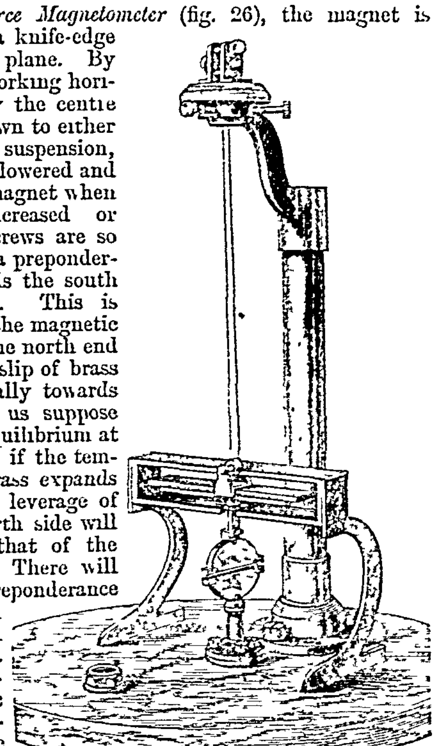

Fig. 25.—Horizontal Force Magnetometer.

21. *Magnetographs.*—The arrangement by means of which these instruments are converted into self-recording magnetographs is very simple. In fig. 23 we see a gas flame burning behind a vertical slit and placed endwise in order to render its light more intense. The light from this illuminated slit passes through a lens, and being reflected from the mirror of the declination magnet throws an image of the slit upon some sensitized paper in the central box. To speak more properly, two images are thrown, one reflected from the upper and movable half and the other from the fixed half of the mirror. The sensitive paper is wrapped round a horizontal cylinder (fig. 27), and the two images are therefore thrown upon different parts of this cylinder. But before reaching the cylinder these two images are by means of a hemicylindrical lens (shown in fig. 27) crushed up into two dots of light. The cylinder moves round regularly by clock-work once in twenty-four hours, and hence the course on the moving paper of the dot of light which comes from the fixed half-mirror will be a straight line, while that of the dot from the moving half-mirror will be a curved line depending on the motions of the magnet. When the paper is developed these lines appear black.

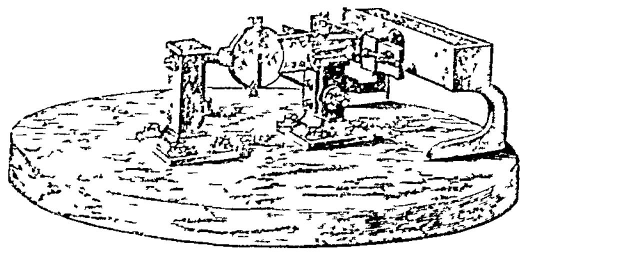

Fig. 26.—Vertical Force Magnetometer.

The arrangement for the horizontal force instrument is precisely similar to that for the declinometer; for the vertical force it is somewhat different, the illuminated slit being horizontal and not vertical, while the mirror oscillates on a horizontal axis and not on a vertical one; the hemicylindrical lens too and the cylinder are vertical and not horizontal. It was found necessary to put the plane of motion of the vertical force magnet 15° out of the magnetic meridian for the following reason. The axes of the telescopes are respectively 30° inclined to the tubes which go from the magnetometers to the central box, and hence had the vertical force magnet swung in the magnetic meridian it would have been necessary to place the mirror inclined at the angle of 15° to the axis of motion of the magnet. This was tried, but it was found that in this position of the mirror the correction for temperature was so excessive that the instrument became a thermometer and not a magnetometer. The mirror was therefore put in a plane passing through the axis of motion of the needle, the needle being made to move in a plane inclined 15° to the magnetic meridian.

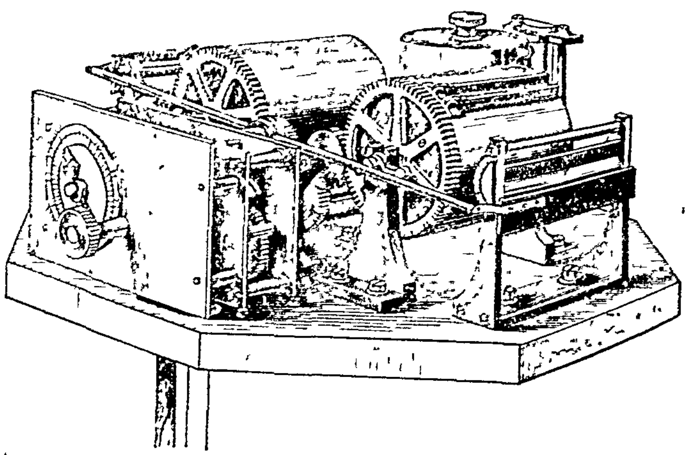

Fig. 27.—Magnetograph.

22. *Scale Coefficients of Differential Instruments.*—It is necessary to know the value of one division of the scale in the magnetometer or of one inch difference in the ordinate of the curve impressed on the photographic paper in the magnetograph. In the declination instrument it is only necessary to obtain the angular deviation corresponding to one division, and this may be done at once by a series of measurements. In the horizontal and vertical force instruments we wish to obtain the value of one division in parts of force. There is more than one method by which this can be accomplished, but that of John Allan Broun is probably the simplest, and it is, we believe, the one adopted at most of the various observatories possessing self-recording instruments. It is given in the *British Association Reports*, 1859.

23. *Temperature Coefficients of Differential Force Instruments.*—Broun has devoted a great deal of attention to the subject of these coefficients, and has come to the conclusion that the best and most unobjectionable method of determining them is to

[1] All the magnets are of the same size.

compare the instrumental readings on days when the temperature is high with the readings on days when the temperature is low.

24. By differential instruments the components of a force affecting the magnet are determined in three directions at right angles to each other. It does not, however, follow that this force is entirely due to changes in the magnetism of the earth. We know that certain forces connected with the sun affect the earth's magnetism, and on certain occasions at least these forces manifest themselves as currents in the upper regions of the atmosphere and in the crust of the earth. Now such currents will have a direct effect upon the needle as well as an indirect effect through the changes which they may produce in the magnetism of the earth. The total influence on the needle will therefore be made up of these two elements, the one denoting the direct influence on the needle of the disturbing force, and the other the indirect influence through the change produced in the earth's magnetism. No attempt has yet been made to separate the action of these two elements.

25. Self-recording instruments after the Kew pattern have been supplied to observatories at the following places:—

Batavia.	Mauritius.
Coimbra (Portugal).	Kolaba (Bombay).
Lisbon.	Vienna.
St Petersburg.	Zi Ka Wei (China).
Florence.	San Fernando (Spain).
Stonyhurst.	Potsdam.
Utrecht (declination only).	Brussels.
Melbourne.	Nice.

There are also self-recording magnetographs of other patterns at Toronto, Montsouris (Paris), Greenwich, Wilhelmshaven (?), Cape Horn, and Havana (?).

We understand that Professor W. G. Adams is at present engaged in making a comparison of simultaneous curves from various stations of these lists.[1]

Magnetic Poles of the Earth—Secular Variation.

26. *Magnetic Poles of the Earth.*—In the article MAGNETISM it has been shown that Dr Gilbert of Colchester had at a very early period grasped the important truth that the earth is a magnet, a truth which was afterwards mathematically demonstrated by Gauss. It was reserved for Halley, the contemporary of Newton, to show that the earth must be regarded as having two poles in the northern and two poles also in the southern hemisphere, so that, unlike ordinary magnets, its magnetic system has four poles altogether. Before proceeding further it will be desirable to state what it was that Halley actually did and what are the conclusions to be derived from his investigations. It has been remarked by Professor Stokes that, while in an ordinary bar magnet we may practically regard the pole as having a physical reality and as being the cause of well-known attractions and repulsions, we are not entitled *a priori* to assume that a point of maximum force in a large spherical magnet like the earth must necessarily be the seat of attractions and repulsions after the same manner as the pole of an ordinary bar magnet. It is to be determined by observation to what extent the earth actually preserves an analogy to an ordinary magnet. Now Halley's conclusions were derived from the pointing of the declination needle, since in his day there were no observations possible on total magnetic force. He argued that there are two points or poles in the northern hemisphere to which the needle appears to be attracted, one in the upper region of America and one above Siberia. So far this conclusion is hardly anything more than a formal one derived from the grouping together of observations. He asserted that these would be as they are known to be if we imagine two such poles or foci of force each exercising a causal influence on the magnetic needle. And the justification of Halley's way of regarding the earth is found in the fact that when force observations came to be made two such foci of force were actually found to exist. We do not, however, mean to imply that these foci have causal properties exactly similar to the poles of a bar magnet, for this is not the case.

In order to exhibit the process of reasoning which led Halley to his conclusion, let us first imagine that the earth has only a single pole or force-focus in the northern hemisphere, and that this is coincident with its geographical pole; then, assuming that this pole has a causative influence on the needle's declination, we should expect all needles to point everywhere due north. If, however, this pole be not coincident with the north pole of the earth, let us draw a meridian circle passing through the magnetic pole and complete it round the earth so as to divide the earth into two halves. At all points in this meridian circle the needle might be expected to point due north, while in the one half of the earth so divided it should point to the east and in the other half to the west of true north. In the next place let us imagine that the earth has two north magnetic poles or foci of equal strength, both being at the same latitude, while their difference in longitude is 180°, and let us draw a complete circle of meridian passing through these poles (fig. 28). Let us start from a point in this circle under one of these poles and pursue our journey eastwards along a circle of latitude. At first the needle will point due north. As we move eastwards the needle will point westwards to the pole we are leaving until we come to a region half-way between the two poles, where it will be equally solicited by each, and will therefore again point due north. Let us call the space we have travelled over since we set out A. As we proceed the needle will now be under the predominant influence of the second pole to our right, and will therefore point to the east until we arrive at the meridian under the second pole. This second space which we have travelled over let us call B. As we proceed we pass through a space C where the needle again points to the west until being once more equally influenced by the two poles it will point due north. After this we pass through a space D of easterly variation until we arrive once more at the point from which we started.

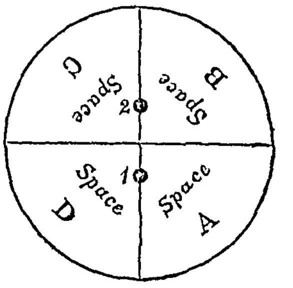

Fig. 28.

Thus there are now four spaces instead of two, and these are shown in fig. 28, where the centre of the circle represents the north geographical pole of the earth, and its circumference the equator. If pole 2 be inferior in power to pole 1 the spaces B and C will be smaller in size than A and D.

27. This last is an arrangement of things that agrees very well with the results of observation, if we add that the two poles are not precisely 180° removed from one another in longitude. Fig. 30[2] represents lines of equal magnetic variation in 1882. There are two lines extending throughout both hemispheres at all points of which there is no variation, and also an oval-shaped district in the northern hemisphere throughout all points in the circumference of which we have no variation. These facts are inconsistent with the hypothesis of a single pole, but they are quite consistent with that of two poles or foci of force, one in northern America and the other in northern Asia, the former being stronger than the latter. In order to see this let us take our stand at the great line of no variation which passes through North America and travel eastwards. We are just south of the American pole or focus, while the Asiatic pole or focus is nearly 180° off, and hence the needle points due north. As we proceed eastwards we leave the American or strongest pole to the westward of us, and hence we have a region of west variation which we have agreed to call A. As we begin to approach the eastern side of Europe we get nearer the Asiatic pole or focus, and at length the line of no variation is reached, the tendency of the American pole to pull the needle to the west being balanced by the tendency of the Asiatic pole to pull it to the east. After this, easterly variation predominates throughout a region B until at length we come to a point in the western boundary of the oval where we may imagine ourselves to be directly south of the Asiatic pole, while the American pole is nearly 180° distant; once more the needle points due north. As we still travel eastwards we leave the Asiatic pole, which is now the predominant one, to our left, and hence we have here a region C of westerly declination. At length we come to the eastern boundary of the oval, where the tendency of the Asiatic pole to pull the needle to the west is balanced by the tendency of the American or stronger pole (acting now towards the right) to pull it to the east, so that we have once more a point of no variation. After this the American pole predominates, and we have a large region D of easterly variation until we travel round once more to the point from which we started.

28. This train of argument receives, as we have already mentioned, corroboration from the fact that in the map of total force we perceive two foci of maximum force, one in northern America and the other in northern Asia, that in America being the strongest. This evidence was not, however, in existence at the time of Halley, and his hypothesis of two poles does the greater credit to his sagacity, inasmuch as he had to deduce it from a comparatively small number of observations of declination and dip, those of force being altogether wanting.

29. We have hitherto spoken of two poles or, more properly, *foci of maximum force*, the positions of which are of course best pointed out in fig. 29; but we have seen that the existence of such

[1] We are indebted to Mr Gordon—and to his publishers Messrs Sampson Low & Co., who have obtained them for us—for the sketches of the instruments for absolute determinations, with the exception of that of Kater's compass, for which we are indebted to Mr J. J. Hicks. For the sketch of the self-recording magnetographs together and in detail we are indebted to the Kew committee and to Mr G. M. Whipple, director of the Kew Observatory.

[2] We are indebted for the admirable charts given in figs. 29–32 to the kindness of the hydrographer, Captain Sir Frederick Evans, who, in order to save time, allowed us to make use of the information he had embodied even before it was officially published, and who likewise placed his plates at our disposal.

foci was first conjectured from the behaviour of the lines of variation or declination. Now it will be noticed by looking at the variation map (fig. 30) that all the lines of equal magnetic variation appear to converge to a point in the extreme north of the American continent. This point is not, however, coincident with the chief *focus of force*, which lies decidedly to its *south*; but it is no doubt coincident with the point denoting a dip of 90°, the locality of which may be inferred from the map of magnetic dip (fig. 31), and it is likewise no doubt *coincident* with the position of a zero of horizontal force which may be inferred from the map of horizontal force (fig. 32). Thus we have a point to the extreme north of America which has the following properties:—(1) the various lines of declination converge to it; (2) the needle points vertically downwards at it; and (3) the horizontal force vanishes at it. At this

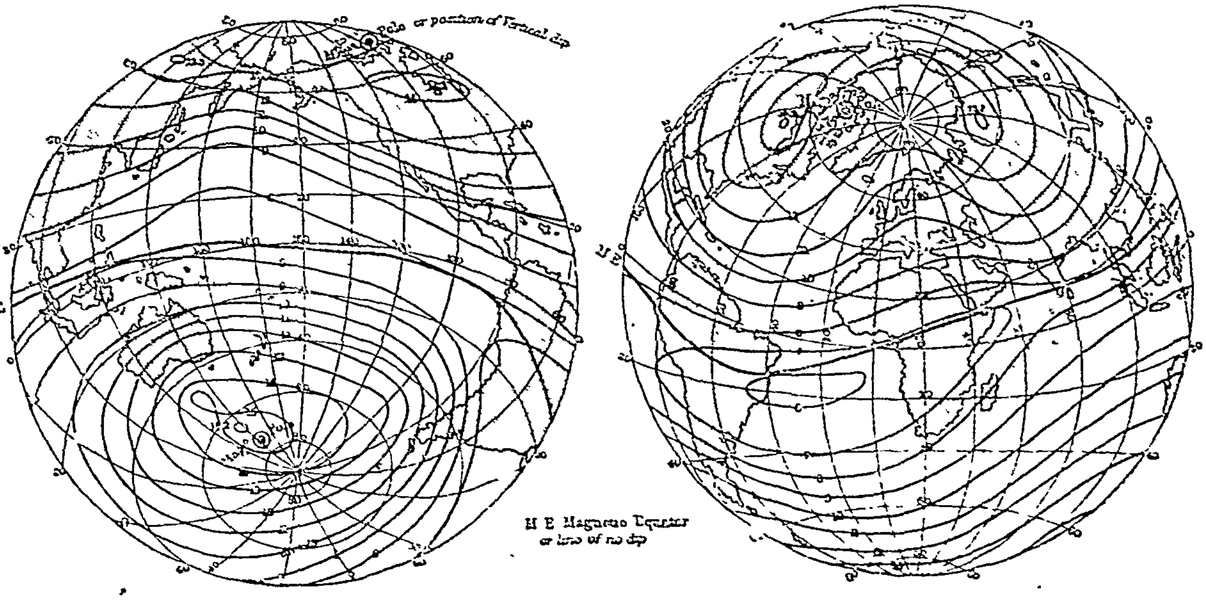

FIG. 29.—The Earth's Magnetism as shown by the Distribution of Lines of Equal Total Force, in Absolute Measure (British miles), with the Position of the Magnetic Poles and Equator,—approximately for 1875.

point therefore the horizontally balanced needle, having no horizontal force acting upon it, will point in any direction.

This point is, strictly speaking, the *pole of verticity*, but, inasmuch as there is only one such point in each hemisphere, these may for convenience sake be termed the magnetic poles, so that we speak of two centres or foci of maximum force and one pole in each hemisphere.

In the northern hemisphere Sir Frederick Evans[1] assumes the stronger or American focus to be in 52° N. and 90° W., and the weaker or Siberian focus in 70° N. and 115° E. In the southern hemisphere he assumes the position of the stronger focus to be 65° S. and 140° E., and of the weaker focus probably 50° S. and 130° E., these being thus not far separated from each other or from the magnetic pole. The nearness together of the southern foci is prob-

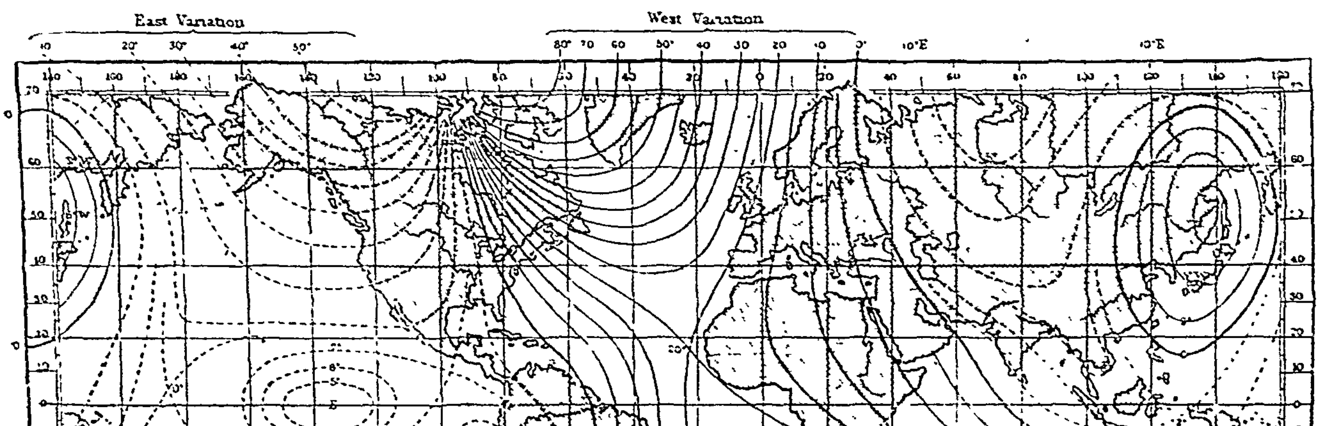

FIG. 30.—Lines of Equal Magnetic Variation, 1882.

ably the reason why the total force is greater at the southern than it is at the northern foci.

The magnetic pole (of verticity) in the northern hemisphere was reached by Sir James Ross in 1831. The position of vertical dip was observed by him to be 70° 5′ N. and 96° 43′ W. The magnetic pole (of verticity) in the southern hemisphere was nearly attained by the same navigator in a voyage made in 1839-43. Its position is probably 73½° S. and 147½° E.

The line of no dip is called the *magnetic* or *dip equator*—its position is given in figs. 29 and 31. The line connecting all the

[1] *Elementary Manual for the Deviation of the Compass in Iron Ships.*

points where the magnetic intensity is least is called the *dynamic equator*. It coincides very nearly with the dip equator.

30. *Secular Variation.*—The earth then as a magnet must be supposed to have two sets of centres of force. We shall next attempt to show that these centres cannot be regarded as constant both in position and intensity.

It should be premised that, while there is no well-established evidence to show that either the pole of verticity or the centre of force to the north of America has perceptibly changed its place, there is, on the other hand, very strong evidence to show that we have a change of place on the part of the Siberian focus and also on the part of its analogue in the southern hemisphere.

Table I. (p. 166), given by Gilpin (*Phil. Trans.*, 1806),[1] exhibits the change in the position of the needle in Great Britain from

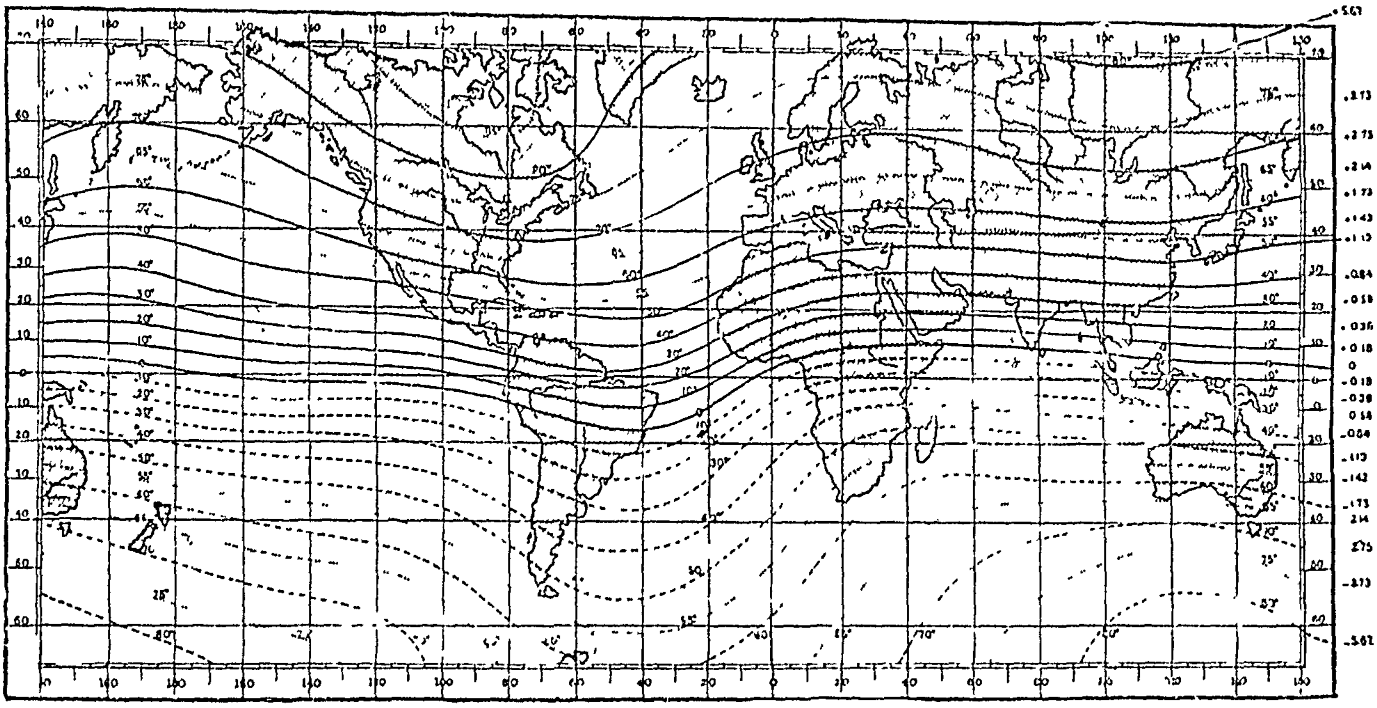

FIG. 31.—Lines of Equal Magnetic Dip, 1882.

the earliest observations up to the beginning of the present century.

31. Between the dates recorded in this table the needle has been pointing more and more to the west, which implies either a relative increase in the power of the American as compared to the Siberian focus, or a motion of the Siberian focus from west to east. On the first supposition the lines to the eastward of the Siberian focus—for instance, the line of no variation depending on a balance between it and the American focus—should be drawn in towards it, or they should travel westwards; but if the latter supposition is true, or this focus has been moving eastwards while retaining its force, the lines to the east of it should be found moving eastwards also. There is strong evidence that the latter is the case, and that in the northern hemisphere there has been a long continued progression

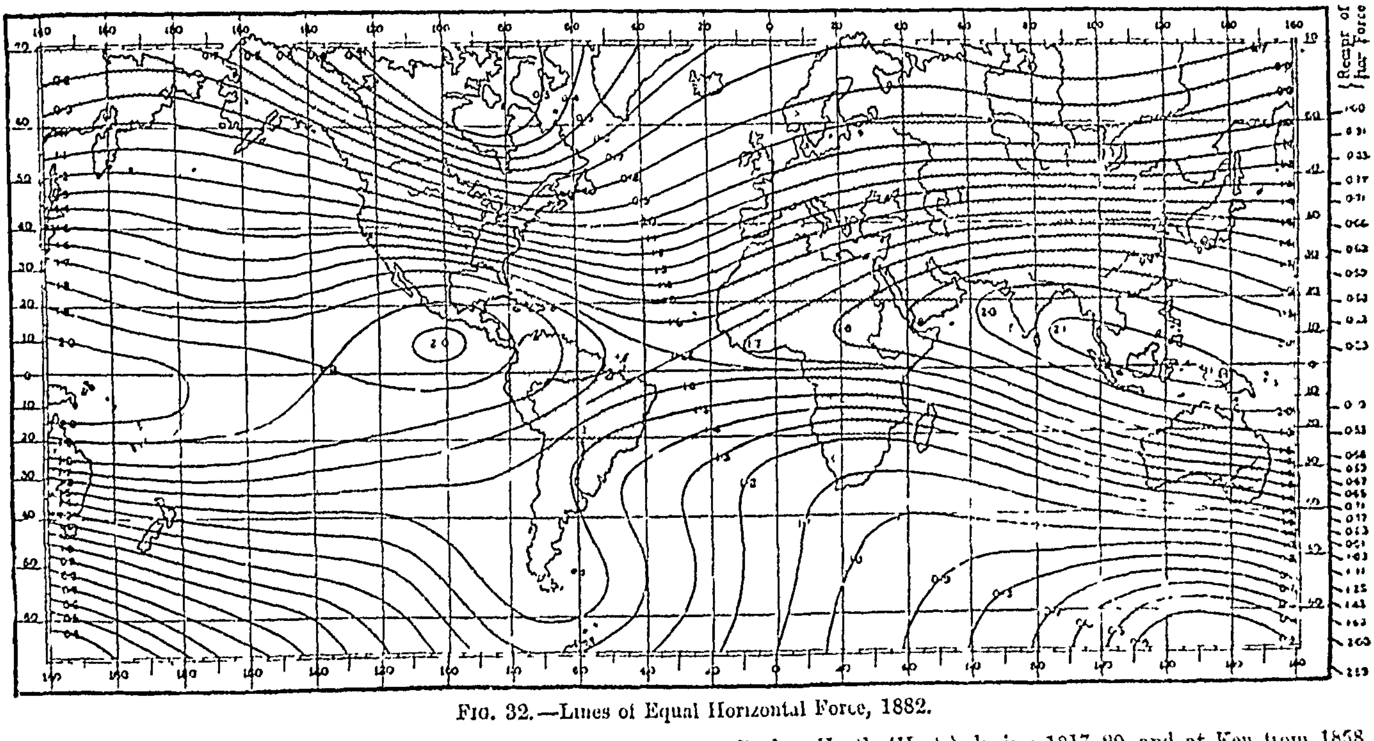

FIG. 32.—Lines of Equal Horizontal Force, 1882.

to the eastwards of the system of magnetic lines on both sides of the Siberian focus. In the southern hemisphere also we have proof that the analogous focus has been travelling, not from west to east, but from east to west.

32. There is some reason to believe that the eastward motion of the Siberian focus has been recently reversed, and that it is now going from east to west. Table II. shows the declination observed at Bushey Heath (Herts) during 1817–20, and at Kew from 1858 to 1882.

It would appear from Table II. that the maximum westerly declination was reached in 1818, and that the needle has since that date been travelling eastwards. A similar change has taken place

[1] Taken from Walker's *Magnetism*.

for the secular change by imagining a solid globe or *terella*,[1] concentric with the earth but rotating independently of the external shell and having a slightly different period of rotation,—the shell having two poles and the terella two others. While continuing to admire Halley's sagacity, we shall not now be disposed to allow such a constitution of the interior of the earth, but will rather be led to look to some external influence as the cause of the secular variation.

While we have strong evidence that the Siberian focus has changed its position, we cannot assert that the American focus has been absolutely stationary, or that neither focus has experienced any changes of force. On these points we must be content to be guided by observation alone.

34. It has been supposed by some magneticians that it is possible to compute with something like certainty the particulars of the motions of the magnetic foci. Hansteen more especially (1811–19) computed both the geographical positions and probable periods of revolution of this dual system of foci of force round the terrestrial pole. Sir Frederick Evans has discussed in connexion with the subject all the most recent observations,[2] and points out two objections to any such theory as that of Hansteen, viz., (1) that, while a magnetic turning point has been reached in certain regions, there are large portions of the earth in which this change has not yet been accomplished, and (2) that in certain districts of the earth very great changes in force have taken place. "If we turn," he says, "to the continent of South America and its adjacent seas, we shall find a diminution of the intensity of the earth's force now going on in a remarkable degree. An examination of the recent observations made by the 'Challenger' officers at Valparaiso and Monte Video, compared with those made by preceding observers, shows that within half a century the whole force has respectively diminished one-sixth and one-seventh,—at the Falkland Islands one-ninth." On the whole, while there is strong evidence that the Siberian focus has until recently been travelling eastwards, and its analogue westwards, and evidence less conclusive that recently a turning point in this motion has been reached, we are disposed to think with Sir Frederick Evans that a formal theory like that of Hansteen does not agree with recent observations. We shall revert to this subject.

35. In Tables III. and IV. certain yearly values of declination, dip, and horizontal force are given for various stations.

Inequalities in or connected with Terrestrial Magnetism depending on the Sun.

36. As there is a marked likeness between the ways in which the sun dominates over the two great divisions of terrestrial phenomena, meteorology and magnetism, let us endeavour to describe the sun's effect upon the latter by referring to its influence on the former, the chief peculiarities of which are well known to all. We find that the temperature of the air at a given station is subject to a diurnal fluctuation having its minimum value shortly before sunrise and its maximum early in the afternoon. We find likewise that the mean temperature for the day, as well as the amplitude of this diurnal oscillation, depends upon the season of the year, both being greatest about midsummer and least about midwinter. Now, if this were the only manifestation of solar influence upon this particular element, it would be possible to predict the temperature for any hour of any day once the mean temperature, the diurnal variation of temperature, and the modification of these for different seasons of the year had been well ascertained. But this amount of regularity is very far from taking place,—the march of temperature being frequently interrupted, cloaked, perhaps even reversed, by the advent of peculiar weather. Thus we may have very cold weather in midsummer and very warm weather in midwinter, or we may have a very cold afternoon and a very warm early morning, by which means the ordinary conditions of temperature will be completely reversed. In like manner weather interferes even to a greater extent with the diurnal oscillation of the atmospheric pressure, so that, in British latitudes at least, it is only possible to obtain this correctly by means of a long series of observations.

Weather, however, does not consist of a perfectly lawless interference with periodical phenomena, but is subject to laws of its own, some of which we are beginning to discover. Sometimes weather may exalt or depress the diurnal fluctuation of temperature without otherwise affecting its character; but sometimes too the turning-points and the general appearance of this fluctuation are greatly influenced by peculiar weather.

37. Now it is believed that we have something of this kind in those fluctuations depending on the sun to which the elements of terrestrial magnetism are subject. Let us take the declination as the most easily studied of the three magnetic elements, and suppose that we are engaged in considering the traces denoting the fluctuations of declination as derived from a set of self-recording magnetographs in Great Britain. Here we shall at once be able to recognize in an unmistakable manner the diurnal variation depending upon the position of the sun, in virtue of which a freely-suspended magnetic needle reaches the easterly extreme of its range about eight in the morning, and the westerly about two in the afternoon. We shall likewise perceive that the range of this diurnal fluctuation is greatest at midsummer and least at midwinter. In fine, the characteristics of this fluctuation, depending as they do upon the hour of the day and the season of the year, are not very different from those exhibited in the diurnal fluctuation of atmospheric temperature. But, however thoroughly we may have ascertained the mean declination and its diurnal oscillation, as well as the modifications of these depending on the season of the year, we shall nevertheless find it impossible to predict the exact position of a freely-suspended magnet at any moment of a particular day. Here then too we have something which may be called magnetic weather, and which interferes with the regular progress of the systematic fluctuations of the magnet. Magnetic weather has, like its meteorological analogue, a set of laws of its own, some of which we are beginning to find out. Sometimes magnetic weather may exalt or depress the diurnal fluctuation of declination without affecting its character, but it is imagined that at other times the turning points and general appearance of this fluctuation may be greatly influenced by peculiar magnetic weather.

38. There is, however, a kind of magnetic change which, so far as we know at present, is not analogous to anything in meteorology, and introduces an additional element of complexity in any attempt to analyse the fluctuations of terrestrial magnetism. We mean the well-known magnetic disturbances or storms which occur simultaneously in places very widely apart. Under these circumstances it becomes a question how we can best deal in a practical manner with this complicated system of things.

We do not think that with our present knowledge any better system can be adopted than that first introduced by Sir Edward Sabine in his discussion of the results of the colonial magnetic observatories. Suppose that we have hourly magnetic observations at a station, then first of all we should arrange these into monthly groups—each hour by itself. We should then reject as disturbed observations all those which differ by more than a certain amount from their respective normals of the same month and hour,—the normals being the hourly means in each month after the exclusion of all the disturbed observations. This method enables us, by its exclusion of disturbances, to ascertain with much accuracy the true form of the solar-diurnal variation of the magnetic elements at a given place corresponding to every month of every year, provided only that the observations are sufficiently numerous. On the other hand it will probably fail in accurately giving us the variations from day to day of the ranges of these diurnal fluctuations caused by the advent of peculiar magnetic weather,—inasmuch as the records of the extreme effects of such weather will probably be cut off from the undisturbed observations and reckoned among the disturbances.

For instance, it is known that the solar influence on terrestrial magnetism varies from year to year, and it is suspected that there are also short-period fluctuations of solar influence. It would not, however, be a safe proceeding to attempt to estimate numerically this last-mentioned element of fluctuation by taking the successive diurnal ranges of those observations at any station, reckoned as undisturbed, by the above process, and plotting them as successive ordinates of a curve, and then supposing that this curve would give us a true graphical representation of solar changes. It would rather probably represent such changes with the tops and bottoms of the larger fluctuations cut off. But if the undisturbed observations fail in this respect we can hardly be wrong in supposing that there has been eliminated from them, as far as possible, all influence due to magnetic storms, and hence that they will afford us a much better means of estimating small fluctuations, such, for instance, as those due to the moon, than we could have had without their aid.

Finally, with regard to that portion of the observations selected as disturbed, we are probably not certain that every such observation represents a true disturbance, or that the absolute times of occurrence of the various observations selected as disturbed at one station will be the same as those at another. Nevertheless Sir Edward Sabine has shown that at the Kew Observatory certain laws of disturbance deduced from the whole body of observations selected as disturbed are closely reproduced when this selection is made on a narrower basis—ninety-five days of prominent disturbance being alone taken. With these prefatory remarks we shall now proceed to discuss the diurnal inequality of terrestrial magnetism.

39. *Total Diurnal Inequality Defined.*—It will be seen further on that disturbed as well as undisturbed observations are subject to a diurnal variation, but these two variations are different, and the name *diurnal inequality* is generally given to the compound variation which is the joint resultant of the two. *Solar-diurnal variation* is that portion of the compound inequality which refers to undisturbed observations, while that which refers to disturbances has received the name of *disturbance-diurnal variation*. It would appear that in the United Kingdom, and perhaps throughout Europe, the total diurnal inequality is not very greatly different either in character or range from its most important component the solar-diurnal variation, at least so far as the

[1] See Walker's *Terrestrial and Cosmical Magnetism*, where the subject is well discussed.
[2] In his lecture to the Royal Geographical Society, March 11, 1878.

declination is concerned. When the diurnal oscillation of a freely-suspended magnet was first observed, the subject of magnetic disturbances was not understood, and the early individual determinations which have been handed down to us are not such as to justify the expenditure of any very great labour upon them for the purpose of separating the disturbed from the undisturbed observations. Inasmuch, however, as the total diurnal inequality of declination (which is in reality the element given by these early observations) does not greatly differ from the solar-diurnal variation, we may with much justice and little risk of error give the history of these early observations in connexion with that of the solar-diurnal variation of declination, which is by far the best known, and perhaps the most important, of all the various magnetic changes produced by solar influence.

40. *Solar-Diurnal Variation of Declination.*—Graham, an instrument maker of London, discovered in 1722 that a freely-suspended magnetic needle is subject to a diurnal oscillation of definite character.[1] The next observer was Canton, who in 1756 began a series of nearly four thousand observations, which he communicated to the Royal Society on December 13, 1759, and from which he concludes that the range of the diurnal variation is greater in summer than in winter. Macdonald's observations at Fort Marlborough in Sumatra in 1795 (*Phil. Trans.*, 1796), and Duperrey's in the tropics in 1825, were perhaps the first that might lead us to conclude that the amplitude of the diurnal oscillations of the needle is less in the tropics than in middle latitudes, and that the motion of the needle in the southern hemisphere is in the opposite direction to that in which it moves in the northern hemisphere at the same hour.

41. *Semiannual Inequality.*[2]—The existence of these early observations had led some magneticians prematurely to conjecture that there must be a line somewhere near the equator at which there is no horary variation in declination. In 1847 Sabine communicated to the Royal Society the results of five years' observations at St Helena, showing that at that station for the half of the year beginning at the vernal and ending at the autumnal equinox the motion of the needle corresponds nearly to that in the northern hemisphere, whilst for the other half it corresponds nearly to that in the southern hemisphere. Sabine afterwards confirmed and extended his conclusions regarding the semiannual inequality by discussing the results obtained at the various colonial magnetic observatories. More recently, as the result of twelve years' observations at Trevandrum, at an observatory established by the rajah of Travancore, John Allan Broun gave in a very complete form the laws of change of the solar-diurnal variation of magnetic declination near the equator, showing the extinction of the mean movement near the equinox.

42. Perhaps the best way of exhibiting what really takes place is the following, which is that adopted by Sabine.

The mean annual value of the solar-diurnal variation is of what may be called the northerly type in places of middle latitude in the northern hemisphere, and of what may be called the southerly type in places of middle latitude in the southern hemisphere. Now let us take a northern station, and consider the mean form of its solar-diurnal variation for the six months beginning with the vernal equinox. Here we shall have an oscillation of the northerly type with a range greater than the annual range. For these six months, therefore, we may imagine that the annual range has been supplemented by the superposition on it of a variation with a type similar to its own. At the same station, during the other six months, the solar-diurnal variation is less than the mean of the year, as if the annual variation had been depressed by the superposition on it of a variation with a type the opposite of its own, that is to say, with a southerly type. At a station in the southern hemisphere, again, the mean annual form of the solar-diurnal oscillation is of the southerly type, reduced during the six months beginning with the vernal equinox by the superposition on it of a variation of northerly type, and increased during the other six months as if by the superposition of a variation of southerly type. Thus when the sun is north of the equator we may superpose a variation of the northerly type upon both hemispheres, with the effect of increasing the range in the northern hemisphere and diminishing it in the southern; and while the sun is south of the equator we may superpose a variation of the southern type upon both hemispheres, with the effect of diminishing the range in the northern and increasing it in the southern hemisphere.

Near the equator, as at Trevandrum, where Broun made his observations, we find the mean annual value of the solar-diurnal variation to be extremely small, if not altogether evanescent. During the six months beginning with the vernal equinox the type is entirely northerly, while for the remaining six months of the year it is entirely southerly in character. In fine, at this station the solar-diurnal variation changes its character at the equinoxes, at which time we have, as already observed, an extinction of the mean movement,—not indeed an absence of all variation, but rather a variation having an undecided character, which for a few days may be of one type and then of the very opposite. There is movement, but no mean movement.

43. In the following table (V.) the solar-diurnal variation is given for Kew, Trevandrum, and Hobart Town. Of these places the first denotes a station in middle latitude (northern hemisphere), the second an equatorial station, and the third a station in middle latitude (southern hemisphere).

Astronomical Hours.	Kew.			Trevandrum.			Hobart Town.

13	+1·23	+1·34	+1·29	+0·18	+0·08	+0·13	−0·75	−0·75	−0·75
14	+1·56	+1·22	+1·39	+0·27	+0·02	+0·15	−0·40	−0·70	−0·55
15	+1·93	+1·09	+1·51	+0·29	−0·11	+0·09	−0·15	−0·65	−0·40
16	+2·58	+1·17	+1·88	+0·31	−0·28	+0·02	−0·02	−0·78	−0·40
17	+3·60	+1·43	+2·51	+0·18	−0·45	+0·01	−0·10	−1·40	−0·75
18	+4·59	+1·54	+3·07	+1·02	−0·66	+0·18	−0·23	−2·37	−1·30
19	+5·31	+1·85	+3·58	+1·48	−0·81	+0·32	−0·50	−3·80	−2·15
20	+5·20	+2·40	+3·80	+1·20	−0·72	+0·24	−1·25	−5·25	−3·25
21	+3·57	+2·32	+2·95	+0·47	−0·36	+0·06	−2·10	−5·30	−3·70
22	+0·38	+0·54	+0·46	−0·32	−0·13	−0·22	−2·20	−3·80	−3·00
23	−3·18	−2·18	−2·68	−0·93	−0·07	−0·50	−1·40	−0·80	−1·15

In this table deflexions towards magnetic east are reckoned positive, deflexions towards magnetic west negative. The scale is in minutes of arc.

Also in fig. 33 we have a graphical representation of the solar-diurnal variation for the whole year at these three stations, from which it will be seen that the range at Trevandrum is extremely small, and that the curve for Hobart Town is opposite in appearance to that at Kew.

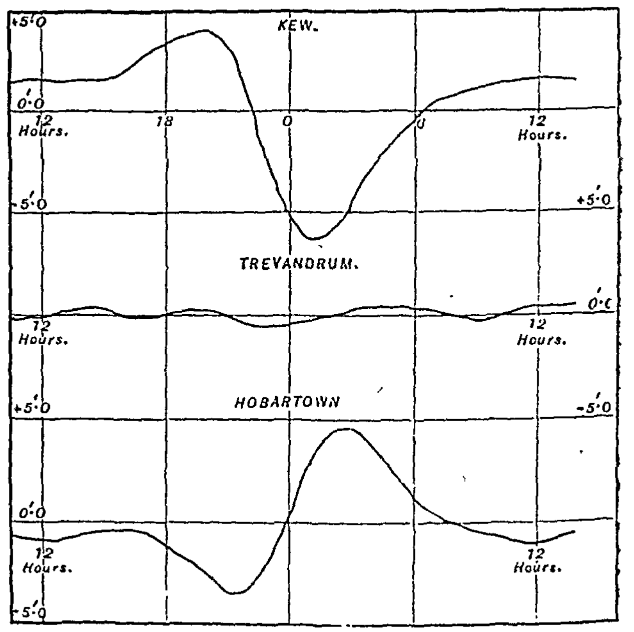

Fig. 33.

Finally, in fig. 34 we have a graphical representation of the semiannual inequality or difference from the whole year's mean of the two half-yearly means of Table V., the one half-year (that with thick lines) commencing at the vernal and the other at the autumnal equinox. It will be seen from this figure that the semiannual inequality is of the same character in both hemispheres, the likeness extending even to its minor peculiarities.

44. *Change from Month to Month.*—Charles Chambers, director of the Kolaba Observatory, Bombay, remarks (*Trans. Roy. Soc.*, December 10, 1868) that "the regular progression from month to month in the diurnal variation is so distinctly shown in the Bombay observations as to lead, on a first inspection, to the supposition that the law of variation is identical throughout the year, the extent only (including a reversal of direction) varying from month to month. But in this respect a different exposition of the character of the variation in different months shows that the first thought would be inaccurate." He then proceeds to discuss

[1] See Walker, *Terrestrial and Cosmical Magnetism.*
[2] This is the name used by Sabine, but its appropriateness may perhaps be questioned.

at length the monthly values of the solar-diurnal variation at Bombay. Broun has likewise (Trevandrum observations) discussed at length the solar-diurnal variation at the Trevandrum Observatory. It would hardly be of service to reproduce here the results of these discussions; but when such analyses become sufficiently

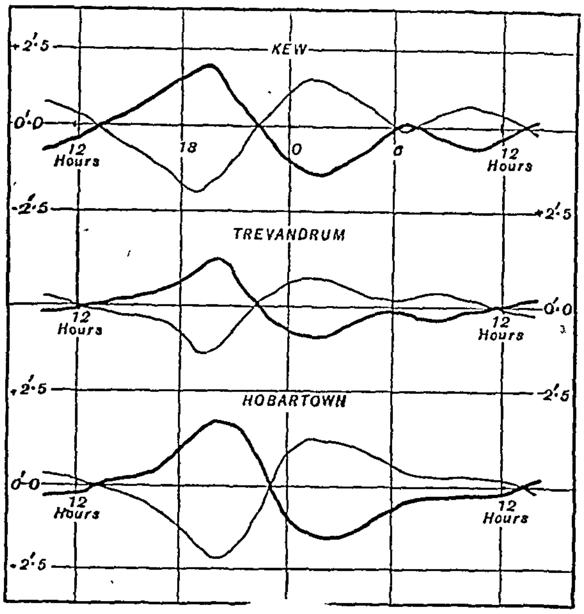

Fig. 34.

extensive they may be expected to throw light upon the cause of the solar-diurnal variation.

In the following table we have mean monthly values of the declination range at the Kew Observatory corresponding to forty-eight points in the year—derived from sixteen years' observations:—

TABLE VI.—*Containing Monthly Means (unit=22'·04) for Forty-eight Points in the Year of the Kew Solar-Diurnal Declination Ranges. Thus January (0) gives the monthly mean of which the middle date is the very commencement of the year, January (1) that for one week after the commencement, and so on.*

	Mean Value.		Mean Value.		Mean Value.
Jan. (0)	·312	May (0)	·593	Sept. (0)	·594
(1)	·323	(1)	581	(1)	·577
(2)	·340	(2)	·573	(2)	554
(3)	·362	(3)	·586	(3)	·532
Feb. (0)	·385	June (0)	·596	Oct. (0)	·513
(1)	·401	(1)	·605	(1)	·496
(2)	·418	(2)	·610	(2)	·478
(3)	·438	(3)	·604	(3)	·463
March (0)	·467	July (0)	·601	Nov. (0)	·445
(1)	·508	(1)	·597	(1)	·418
(2)	·548	(2)	·591	(2)	·389
(3)	·587	(3)	·593	(3)	·360
April (0)	·615	Aug. (0)	·594	Dec. (0)	·340
(1)	·632	(1)	·601	(1)	·322
(2)	·639	(2)	·611	(2)	·308
(3)	·620	(3)	·606	(3)	·308

It will be seen from this table that, while we have a maximum about the summer and a minimum about the winter solstice, we have unmistakable indications of maxima at or about the equinoxes. This does not take place at a tropical station such as Trevandrum.

45. *Behaviour near the Magnetic Pole.*—Figs. 33 and 34 exhibit the most prominent features of the solar-diurnal variation of declination in the extra-tropical regions of the northern hemisphere. If an observer stand over the centre of the needle and look towards the marked end, or that which points to the north, he will perceive a deflexion towards his right hand which will reach its extreme about 8 A.M. and a deflexion towards his left hand which will reach its extreme about 2 P.M. But are these deflexions to the right and left hand of geographical or of magnetical north? This question has been answered by Sabine in his discussion of the results of hourly observations of the magnetic declination at Port Kennedy (*Phil. Trans.*, 1863, p. 660). This station is 72° 0' 49" N. lat. and 94° 19' W. long., and here the marked end of the needle, while it points towards the magnetic pole, points in reality about 35° to the west of south. Now the marked end of the needle when viewed at 8 A.M. is seen at Port Kennedy to have moved to the geographical west but to the magnetical east. It would thus seem that throughout the extra-tropical regions of the northern hemisphere the 8 A.M deflexion of the needle is always towards the magnetic east but not always towards the geographical east, while the deflexion at 2 P.M. will always tend towards the magnetical west but not always towards the geographical west. In fine the oscillations have reference to the north magnetic pole of the earth and not to the north geographical pole. No observations of this nature have been made in the southern hemisphere.

46. *Long-Period Inequalities of Declination Range.*—It was first observed by Lamont that the yearly values of the diurnal range of magnetic declination at Munich presented signs of a long-period variation. In 1852 Sabine (*Phil. Trans.*, 1852, p. 103) showed that this inequality corresponded in its progress with that of the frequency of black spots on the surface of the sun.

The existence of black spots on the disk of the sun was long ago known to the Chinese. In Europe they were first scientifically observed after the invention of the telescope, and it was deduced from their behaviour that the sun revolves about his axis in about twenty-six days. Hofrath Schwabe of Dessau, from a long series of forty years' observations of the sun, was the first to show that the state of the sun's surface as regards spots was not uniform, but that their frequency was subject to an inequality the average period of which was about eleven years. Other inequalities both of longer and shorter periods have been supposed to exist, but the eleven-yearly period is the most prominent and is best assured. Although the sun-spot catalogue of Schwabe is the first with pretensions to completeness, yet Professor Rudolf Wolf has endeavoured to render observations of sun-spots made at different times and by different observers comparable with each other, and has formed a list exhibiting approximately the relative number of sun-spots for each year. This list extends back into the 17th century, and is of great value in confirming past all doubt the existence of the eleven-yearly period. It will appear below that the sun is probably to be regarded as giving out most light and heat at those times when sun-spots are most frequent. The most accurate and now universally adopted method of estimating sun-spots is to take the spotted area expressed in millionths of the sun's visible hemisphere.

To return from this digression,—the correspondence between sun-spots and declination ranges detected by Sabine was of such a nature that years of large declination range agreed with those of many sun-spots, and *vice versa*. In the same year with Sabine (1852) Dr Rudolf Wolf and M. Gautier independently remarked the same coincidence. Subsequent discussions have entirely confirmed the fact of this connexion, and in May 1879 William Ellis (*Phil. Trans.*, 1880, p. 541) showed that the observations made at the Greenwich Observatory during the years 1841–77 indicated a relation of this nature between the diurnal ranges of horizontal force as well as those of magnetic declination on the one hand and the amount of sun-spot frequency on the other. The general character of this coincidence between sun-spot frequency and declination range is exhibited graphically in fig. 39 below.

47. *Ratios of Ranges in Years of Maximum and Years of Minimum Sun-Spot Frequency.*—Broun (*Trans. Roy. Soc. of Edin.*, vol. xxvii.) has shown that the ratios of the diurnal ranges of declination in years of maximum to those in years of minimum sun-spot frequency for places widely apart on the surface of the earth are very nearly alike. This will be seen from the following table:—

TABLE VII.—*Ratios of Declination Ranges in Years of Maximum and of Minimum Sun-Spot Frequency.*

Place	Mean Ratio $\left(\frac{\text{max}}{\text{min.}}\right)$	Observer.
Paris..........................	1·71	Cassini and Arago.
Göttingen..................	1·74	Gauss.
Munich......................	1·66	Lamont.
Dublin........................	1·52	Lloyd.
Hobart Town..............	1·57	Kay.
Toronto.......................	1·51	Younghusband and Lefroy.
Trevandrum...............	1·56	Broun.

48. *Closeness of Correspondence—Lagging behind of Ranges.*—Stewart has shown from a discussion of the declination ranges at Kew, Trevandrum, and Prague (*Proc. Roy. Soc.*, March 22, 1877, February 8, 1878, May 16, 1878) that this correspondence between the state of the sun's surface and the diurnal range of declination extends to inequalities of short period as well as to that of which the period is approximately eleven years, but that a particular state of the sun's surface precedes in point of time that of the declination range to which it corresponds,—in fine, that the solar cause precedes the terrestrial effect, which latter lags behind to an extent that is sometimes considerable. These conclusions have been confirmed by Ellis (*ut supra*), and have likewise been extended by him to the horizontal force. The close nature of this correspondence, as well as the lagging behind of the terrestrial magnetic effect, will be seen from fig. 35.

There are indications that this lagging behind of the magnetic effect is greater for sun-spot inequalities of long than for those of short period, a method of behaviour quite similar to what we find in meteorological phenomena.

49. *Analysis of Long-Period Inequalities.*—We possess no sun-spot

data sufficiently accurate for a discussion, in a complete manner, of questions relating to solar periodicity before the time when Schwabe had finally matured his system of solar observations, which was not until the year 1832. We have, however, a much longer series of the diurnal ranges of magnetic declination, which we have seen to

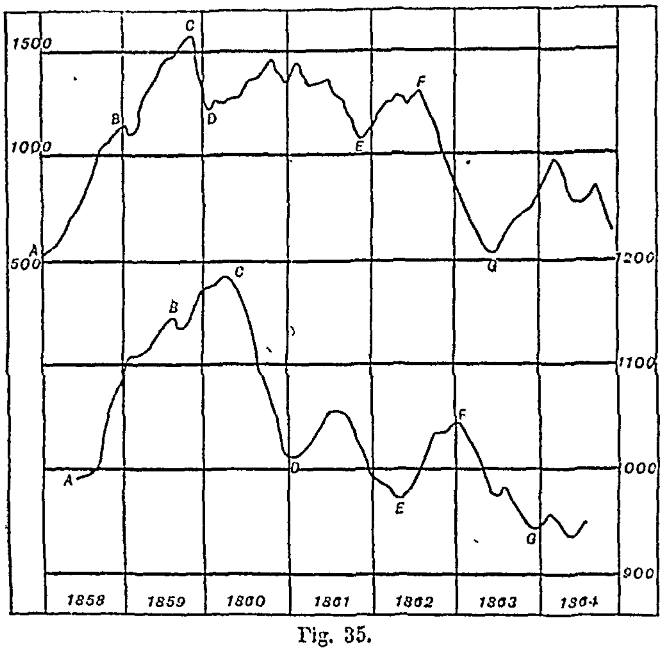

Fig. 35.

follow very closely all the variations of sun-spot frequency, so it is conceivable that they may give us a better estimate of true solar activity than that which can be derived from the direct measurement of spotted areas.

These considerations have induced Messrs Stewart and Dodgson to attempt an analysis of the diurnal ranges of magnetic declination, their method being that which has been pursued by Baxendell and probably other astronomers with observations of variable stars.[1] The observations at their disposal for this research were those which had been used by Professor Elias Loomis in his comparison of the mean daily range of the magnetic declination with the extent of the black spots on the sun (*American Journal of Science and Arts*, vol. I. No. cxlix.). These observations are recorded as monthly means of diurnal declination range, and it was found necessary to multiply each by a certain factor, first on account of the change of declination range from one month to another, and secondly to bring them all to the standard of the Prague observations,—Prague being the place where the longest series of such observations has been made. For this latter purpose precisely the same corrections were applied as those made by Professor Loomis.

The result of this analysis has been to indicate the existence of three inequalities,—two dominant ones with periods of about ten and a half and twelve years, and a subsidiary one with a period of about sixteen and a quarter years. By these means the observed annual values of declination range have been reproduced with an average error of 39″. The amount of agreement between the observed and calculated values will be seen from the following diagram (fig. 36).

50. Notwithstanding the considerable amount of agreement

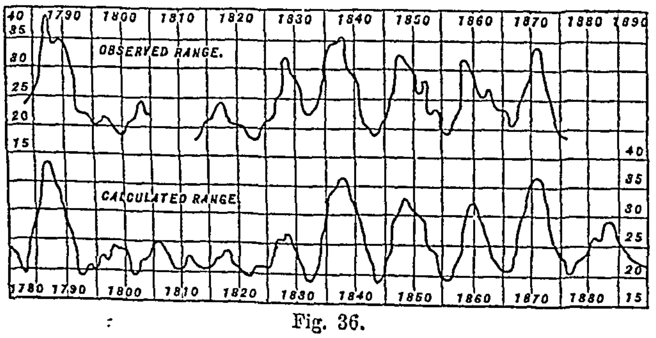

Fig. 36.

between the results of observation and calculation which appears in the diagram, it would seem that the series of observed values at present obtainable is too short to render the analysis a very accurate one. It will certainly not bear carrying back forty or fifty years beyond its starting point, which was in 1784, and it would be very hazardous to carry it forward any considerable length into the future. It will be seen that calculation indicates a maximum of declination range about 1884, but not so pronounced a maximum as that of 1871. Here then we have a prevision which observation will either fulfil or contradict, giving us a practical test of the value of this analysis.

51. The remarks now made would seem at first sight to imply that we are not yet furnished with sufficient yearly records either of declination ranges or of accurate sun-spot observations to enable us to analyse the long-period solar inequality with such completeness as to carry our calculations more than a very short distance into the future with any chance of success, and that we may have to wait for another hundred years' observations before we are able to do so. On reflection, however, it would seem that long-period inequalities may be caused by the superposition of those of short period, and thus that an analysis of the latter may lead to that of the former. It would relieve us if this were found to be the case; for the observations at our disposal may be sufficient to enable us completely to analyse short-period inequalities, assuming that we have in such the elements of a true periodicity.

A remark made by the authors of the above analysis would seem to indicate that a connexion of this nature between long and short periods does in all probability exist. It is a well-known fact that the so-called eleven-yearly oscillations of declination range are at certain times large and at other times small. Thus, for instance they have been large for the last forty years, but they were small about the earlier part of the present century. Now it is clear from an inspection of the observations (see fig. 36) that a series of large oscillations is accompanied with an exaltation of the base line, or line denoting average efficiency, while a series of small oscillations is accompanied with a depression of the same. The result is a long-period curve of the base line, the beat period, so to speak, of the eleven-yearly inequality.

Now a phenomenon precisely similar occurs in connexion with shorter periods. If we take inequalities having a period of three or four months, we find that such are alternately well-developed or of large range and badly-developed or of small range, and that a large range of such is accompanied with an exaltation of the base line or line of average efficiency, while a small range is accompanied with a depression of the same. The result is a curve of the base line of which the period is roughly speaking eleven years. May we not therefore imagine that the so-called eleven-yearly period, or, to speak more correctly, the ten and a half and twelve-yearly periods into which the eleven-yearly period may perhaps be analysed, may be in reality beat periods for shorter disturbances? Is it not therefore possible that a study of these shorter periods may give us information regarding the nature of the eleven-yearly period, whether for sun-spots or declination ranges, which the small series of actual observations is incompetent to afford?

52. *Declination-Range Weather.*—Allusion has already been made to magnetical weather as perhaps having laws similar in some respects to those which regulate meteorological weather. Now the diurnal ranges of magnetic declination and those of atmospheric temperature present us with elements of the two weathers that can easily be discussed. Again there is strong evidence for supposing that an element of meteorological weather, such, for instance, as temperature-range, travels as a rule from west to east, so that a peculiar style of temperature-range might be expected to appear first in America and some days afterwards in Great Britain. It becomes therefore a question for inquiry whether this travelling from west to east applies also to magnetical weather as evidenced by the diurnal declination-range. Stewart is of opinion that this law of travelling applies to both, but that magnetical weather travels faster than meteorological (see *Proc. Roy. Soc.*, January 10, October 23, 1879, and June 9, 1881). From the preliminary discussion made by him it would appear that Kew lags behind Toronto as regards phase of magnetical weather by 1·6 days, that Prague lags behind Kew 0·7 days, and that Trevandrum lags behind Kew by 9·7 days. This conclusion cannot, however, be regarded as established until it is confirmed by a more complete discussion of observations.

53. *Disturbance-Diurnal Variation of Declination.*—Magnetic storms (§ 38) were so named by Baron Humboldt, one of the first observers of such phenomena. From observations at Paris, Berlin, and Freiburg he found that very frequently, though not universally, these three stations were simultaneously affected by such storms. The observation of magnetic disturbances was afterwards pursued in a systematic manner by Gauss and Weber of Göttingen. Term days were instituted for this purpose by these observers,—that is to say, periods each of twenty-four hours length during which observations were simultaneously made at intervals of five minutes at Göttingen and about twenty other stations distributed generally over the continent of Europe. Finally, the establishment by the British Government of the colonial magnetic observatories, and the energy and sagacity of their director, Sir E. Sabine, have very greatly increased our knowledge of these remarkable phenomena.

Sabine has not merely separated the disturbed from the undisturbed observations as explained in § 38, but he has divided the former into two categories—(1) those tending to increase westerly

[1] *Proc. Lit. and Phil. Society of Manchester*, March 8, 1881.

declination and either element of force, and (2) those tending to diminish the same. He finds that these two categories obey different laws, from which he argues that there are at least two sets of disturbing forces. In fact, if we have to give up the idea of a single force of constant type, it is natural to ask if the phenomena of disturbance can be approximately represented as due to the united action of two independent types of force. It was probably some such idea that led Sabine to separate disturbances into these two categories above mentioned. Here there is no attempt to assert that these two types represent an ultimate and complete analysis of the forces concerned. We merely use the separation as the most convenient method at our disposal in the present state of our knowledge for ascertaining whether there be indications of a dual system.

54. *Results in the Northern Hemisphere.*—Sabine's method of viewing the phenomena has enabled him to obtain the disturbance-diurnal variation for the following stations:-

Kew	51° 29′ N. lat.	0° 8′ W. long.
Peking	39 54 N. „	116 6 E. „
Nertchinsk	51 19 N. „	114 9 E. „
Toronto	43 40 N. „	79 0 W. „
Port Kennedy	72 01 N. „	94 20 W. „
Point Barrow	71 21 N. „	156 15 W. „

The above stations have been so chosen that Kew may be regarded as on one side and Peking and Nertchinsk as probably on the other side of the Asiatic pole, while Toronto may be regarded as on one side and Port Kennedy and Point Barrow as on the other side of the American pole (§ 29). The question as to what influence, if any, these poles have upon the disturbance-diurnal variation of declination is thus one which may be answered by examining the results obtained at these various stations. For this purpose, instead of recording the aggregate disturbances at the various hours, the result is expressed in ratios,—the mean hourly ratio for the day being taken as unity, or in other words the whole body of disturbances for the twenty-four hours being reckoned as twenty-four. The results of this method are graphically represented in fig. 37, where in the left-hand curves Kew time is used, and in the right-hand curves local time, each starting at 0h.[1]

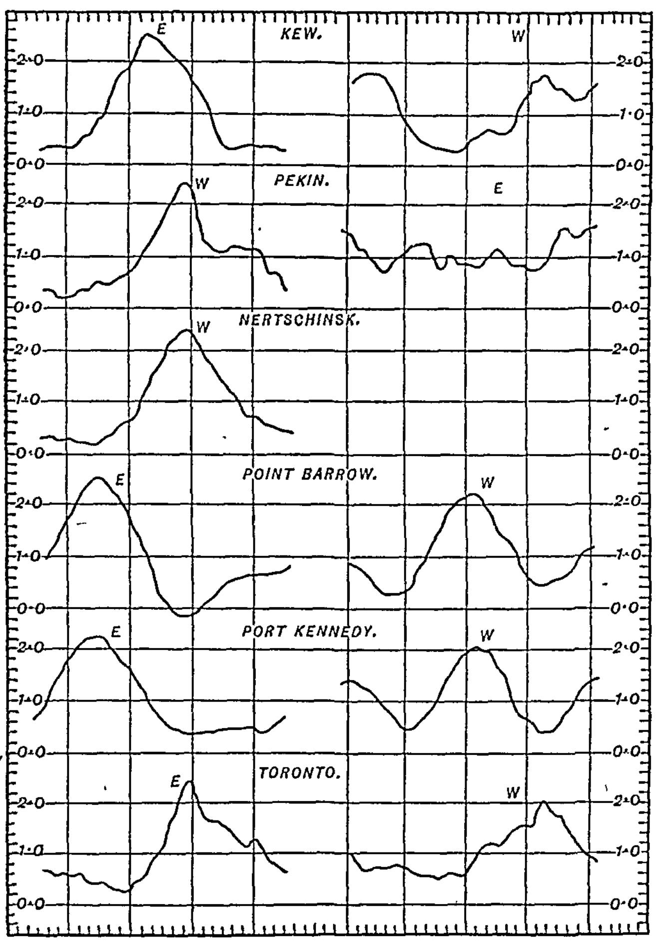

Fig. 37.

55. At all the various stations one curve exhibits unmistakably a single progression, while the other exhibits more or less distinctly a double progression. At Kew, Toronto, Port Kennedy, and Point Barrow it is the easterly disturbances which exhibit this single progression; while, on the other hand, at Peking and Nertchinsk, stations which are oppositely related to the Asiatic magnetic centre, it is the westerly disturbances which do so. It is imagined by Sabine and others that this peculiar reversal is due to the fact that Kew and its associated stations may be regarded as on one side and Peking and Nertchinsk as on the other side of the movable magnetic system.

Sabine has likewise remarked that the single-progression curves, whether denoting easterly or westerly disturbances, exhibit maxima which take place not far from the same absolute time. We have therefore plotted all the left-hand curves according to Kew time, that the eye may readily see the amount of simultaneity which their corresponding phases exhibit. It will be noticed that there is a very striking simultaneity between the maxima of Kew, Toronto, Peking, and Nertchinsk, but that the maxima for Port Kennedy and Point Barrow, while both occurring about the same time, fall at a time decidedly if not very greatly different from that of the other maxima. Indeed the time of maximum for Port Kennedy and Point Barrow is not far from the time of minimum for the other stations. Now it has been noticed by Sabine that Port Kennedy and Point Barrow may be regarded as on one side of the American magnetic centre of intensity, while Toronto and the other associated stations are on the other side. It seems therefore possible to connect this last fact with the change in the time of maximum. Sabine has likewise remarked that the aggregate amount of disturbances is much greater at Point Barrow than at any other station. Now Point Barrow is likewise that spot where auroras are most frequent. Thus in the phenomena we are now discussing there is first of all a marked reference to the Asiatic pole; secondly, a reference not so marked, perhaps, to the American pole; and thirdly, a reference to the centre of auroral activity. Sabine, whose experience of such matters is very great, appears to think most of the reference of these phenomena to the Asiatic pole. He thinks that "of the two magnetic systems which are distinctly recognizable in the magnetism of the globe one has a terrestrial and the other a cosmical source," and that it is "the latter of these two systems which, by its progressive translation, gives rise to the phenomena of secular change and to those magnetic cycles which owe their origin to the operation of the secular change," concurring with the conclusion of Walker that "the magnetic influence at any point of the globe is the result of two distinct magnetic systems, the principal of which is the magnetism proper of the globe, having its (northern) point of greatest attraction in the north of the American continent, whilst the weaker system is that which results from the magnetism induced in the earth by cosmical action, and of which the northern point of greatest attraction is at present in the north of the Asiatic continent. Thus the direction of the magnet at any point results from the superposition of these two systems, the nearest pole being always predominant over the more remote" (*Phil. Trans.*, 1868). While disposed to think that something of this nature should be accepted as a working hypothesis, we would, however, point out that the Asiatic pole cannot be regarded as accounting for all the phenomena of disturbances, but that the focus of disturbance is probably nearer the focus of auroras than it is to either of the foci of magnetic intensity.

The right-hand curves representing these disturbance-diurnal variations which have two maxima are, except for Port Kennedy and Point Barrow, decidedly irregular. Sabine remarks also that, instead of having a reference to absolute time like those with one progression, their reference is rather to local time. We have therefore plotted all these curves according to local time; nevertheless this reference does not come out with very great distinctness; but it must be remembered that our analysis of disturbances into easterly and westerly, although, in the hands of Sabine, it has given us much new information, has no claim to be regarded as final and complete.

56. *Results in the Southern Hemisphere.*—Table VIII. shows the disturbance-diurnal variation of declination exhibited for St Helena, 15° 56′·7 S. lat., 5° 40′·5 W. long.; Cape of Good Hope, 33° 56′ S. lat., 18° 28′·75 W. long.; Hobart Town, 42° 52′·5 S. lat., 147° 27′·5 E. long.

At St Helena and the Cape the easterly disturbances present the appearance of a single progression, while the same remark slightly modified applies to the easterly disturbances at Hobart Town. Again the times of easterly maxima for St Helena and the Cape are very nearly simultaneous, while Hobart Town, which we may regard as situated on the opposite side of the chief southern magnetic centre from St Helena and the Cape, has its maximum nearly coincident in absolute time with the minimum of the other two stations. It would thus seem that the chief magnetic centre of the south is similar in its action as regards these phenomena to the chief magnetic centre of the north. Again the absolute time of single maximum for the south as determined by St Helena and the Cape is about twelve hours different from the corresponding time for the north as determined by Kew, Toronto, Peking, and Nertchinsk. All this is in favour of the working hypothesis already mentioned.

[1] If we refer to a paper by C. Chambers, director of Bombay Observatory (*Phil. Trans.*, 1868), it will be seen that westerly disturbances at Bombay present the same characteristics as westerly at Peking or Nertchinsk, the maximum being about twenty-two or twenty-three hours Bombay astronomical time.

TABLE VIII.

Local Astronomical Hours.	St Helena.		Cape of Good Hope.		Hobart Town.	
	Easterly Ratios.	Westerly Ratios.	Easterly Ratios.	Westerly Ratios.	Easterly Ratios.	Westerly Ratios.
0	3·24	2·46	2·1	1·6	1·14	0·65
1	3·17	2·39	2·1	1·2	1·26	0·64

4	0·89	1·29	0·8	0·7	1·39	0·56
5	0·34	0·76	0·4	0·6	1·32	0·52
6	0·14	0·45	0·4	0·8	1·16	0·72
7	0·05	0·50	0·1	1·2	0·62	1·04
8	0·03	0·44	0·1	1·2	0·40	1·31
9	0·03	0·37	0·2	1·2	0·32	1·79
10	0·07	0·43	0·1	1·1	0·28	1·96
11	0·00	0·42	0·2	0·8	0·74	2·31
12	0·00	0·31	0·3	0·7	0·62	2·05
13	0·00	0·32	0·4	0·6	0·55	1·72
14	0·01	0·24	0·2	0·6	0·63	1·52
15	0·00	0·29	0·4	0·5	0·85	1·26
16	0·00	0·28	0·4	0·4	1·07	0·84
17	0·08	0·24	0·5	0·4	0·87	0·47
18	0·39	0·42	1·0	0·8	1·02	0·44
19	0·87	0·89	1·8	1·2	1·53	0·53
20	1·52	1·52	2·3	1·4	1·58	0·70
21	2·51	1·72	2·3	1·7	1·41	0·55
22	3·08	2·21	2·5	1·8	1·27	0·55
23	2·78	2·60	2·7	1·7	1·24	0·62

Finally, the westerly disturbances at the three southern stations bear greater marks of a double progression and of irregularity just as they did in the northern hemisphere, and moreover like their northern analogues they are regulated by local rather than by absolute time.

57. *Distribution of Declination Disturbance over the Various Months of the Year.*—Broun was probably the first to remark in reducing the Makerstoun observations that the disturbances were greatest at the equinoxes and least at the solstices. His method was to find for each month the mean diurnal inequality, and then to consider the difference of each individual observation from the monthly mean for that hour as a disturbance, the summation of all such differences for the month denoting the monthly disturbance value. The following table embodies the results at various stations—those at Toronto, Hobart Town, and the Cape being given by Sabine, and that at Bombay by C. Chambers, who has pursued Sabine's method of separating disturbances:—

TABLE IX.—*Monthly Distribution of Declination Disturbances.*

	Toronto.		Bombay.		Cape of Good Hope.		Hobart Town.	
	Easterly.	Westerly.	Easterly.	Westerly.	Easterly.	Westerly.	Easterly.	Westerly.
January	0·55	0·57	0·84	0·88	2·1	1·4	1·62	1·54
February	0·81	0·85	0·89	0·67	1·7	1·3	1·16	1·05
March	0·97	0·89	1·29	0·93	0·7	1·1	1·11	1·11
April	1·23	1·24	1·04	1·29	1·3	1·6	1·26	1·18
May	0·94	0·93	0·57	1·00	0·3	0·9	0·65	0·51
June	0·83	0·55	0·73	0·82	0·3	0·4	0·30	0·32
July	1·35	1·13	1·18	1·83	0·6	0·6	0·51	0·54
August	1·37	1·17	1·64	1·29	0·4	0·4	0·84	0·73
September	1·63	1·66	1·20	1·04	0·8	0·9	1·29	1·50
October	1·12	1·17	1·52	1·31	1·2	1·0	1·22	1·27
November	0·70	0·88	0·40	0·41	1·2	1·0	0·73	0·95
December	0·50	0·98	0·68	0·53	1·2	1·2	1·29	1·29

58. A careful inspection of this table, without attempting a more complete analysis, will, it is thought, lead to the following conclusions:—

(1) Although for any station the distribution of the easterly disturbances over the various hours of the day is generally different from that of the westerly, yet the same law of distribution over the various months of the year is followed by the easterly and by the westerly disturbances at any station—the law at one station being, however, different from that at another.

(2) In all stations there is first an annual inequality exhibiting a maximum generally a short time after the summer solstice with a corresponding minimum for the winter solstice, and secondly a semi-annual inequality exhibiting a maximum generally a little after each equinox.

(3) The equinox maximum is very conspicuous at Toronto; but the summer maximum is most conspicuous at the other stations.

59. In § 38 it was observed that the observations selected as disturbed at any station may nevertheless be a mixture of what may be termed true disturbances and of the more prominent specimens of magnetic weather. The truth of this statement would appear to be borne out by the laws now given. In one of these we find that disturbances, at all stations, have a maximum about the time of the summer solstice and a corresponding minimum about the time of the winter solstice. But the absolute time of the summer solstice for stations north of the equator corresponds with that of the winter solstice for stations south of the line. It would therefore appear that in so far as this law is concerned such disturbances lack the element of simultaneity. On the other hand, a law of this nature would naturally hold for magnetic weather. For at any station the diurnal range of declination is greatest at the summer solstice, and hence any considerable proportional variation of this would, if represented by a fixed scale, present the appearance of being greatest likewise at this time. The question thus arises whether this law does not rather apply to magnetic weather than to real disturbance.

Again the semiannual inequality of disturbance exhibits throughout the globe a maximum at the equinoxes, and thus presents the element of simultaneity which was wanting in the annual. This law may therefore refer to true disturbance, and this view is supported by the fact that the aurora—which may be regarded as the universal accompaniment of great and simultaneous disturbances—obeys, as we shall afterwards see, in those stations where it has been well observed, this very same law, that is to say, it has likewise maxima at the equinoxes.

60. *Distribution of Declination Disturbances over Various Years.*—In 1852 Sabine discovered (*Phil. Trans.*, 1852, p. 103) that disturbances have a long-period inequality allied to that of sun-spots in such a way that a maximum and a minimum of disturbance coincide with a maximum and a minimum of sun-spot frequency.

This will be seen from the following table (X.), in which we have the relative values of declination disturbance at Toronto and Hobart Town compared with the number of groups of spots observed on the sun's disk:—

	Values of Declination Disturbance.		Groups of Sun-Spots.
	Toronto.	Hobart Town.	
1843	0·55	0·48	34
1844	0·73	0·82	52
1845	0·62	0·67	114
1846	1·26	1·03	157
1847	1·40	1·44	257
1848	1·43	1·60	330

61. The following table (XI.) exhibits the same thing for Bombay. The first column of this table is derived from the magnetic results of C. Chambers, while the sun-spot areas are those of Messrs De la Rue, Stewart, and Loewy.

	Aggregate Values (in Minutes) of Declination Disturbances.	Sun-Spot Areas.
1859	1532·1	1352
1860	1421·6	1313
1861	951·8	1297
1862	1240·5	1211
1863	691·1	676

We may conclude from these tables that declination disturbances march with sun-spots, but that the alliance between these two phenomena is probably not so intimate as that between declination ranges and sun-spots.

62. *Distribution of Declination Disturbances over the Surface of the Globe.*—It is well known that disturbances are comparatively small near the equator, while they are great near the magnetic poles, and greatest of all perhaps near the position of maximum auroras. If we adopt Sabine's system of separating disturbed from undisturbed observations, it is thus clear that the same separating value cannot be adopted at all stations. At first sight this would seem to introduce an element of uncertainty in the estimation of disturbances, but it was soon found by Sabine that no very great nicety is required in this matter. Not only do the laws which regulate disturbances at a given station remain comparatively unaffected by the magnitude of the separating value, but it is likewise easy to tell whether the aggregate disturbance value at one station is decidedly greater or less than at another. Probably at present it would be impossible to obtain more definite information than this.

63. The following table (XII.) exhibits the proportion between the aggregate amount of easterly and that of westerly disturbances of the declination at various stations in both hemispheres:—

Name of Station.	Easterly.		Westerly.
Toronto	1·40	:	1
Point Barrow	1·63	:	1
Port Kennedy	1·85	:	1
Carlton Fort	1·74	:	1
Kew	1·19	:	1
Peking	1	:	1·21
Bombay	1·6	:	1
St Helena	1	:	1·30
Cape of Good Hope	1	:	1·51
Hobart Town	1	:	1·40
Falkland Isles	1·66	:	1

64. *Annual Variation of Declination.*—The declination fluctua-

tions of short period hitherto discussed are not necessarily accompanied by a permanent change of mean position of the needle. We have now to inquire whether there be any fluctuations of long period (besides the secular change discussed in §§ 30-33) tending to alter perceptibly the position of the magnetic needle. This leads us at once to the annual variation, for our knowledge of which we must look to the later-made and more accurate observations, in which all possible sources of error have been carefully eliminated. Broun has made an exhaustive experimental inquiry into the various sources of error which could possibly influence his declination needle at Trevandrum. His conclusion was that the variations of torsion of a well-made thread are not sufficient to produce a sensible effect upon the position of a powerful magnet. In fact Grubb's magnet, weighing 6000 grains, and Adie's, weighing 1100 grains, give almost identical results. We may extend these conclusions to other observatories where well-devised instruments have been established, and look with much confidence to such instruments registering correctly the secular as well as the annual change of declination that may be taking place at each locality.

65. The following table (XIII.), borrowed, with the exception of the Trevandrum and Bombay results, from E. Walker's *Terrestrial Magnetism*, shows the annual variation at seven stations:—

	Mean Declination.	Mean Annual Secular Change.	Observation Years.
	° ′	″	
Kew	21 39 W.	7 39·00 E.	1858–62
Hobart Town	9 56 E.	1 23·20 W.	1844–48
St Helena	23 27 W.	7 57·00 W.	1841–49
The Cape	29 7 W.	0 29·40 W.	1841–46
Toronto	1 35 W.	1 57·12 W.	1845–51
Trevandrum	0 35 E.	1 35·4 E.	1854–69
Bombay	0 31 E.	3 1·0 E.	1859–65

TABLE XIV.—*Showing the Mean Annual Variation for each Month of the Year at Seven Stations.*

	Kew.	Toronto.	St Helena.	Cape of Good Hope.	Hobart Town	Trevandrum.		Bombay.
						Grubb.	Adie.	
	″	″	″	″	″	″	″	″
April	+ 1·5	− 0·6	− 2·4	+64·2	−22·2	+ 1·2	+ 6·3	+11·0
May	−41·8	− 9·6	− 1·2	−10·8	−28·7	+ 3·4	+ 8·7	+16·3
June	−50·6	−17·4	−13·8	−62·4	−24·1	+ 5·6	+ 8·7	+ 9·8
July	−70·3	−42·6	+ 8·4	−58·2	−20·6	+ 1·6	+ 2·2	+ 1·7
August	−20·7	− 4·2	− 3·6	−61·8	−12·2	− 2·8	− 3·2	+ 1·6
September	+ 9·8	+47·4	−19·8	−43·2	− 4·5	− 8·7	−10·5	+ 0·4
October	+49·6	+61·0	+ 1·8	− 4·8	+13·6	− 8·0	−11·1	− 8·9
November	+34·8	+24·6	+ 7·2	+25·2	+27·6	+ 1·2	− 3·0	+ 1·2
December	+39·6	+19·8	+ 7·2	+42·6	+38·5	+ 3·3	− 1·3	−18·2
January	+ 2·6	+ 4·2	− 3·0	+29·4	+32·9	+ 7·1	+ 3·2	−10·9
February	+34·2	+ 0·6	+18·0	+43·2	+ 7·9	+ 2·3	+ 2·6	+ 3·1
March	+29·8	− 7·8	+10·2	+49·8	+16·7	− 4·9	− 1·2	− 7·0

Here + indicates that the marked pole of the needle is to the west and − that it is to the east of its mean position for the year.

66. To cancel the irregularities of this table let us take the means from April to September and from October to March, the former embracing the months around the June solstice and the latter those around the December solstice (Table XV.):—

	Means from April to September.	Means from October to March.
	″	″
Kew	−28·7	+31·8
Toronto	− 4·5	+17·1
St Helena	− 5·4	+ 6·9
Cape of Good Hope	−28·7	+30·9
Hobart Town	−18·7	+17·3
Trevandrum	+ 2·1	− 1·6
Bombay	+ 6·8	− 6·8

It will be seen from the above that the means for Trevandrum and Bombay present opposite signs to those for the other stations. The whole amount for Trevandrum is no doubt very small, and Chambers does not regard the evidence for Bombay as conclusive; but on the whole it would appear that two observatories near one another present evidence of a similar behaviour in declination, and we are therefore disposed to regard it as a reality.

67. *Semiannual Variation of Declination.*—If we look at the numbers of Table XIV., we shall see that there are traces of turning points at the equinoxes. Let us, in order to exhibit this, compare together the sums for the six months grouped around the two equinoxes with those for the six months grouped around the two solstices—that is to say, compare the sums for February, March, April, August, September, October, with those for November, December, January, May, June, July—and we thus obtain the following table (XVI.):—

	Sums around Equinoctial Months.	Sums around Solstitial Months.
Kew	+104·2	−85·7
Toronto	+ 96·4	−21·0
St Helena	+ 4·2	+ 4·8
Cape	+ 47·4	−34·2
Hobart Town	− 0·7	+25·6
Trevandrum	− 19·0	+20·3
Bombay	+ 0·2	− 0·1

68. *Solar-Diurnal Variations of the Horizontal and Vertical Components of Magnetic Force.*—Although self-recording magnetographs have been established in many observatories throughout the globe, yet, owing to the peculiar difficulties of the task, and the labour of the process of reduction, very little has been done towards determining the solar-diurnal variation of the horizontal and vertical components of the earth's magnetic force. Senhor Capello of the Lisbon Observatory has, however, made progress with his reductions, and has already published valuable information regarding the solar-diurnal fluctuation of the two force elements at his observatory.

In his attempts to eliminate the disturbances of horizontal and vertical force by the method of Sir E. Sabine, Senhor Capello has experienced considerable difficulty, more particularly with the records of the vertical force magnetograph. This instrument and the bifilar have very often been found by him to change their position of equilibrium after strong perturbations. Again there is generally, for any hour, a variation at the beginning and end of the month from the monthly normal value for that hour owing to change of temperature, and this cannot be completely corrected inasmuch as the coefficient of temperature is not exactly known. These two causes combined tend to falsify the results when the plan adopted is the method of comparison between the individual values of any hour and the normal monthly average of that hour. Senhor Capello has found it necessary to select and extract the disturbances, not directly from the hourly values, but by comparing the variation of an individual day with the average diurnal variation derived from the month.

To illustrate this method by means of an example, let us imagine that the sum of the twenty-four hourly values for a particular day is 24,000, and that the average monthly diurnal variation would indicate that a particular hour of this day should have a value 990, then, if the value for this hour should prove to be greater or less than 990 by more than a certain amount, it would be set aside as a disturbed observation. Senhor Capello rather thinks it will be desirable somewhat to modify this method, and he concludes his remarks by observing that for this and other similar questions it is most necessary that directors of establishments possessing magnetographs should agree together to employ the same method in their reductions in order that their results may be comparable with each other. With the view of adding weight to these remarks, we may quote the observation of Sir William Thomson, that our ability to analyse mathematically that influence which produces the diurnal variation will depend upon our knowing at a certain number of stations the exact nature of this diurnal variation for each of the three magnetic elements. A complete theory of this diurnal influence must therefore wait upon the concerted action of the directors of the various establishments possessing magnetographs.

69. *Change in Horizontal Force Range from Month to Month.*—Although we do not possess finally accurate determinations of the solar-diurnal variations of either element of the force, yet we are in possession of information regarding the change in the diurnal range of the horizontal force from month to month at the Greenwich Observatory. William Ellis has given us the following table (*Phil. Trans.*, 1880) representing the monthly mean diurnal range of horizontal force at that observatory expressed in ten-thousandths of the whole horizontal force. In the formation of these means, days of great magnetic disturbance were rejected, and also certain other days on which there prevailed a smaller but considerable amount of disturbance estimated according to a general standard formed in the examination of many thousands of photographs.

TABLE XVII.—*Monthly Mean Diurnal Range of Horizontal Force at Royal Observatory, Greenwich.*

Jan.	Feb.	Mar.	April.	May.	June.	July.	Aug.	Sept.	Oct.	Nov.	Dec.
13·5	14·8	20·1	27·4	26·9	27·3	27·2	25·2	23·2	19·8	14·3	11·6

Thus, like the declination range (§ 43), the horizontal force range has a maximum in summer and a minimum in winter, and exhibits a tendency towards maxima at the equinoxes.

70. *Long-Period Inequalities of Horizontal Force Range.—Lagging Behind.*[1]—Ellis has compared the diurnal range of the horizontal force as well as that of the declination at Greenwich with the period of sun-spot frequency, his comparisons extending from 1841 to 1877, and he has deduced the following conclusions:—

[1] Secchi (*Wolf's Astronomische Mittheilungen*, No. 21) seems to have been the first to indicate a relation between the state of the sun's surface and the diurnal variation in the horizontal force.

(1) The diurnal ranges of the magnetic elements of declination and horizontal force are subject to a periodical variation, the duration of which is equal to that of the known eleven-year sun-spot period.

(2) The epochs of minimum and maximum of magnetic and sun-spot effect are nearly coincident, the magnetic epochs on the whole occurring somewhat later than the corresponding sun-spot epochs. The variations of duration in different periods appear to be similar for both phenomena.

(3) The occasional more sudden outbursts of magnetic and sun-spot energy, extending sometimes over periods of several months, appear to occur nearly simultaneously, and progress collaterally.

71. *Disturbance-Diurnal Variation of Force Components.*—We may derive the following conclusions from the results obtained by Sabine for the observatories of Toronto, Kew, and St Helena. For each element there are two categories, namely, those disturbances which tend to increase and those which tend to diminish the element in question.

(1) At Toronto the disturbances increasing both elements of force well represent single progressions with maxima occurring for both about 4 or 5 hours local time. Again the disturbances decreasing both elements represent fairly well single progressions with maxima occurring for both at about 14 or 15 hours local time.

(2) At Kew the disturbances increasing both elements represent well single progressions with maxima occurring for both about 5 hours local time. On the other hand, the disturbances decreasing the horizontal force represent signs of a double progression and those decreasing the vertical force signs of a single progression, the maximum for the latter falling between the two maxima for the former, and occurring at 14 hours local time.

(3) There is not the same close correspondence between the progress of the disturbances which tend to increase both elements nor between the progress of those which tend to decrease both elements at St Helena as there is for the other stations, nor is there the same likeness between the numbers for St Helena and those of Toronto or Kew as there is between the numbers of Toronto and those of Kew.

72. The fact that the disturbance-diurnal variations of the two force elements at Kew are very like each other while neither of them is very like the corresponding declination variation (§ 54) receives confirmation from a visual inspection of the Kew curves. In the *Philosophical Transactions* for 1862 Stewart thus describes the result of an inspection of the disturbances of these curves for the years 1858, 1859, 1860 (disturbance years):—

"There are twenty-two cases in which the declination is raised or lowered along with the horizontal force, and only seven cases of an opposite description. Also there are twenty-two cases in which the declination is raised or lowered along with the vertical force, and only eleven cases of an opposite description. Finally, there are thirty-one cases in which both forces are raised or lowered together, and only two cases of an opposite description. There is therefore a decided tendency in the curves of all the elements to be raised or lowered simultaneously, but this tendency is stronger between the horizontal and vertical force curves than between either of these and the declination. It may at the same time be affirmed that with the exception of the disturbance of August to September 1859 there is no very prominent case in which the three elements do not rise or fall together."

73. *Peaks and Hollows.*—These are certain small but abrupt magnetic changes which from the fact that they generally fall within the separating value are not usually regarded as disturbances. These changes can only be brought to light where there is a continuous record of magnetic phenomena such as that derived from self-recording magnetographs. They were first studied at the Kew Observatory by Stewart (*Phil. Trans.*, 1862). We have seen that more than one type of force must be concerned in producing magnetic disturbances. This is confirmed by the appearance of the Kew records, from which it may be seen that no disturbance of any magnitude is due to the action of a single force varying merely in amount but not in direction. For if there were only one type of force the distance at any moment of a point in the curve of one of the elements from its normal position should bear throughout a disturbance an invariable proportion to the distance of a corresponding point in the curve of another of the elements from its normal; but this is by no means the case.

But even if several independent forces are at work it may be thought unlikely that at the same moment a sudden change should take place in all; there is thus a probability that sudden changes of force, as exhibited in peaks and hollows, are changes in one of the elementary forces concerned. Even if the change is not a very abrupt one, provided that we confine ourselves to such peaks and hollows as present a similar appearance for all the curves, we may suppose that we are observing changes in one only of the elementary disturbing forces; for it is unlikely that two or more independent forces, changing independently, should produce similar appearances in all of the three curves.

Assuming it as probable that similarity of appearance in the curve variations of the three elements denotes a simplicity in the disturbing force, Stewart has discussed all such peaks and hollows at Kew extending over the first two years of their production, and has obtained a result which is embodied in the following table:—

TABLE XVIII.—*Hourly Ratios and Frequency of the Kew Peaks and Hollows, the Vertical Force Disturbance being taken as Unity.*[1]

Hour.	Declination.	Hor. Force.	Number of Observations.	Hour.	Declination.	Hor. Force.	Number of Observations.
0– 1	2·14	2·06	7	12–13	1·76	2·68	3
1– 2	1·97	2·16	7	13–14	2·00	2·04	3
2– 3	1·86	1·99	11	14–15	2·10	2·14	5
3– 4	1·81	2·05	7	15–16	2·65	2·11	10
4– 5	1·38	1·73	4	16–17	3·48	2·16	15
5– 6	1·57	1·71	1	17–18	3·80	2·14	22
6– 7			0	18–19	3·94	2·18	28
7– 8	1·82	1·91	2	19–20	3·97	2·25	21
8– 9	1·60	2·20	1	20–21	3·41	2·21	23
9–10			0	21–22	3·26	2·30	16
10–11	1·33	3·16	1	22–23	2·79	2·00	10
11–12	1·30	2·32	3	23–24	2·30	2·04	13

74. It will be seen from this table that the ratio between simultaneous peaks and hollows of the two components of the force is very nearly constant, the horizontal force disturbance being about double that of the vertical force, so far as size on the curve is concerned. It will also be seen that there is a very marked diurnal range in the ratio which the declination peak or hollow bears to that of the vertical force, this ratio being greatest about 7 A.M. About this hour we have also most peaks and hollows, while in the evening and early morning hours there is so great an absence of these phenomena that the ratios are doubtful.

75. A preliminary comparison between the peaks and hollows at Lisbon and at Kew has been made by Capello and Stewart (*Proc. Roy. Soc.*, January 28, 1864) with the following conclusions.

(1) The Kew peaks and hollows are simultaneously produced at Lisbon in all the elements, but to a smaller extent than at Kew.

(2) The direction is the same at both stations for the declination and horizontal force peaks and hollows, but it is reversed in the case of the vertical force, so that a sudden small increase of vertical force at Kew corresponds to a diminution of the same at Lisbon.

It would be manifestly impossible to discuss with any advantage the nature and origin of these peculiar changes until more extensive observations of them have been made. As the peak and hollow force is probably of a simple nature, a further knowledge of its character may be of much importance to the theory of terrestrial magnetism.

It is interesting to remark that we have in peaks and hollows the same close relation between the variations of the two force elements that we find in the larger disturbances.

It is believed too that during violent disturbances a certain change of type is produced in the peak and hollow force, and more especially is this remarkable in the great disturbance in August and September 1859, where the declination would seem to march in the opposite direction from the two components of the force. We have seen that the same peculiarity characterized on this occasion the larger and more apparent magnetic changes. We shall afterwards refer to a circumstance which may perhaps throw light upon this peculiarity (§ 93), meanwhile we conclude by again remarking that during comparative magnetic calms the peak and hollow force shows signs of remaining constant in type, and that it is therefore of great importance that the directors of observatories possessing self-recording magnetographs should take united action to observe this force.

76. *Other Inequalities of the Disturbance-Diurnal Variation of the Force Components.*—Sabine has shown that disturbances of the force components present a distribution over the various months of the year very similar on the whole to that which is exhibited by disturbances of declination. He has likewise shown that disturbances of the force components present a distribution over various years similar to that exhibited by disturbances of declination. Finally, we may probably conclude that disturbances of the force components are smallest at those portions of the earth's surface where disturbances of the declination are smallest, and largest at those portions where such disturbances are largest.

77. *Annual and Semiannual Variation of Horizontal Force and Dip.*—Broun (*Trans. Roy. Soc. Edin.* for 1861) has discussed the results obtained by Sabine at his magnetical stations, and has shown that differential and absolute observations agree in telling us that the horizontal force is smallest at the equinoxes and greatest at the solstices. Whipple has recently obtained the same result from the Kew observations.

We have deduced the following table (XIX.) from the various absolute determinations that have been made at sundry places. In it the annual and semiannual variations of declination, horizontal force, and dip are exhibited, "increase" denoting a push to the west, and "decrease" a push to the east. The method of obtaining these has already been indicated in §§ 66, 67.

[1] We ought to mention that, with the exception of the one occasion already alluded to, a peak of one element always corresponds to a peak of another element, and a hollow of one element to a hollow of another.

Station.	Effect on Declination.		Effect on Horizontal Force.		Effect on Dip.	
	At Equinoxes compared to Solstices.	At June Solstice compared to December Solstice.	At Equinoxes compared to Solstices.	At June Solstice compared to December Solstice.	At Equinoxes compared to Solstices.	At June Solstice compared to December Solstice.
Makerstoun or Kew	Increase.	Decrease.	Decrease.	Inappreciable.	Increase.	Decrease.
Toronto	Increase.	Decrease.	Decrease.	Increase.	Inappreciable.	Decrease.
Cape of Good Hope	Increase.	Decrease.	Decrease.	Increase.		
Hobart Town	Decrease.	Decrease.	Decrease.	Decrease.	Decrease.	Decrease.
Trevandrum	Decrease.	Increase.				
Bombay	Undecided.	Increase.				
St Helena	Undecided.	Decrease.				

78. In discussing the results of this table we shall assume that the sun acts, and in all probability acts indirectly, upon the magnetic system of the earth. This point will afterwards be further examined. Meanwhile, assuming this indirect action of the sun, and assuming, to fix our thoughts, that it is in close alliance with the convection system of the earth's atmosphere, we can readily imagine that such solar action would act most strongly on the earth's magnetic poles at the solstices, and that in the June solstice the pole or poles in the northern hemisphere and in the December solstice those in the southern hemisphere would be most affected. Now a strong action of this kind upon either magnetic pole may well be presumed to increase the general magnetism of the earth, or at least that portion of it which is most readily affected by external action, that is to say, the induction system. Again, if the solar magnetic influence is connected with the convection currents of the earth, we can readily imagine that the influence in the northern hemisphere where there is much land should exceed that in the southern hemisphere where there is much water.

If these views be reasonable we might expect two things to follow:—(1) the earth's induction system should be stronger at the solstices than at the equinoxes, and (2) it should be more especially strong at the June solstice, when the sun acts in the northern hemisphere. We must bear in mind, however, that so vast is the earth that a stimulus applied to its particles most susceptible of magnetism may not be instantaneously propagated throughout its mass, but that time may enter as an element of the question, in which case, inasmuch as the action of the sun at the June solstice is in the northern hemisphere, a station near the south pole may not fully partake of the magnetic effects of this action.

79. An hypothesis of this nature would appear to be consistent with the results of Table XIX.

In the first place, if the earth should become stronger as a magnet in one or in both of its magnetic systems this would show itself by an increase of horizontal force at least in all such stations as those at which absolute observations are made. An influence which increases the horizontal force at these various stations is therefore naturally regarded, and was regarded by Broun, as one increasing the strength of one or both of the magnetic systems of the earth—whether of one or of both will presently appear. We may therefore assume from our observations that one or both of the earth's magnetic systems are strongest at the solstices.

In the next place we may imagine that the changes of declination and dip which the table exhibits as occurring at the solstices are the very changes which would be wrought in these elements by an increase of power in the earth. For we see very well that an increase of horizontal force at the various stations may be regarded as denoting an increase of the earth's magnetic power. We cannot, however, see with equal facility what changes would be produced in the declination and dip by an increase in power of one or both of the magnetic systems; but we may well imagine that such changes of these elements as are found to accompany an increase of horizontal force are those that denote an increase of the earth's power.

We have thus ascertained the probable nature of those changes of the three elements which denote an increase of power. Now it will be noticed from the table that the effect at the June as compared with that at the December solstice is of the opposite nature to the effect at the equinoxes as compared with the solstices,—that is to say, the earth is more powerfully affected in June than in December, the only well-established exception to this being Hobart Town in the far south. But, assuming that time is an element in the development of this preponderating influence acting in the north, it is easy to see why Hobart Town should not exhibit its full effect.

It remains to determine from the observations themselves which of the magnetic systems it is that exhibits these oscillations. Analogy would of course point to the induction system, but it is desirable to determine this from the observations themselves.

In § 54, when discussing the disturbance-diurnal variation of declination, it was found that Toronto and Kew may be regarded as on one side of the Siberian pole, while Peking, Nertchinsk, and Bombay are on the other. Now, if it be this pole that is influenced by the oscillations under discussion, we might expect that the influence on declination at Toronto and Kew should be the opposite of that at Trevandrum and Bombay. We find by the table that this is the case, and we are thus inclined to attribute these changes to the Siberian instead of the American pole. It would thus appear that the observations of Table XIX. bear out the provisional working hypothesis which we have ventured to introduce. It is quite possible that these remarks may not stand the test of more complete inquiry, but they are here introduced rather as denoting a method of looking at the subject which ought we think to be pursued than as embodying conclusions of a final nature.

80. *Effect of the State of the Sun's Surface upon the Absolute Magnetism of the Earth.*—We have now to consider whether the state of the sun's surface permanently influences the magnetism of the earth. It will at once be seen that any such action will apparently manifest itself as an oscillation in the secular change. We must, however, carefully guard ourselves against prematurely concluding that it implies a variation in the amount of true secular change. There may be two distinct things—true secular change due to one cause, and action depending on sun-spots due to another. These, from the nature of the case, are necessarily mixed up together in the yearly changes which we examine; it does not, however, follow that there is any real identity between them. We shall now give one example of the method to be pursued in the attempt to detect a solar influence of this nature. Let us turn to Table III., and take the declination yearly values at Toronto from 1856 to 1871. Subtracting the value for 1856 from that for 1871, we find that the westerly declination had increased in fifteen years 51′·6, that is to say, at the mean rate of 3′·44 per annum. Again, the average declination for the sixteen years 1856–71 is 2° 20′·8 corresponding to the epoch at the commencement of the year 1864. Taking the average value and epoch, and also the average yearly increase above given, we are able to construct the following table (XX.), in which calculated and observed values at Toronto are compared together:—

	Observed.	Calculated.	Difference.
	° ′	° ′	′
1856	1 56·30	1 55·00	+1·30
1857	2 0·50	1 58·44	+2·06
1858	2 4·50	2 1·88	+2·62
1859	2 7·40	2 5·32	+2·08
1860	2 10·60	2 8·76	+1·84
1861	2 14·40	2 12·20	+2·20
1862	2 15·70	2 15·64	+0·06
1863	2 19·10	2 19·08	+0·02
1864	2 21·90	2 22·52	−0·62
1865	2 24·80	2 25·96	−1·16
1866	2 27·60	2 29·40	−1·80
1867	2 29·80	2 32·84	−3·04
1868	2 33·20	2 36·28	−3·08
1869	2 37·10	2 39·72	−2·62
1870	2 41·90	2 43·16	−1·26
1871	2 47·90	2 46·60	+1·30

It may be gathered from this table that the years which correspond to minimum sun-spots have in the last column a greater negative or lower positive sign than those which correspond to maximum sun-spots, and hence we may conclude that at Toronto the tendency of many sun-spots is to increase the westerly declination.

81. Performing a similar operation for all those cases in which we have a sufficiently extensive series of observations to work upon, we obtain the following table:—

TABLE XXI.—*Effect of Numerous Sun-Spots on the Values of Magnetic Elements.*

Station.	Declination.	Horizontal Force	Dip.
Kew	Increase.	Inappreciable.	Increase.
Toronto	Increase.	Increase.	Increase.
Hobart Town	Increase (?).	Uncertain.	Increase.
Cape of Good Hope	Decrease.		
Trevandrum	Increase.		

82. We have good grounds for supposing that the sun is most powerful when there are numerous spots on his surface, and therefore the above table represents a state of things which we may imagine to be caused in one way or another by increased solar power. Now the most natural hypothesis is to imagine that an increase of spots acts in producing an increase of disturbances, and that for those stations at which the disturbances tend on the whole to affect the elements in a definite direction there will be left behind a permanent effect in this direction. A comparison of Table XXI. with Table XII. will, however, show that this explanation is not valid. For instance, at Toronto and Kew disturbances tend rather to diminish

than to increase the westerly declination, while the effect of numerous sun-spots is to increase it. Again, at the Cape the tendency of disturbances is to increase the westerly declination, while that of numerous sun-spots is to decrease it. At Trevandrum again (if we judge of it by Bombay) the effect of disturbances will be to increase the easterly declination, while that of sun-spots is to decrease it. Again, it is believed that at Kew and Toronto the supposed disturbance effect on the dip agrees in character with the sun-spot effect. On the whole, therefore, there is no definite relation between the two effects.

Now if we take Hobart Town, the Cape, and Trevandrum in the above table, we find from Table XIX. that these stations seem to indicate that the magnetic state of the earth is most powerful at times of maximum sun-spots. Kew and Toronto, however, so far as declination and dip are concerned, appear to go the other way. If, however, we suppose that during the several years of maximum sun-spots the American pole as well as the Siberian is affected, and that on such occasions of long continuance the former has more influence than the latter, we shall be able to reconcile our results with the hypothesis of increased solar action. We can understand too that time must be an important element in any influence communicated to the American pole, and that, although such influence might be apparent at Toronto and Kew, which are comparatively near the pole, it would not be apparent at the other stations of Table XXI. We shall recur to this subject when discussing secular change.

VARIOUS PHENOMENA CONNECTED WITH THE SUN AND WITH TERRESTRIAL MAGNETISM.

83. *Closeness in Time between Solar Changes and Magnetic Disturbances.*—Loomis (*American Journal of Science*, vol. l.) has registered the extent of sun-spots for the six days preceding and following each of the great magnetic disturbances at Greenwich, and has compared these values with that for the very day of the disturbance. In this manner he has treated all the days of great magnetic disturbance at Greenwich for a period of twenty-three years, with the exception of those cases in which very few observations of sun-spots were made. The cases of disturbance thus treated amount to one hundred and thirty-five, and the following result has been obtained:—

TABLE XXII.—*Extent of Spotted Solar Surface.*

	Days before Storm.						Storm.	Days after Storm.					
	6	5	4	3	2	1		1	2	3	4	5	6
Mean of 135 Days.	47·9	50·1	54·8	53·5	52·3	48·9	57·9	49·0	45·1	49·3	45·6	45·2	45·3

From this result Loomis draws the following conclusions:—(1) great disturbances of the earth's magnetism are accompanied by unusual disturbances of the sun's surface on the very day of the magnetic storm; (2) the great disturbance of the sun's surface which accompanies a terrestrial magnetic storm is generally heralded by a smaller disturbance three or four days previous, succeeded by a comparative calm which immediately precedes the magnetic storm.

84. There is one instance on record of a sudden solar change which was practically simultaneous with a magnetic disturbance.[1] On September 1, 1859, a little before noon, R. C. Carrington was observing by means of a telescope a large sun-spot, when, to quote his own words—

"Within the area of the great north group (the size of which had previously excited general remark) two patches of intensely bright and white light broke out. . . . I noted down the time by the chronometer, and, seeing the outburst to be very rapidly on the increase, and being somewhat flurried by the surprise, I hastily ran to call some one to witness the exhibition with me, and on returning within sixty seconds was mortified to find that it was already much changed and enfeebled. Very shortly afterwards the last trace was gone; and, although I maintained a strict watch for nearly an hour, no recurrence took place. . . . The instant of the first outburst was not fifteen seconds different from 11^h 18^m Greenwich mean time, and 11^h 23^m was taken for the time of disappearance. In this lapse of five minutes, the two patches of light traversed a space of about 35,000 miles. . . . It was impossible, on first witnessing an appearance so similar to a sudden conflagration, not to expect a considerable result in the way of alteration of the details of the group in which it occurred; and I was certainly surprised, on referring to the sketch which I had carefully and satisfactorily finished before the occurrence, at finding myself unable to recognize any change whatever as having taken place. The impression left upon me is that the phenomenon took place at an elevation considerably above the general surface of the sun, and accordingly altogether above and over the great group in which it was seen projected.

"It has been very gratifying to me to learn that Mr Hodgson chanced to be observing the sun at his house at Holloway on the same day, and to hear that he was a witness of what he also considered a very remarkable phenomenon."

At the very moment when Carrington observed this phenomenon the three magnetic elements at Kew were simultaneously disturbed. This disturbance occurred as nearly as possible at 11^h 15^m A.M., affecting all the elements simultaneously, and commencing quite abruptly. The first or most abrupt portion of the disturbance lasted only about three minutes for all the elements; but after that there was a more gradual change in the same direction before the curve turned. This more gradual continuation of the first sudden movement lasted about seven minutes for all the elements. This magnetic disturbance was, however, in reality a small one, and was followed by a very great disturbance which took place not many hours afterwards.

85. *Simultaneity of Changes of Horizontal Force at Various Parts of the Earth.*—We have already (§ 79) alluded to the superiority of the horizontal force in indicating by its changes what is taking place in the magnetic system of the earth. If this system be strengthened as a whole we shall no doubt find the horizontal force increased in value at our various stations, while if the earth's power be weakened as a whole we shall find the horizontal force diminished.

Broun has discussed this subject at great length in a memoir already mentioned, and has embodied his observations in numerical results from which the following table has been extracted:—

TABLE XXIII.—*Daily Means of Horizontal Force at Makerstoun,* (M.), *Trevandrum* (T.), *Singapore* (S.), *and Hobart Town* (H.).

1844.	M.	T.	S.	H.	1844.	M.	T.	S.	H.

,, 15	22·12	10·09	18·63	16·85	,, 31	17·06	02·27	11·81	10·27

This table shows a considerable likeness between the daily changes of the horizontal force at the four stations. For instance, we have a minimum which occurs on March 5 at Makerstoun and March 6 at the other stations; we have likewise a well-defined maximum occurring at all stations on March 14, and another occurring at Trevandrum on March 25, and at the other stations on March 26. Finally we have a well-defined minimum occurring at Trevandrum on March 31, and at the other stations a day earlier.

Broun has extended a similar treatment to daily means for every hour, and fig. 38 conveys a good idea of the amount of simultaneity which obtains in the changes of such values of horizontal force at stations far apart.

86. *Recurrence of Disturbances at Intervals of about Twenty-six Days.*—Broun[2] and likewise Hornstein[3] have observed that there is a tendency in large magnetic changes to recur at intervals of about twenty-six days. At first it was natural to suppose that we have here a magnetical indication of the true time of the sun's synodical rotation, the interval between two disturbances denoting that which elapses between two presentations to the earth of a peculiarly powerful solar meridian. It seems unlikely, however, that there is a really permanent one-sidedness of this kind in our luminary; but the result of observation seems to show that for a limited period, say two or three years, certain meridians of the sun appear to be peculiarly powerful. The cause of this we shall not here discuss, but simply treat the phenomenon as a fact derived from observation. Broun in his paper above quoted (*Phil. Trans.*, 1876) makes the following remarks:—

"We have seen that when one side of the sun is presented to the earth the magnetic force of the latter is greater than when the other side is turned towards us; we may even say that the intensity is greatest for a given solar meridian; this, however, may be simply an integral effect resulting from the actions due to all the meridians. But can we suppose when a great and sudden increase or diminution of the earth's magnetic force occurs that this is produced by some change occurring on a particular solar meridian? This does not seem at all improbable.

"In order to examine the facts, all the cases were noted during the years 1844 and 1845 in which the daily mean horizontal force diminished one-thousandth of its whole value within an interval of three days; they were found to be twenty-eight in number. If we call the solar meridian presented to us on the 1st January 1844 the zero meridian (0), and consider the time of rotation to be twenty-six days, and that there are twenty-six meridians, we find that the solar meridians presented to us when these great movements occurred may be arranged in a few groups, as in the following table" [Table XXIV., p. 177].

"An examination," continues Broun, "of this table will show that nearly half of the great changes began when the eighth meridian after the zero had passed, while five began near the twelfth after, and five near the zero itself. . . . If any doubt existed as to the possibility of these being mere accidental coincidences, it would be removed, I think, by a consideration of the marked succession occurring between July 31 (No. 18) and December 11, 1845 (No. 28). . . . If we neglect the two cases of July 31 and August 26, which commence at +6 and +5 respectively, we have five cases of successive solar rotations in which the diminutions of intensity began on the +8 day. This exact recurrence at the end of twenty-six days of a marked diminution of force proves, it seems to me, that the actions are all due to the sun, whose time of rotation must be nearly twenty-six days.

"An examination will show that the sudden diminutions of terrestrial magnetic force are in nearly every case preceded by a sudden increase."

In the above extract we have given the author's exact words, but, while thinking with him that these actions are due to the sun, it does not appear to us to follow that the time of the sun's rotation

[1] *Phil. Trans.*, November 21, 1861.

[2] *Phil. Mag.*, August 1858; *Phil. Trans.*, 1876.
[3] *Vienna Acad. S.*, June 15, 1871.

must be nearly twenty-six days. This assumes that the meridian of peculiar power is fixed on the solar surface. It does not, however, seem impossible to imagine that such a meridian may have a proper motion of its own, and indeed the planetary hypothesis of the origin of sun-spots would rather lead to this conclusion. But if this be the case we shall be unable to deduce from recurrent magnetic disturbances the true value of the period of solar rotation.

87. *Repetitions of Magnetic Changes.*—J. B. Capello, director of the Lisbon observatory (*Proc. Roy. Soc.*, October 1868), has remarked that at periods of disturbance there are nearly synchronous movements of the declination needle during corresponding hours for two, three, or more days. He thus describes these phenomena:—

"In some cases the repetition is only in two or three parallel movements; in others there are true periods of repetition of some hours in duration. The repeated periods are not entirely similar, their phases being so modified that in some cases their identity can only be recognized by a very minute investigation. The same periods, when repeated, have not always the same total duration; nor do they recommence at the same precise hour, but sometimes earlier and sometimes later, the differences varying from a few minutes to two or three hours. We also see that the greatest number of repetitions belong to the night hours, that is to say, those hours when the movements of the needle are easterly. In the morning hours there do not appear to be any well-marked repetitions. There are twenty-four examples now given, fifteen of which show repetition on two days, eight on three days, and only one where the curve appears repeated for four days. It appears that all the facts exhibited in these examples agree with the cosmical theory; the cause (existing in the sun or in space) appears to continue sometimes during two, three, or several days without undergoing remarkable transformations. The repetition, being sometimes earlier sometimes later, seems also to indicate that the cause possesses a proper movement; the cause persists, but only comes again into operation when the earth by its diurnal rotation is placed in a similar position or conjunction to that of the preceding days."

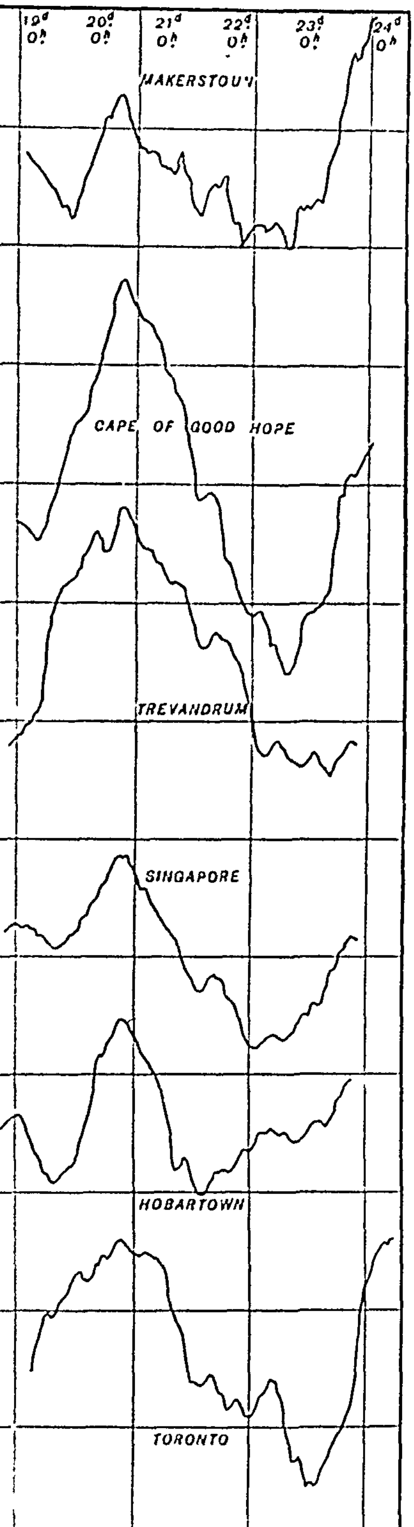

Fig. 38.

Stewart, having compared Capello's curves with the corresponding traces of the declination at Kew, found that the Lisbon disturbances are almost invariably reproduced at Kew at the same time, only to a greater extent, and also that the same amount of similarity which the various Lisbon curves exhibit is exhibited in the corresponding Kew curves. The strongest point in favour of the hypothesis is, he thinks, "not so much the repetition of a single disturbance as the repetition of a complicated disturbance in most if not all of its sinuosities." Several examples of this occur in the diagrams. It would seem that something of the above nature was suspected by Humboldt, the earliest investigator of disturbances. Humboldt was astonished to discover the frequency with which nocturnal perturbations occurred, sometimes recurring at the same hour on several successive

TABLE XXIV.—*Cases in which the Earth's Magnetic Force diminished One-thousandth of its Value or more in* 1844-45 (§ 86).

No. of Case.	Date (Jan. 1, 1844=0).	Change of Force in Hundred-thousandths.	Solar Meridians.

26	696 to 698	−110			(−6 to −4)
27	702 to 703	−291			−0 to +1
28	710 to 712	−122	+8 to +10		

nights (Walker's *Magnetism*, p. 80). We would make two suggestions before dismissing this subject.

(1) If we imagine that these changes are caused by the solar influence acting vertically on some susceptible region of the earth, then, inasmuch as they occur at the evening or early night hours, this region must lie considerably to the west.

(2) The region must also have a proper motion of its own (see Capello's remark). Is it possible that this proper motion is on the whole from west to east,—a motion which we know is pursued by meteorological weather, and in which it is imagined (§ 52) that magnetical weather as defined by us likewise participates?

88. *Comparison of Declination Changes at Stations near each other.*—Messrs Sidgreaves and Stewart (*Pro. Roy. Soc.*, October 1868) have compared together certain curves of the Kew and Stonyhurst declination magnetographs. These magnetographs are of the same pattern, and it was found that on ordinary occasions the declination traces at both stations were precisely alike. This was confirmed by placing the curves the one over the other, when they were found to coincide even in their most minute features. In times of disturbance, however, it was found that the motions exhibited by the Stonyhurst curves were greater than those at Kew, and this excess of Stonyhurst over Kew depended not so much on the absolute size of the disturbance as on its abruptness.

This feature of the comparison is exhibited in the following table (XXV.), in which the excess of Stonyhurst over Kew in scale divisions is compared with the abruptness of the disturbance, this element being measured by the changes occurring in unit of time:—

Group I.		Group II.		Group III.		Group IV.	
Excess (under 5).	Abruptness.	Excess (under 10).	Abruptness.	Excess (under 20).	Abruptness.	Excess (above 20).	Abruptness.
2	3·7	6	4·2	10	·5	21	7·3
2	6·4	6	2 6	10	0	25	2·9
-3	4 0	8	6 3	11	7	25	10·7
0	3·1	5	3·3	10	0	20	7·0
0	3·1	8	8 7	10	·8	21	6·6
4	2 9	5	3·5	15	6·4	21	11·2
1	1·8	7	6·3	11	4·9	22	9·6
4	3·3	9	4·7	13	7·4	24	7·8
3	5·2	5	4·1				
Means 1·5	3 7	6 6	4·9	11	6·5	22	7·9

It is very desirable that further comparisons of this nature should be made.

89. *Auroral Displays.*—These are very frequent if not continuous near the magnetic poles, while in middle latitudes they are the invariable accompaniments of all considerable magnetic storms. Near the equator they hardly ever occur.

There is a considerable variety in the forms assumed by these displays, and it is possible that this may denote a corresponding variety in the cause or causes which give rise to this phenomenon.

Loomis (*Smithsonian Report* for 1865) specifies five such varieties: (1) a horizontal light like the morning aurora or break of day; (2) an arch of light which frequently extends entirely across the heavens from east to west and cuts the magnetic meridian

nearly at right angles,—in the polar regions five such arches have been seen at once; (3) slender luminous beams or columns well-defined and often of a bright light; (4) the corona, the centre of which is invariably near the magnetic zenith, but not always exactly coincident with it; and (5) waves or flashes of light.

90. Auroras exhibit the same annual variation as magnetic disturbances, and are most frequent about the equinoxes—a fact first observed by Maizan. Kaemtz in his *Meteorology* gives the following table, which is applicable to European auroras.

TABLE XXVI.—*Monthly Frequency of European Auroras.*

Jan.	Feb.	Mar.	April.	May.	June.	July.	Aug.	Sept.	Oct.	Nov.	Dec.
229	307	440	312	184	65	87	217	405	497	285	225

Loomis again in the memoir already quoted gives the distribution of American auroras over the various months derived from one hundred and thirteen years' observations at New Haven and Boston, twenty-five years' observations at New York, and two years' observations in Canada. His results are represented in the following table:—

TABLE XXVII.—*Monthly Frequency of American Auroras.*

	Boston and New Haven.	New York.	Canada.	Sum.
January	81	76	16	173
February	93	86	31	210
March	110	106	24	240
April	104	125	38	267
May	86	83	22	191
June	83	79	17	179
July	123	100	21	244
August	102	122	14	238
September	143	131	19	293
October	99	110	27	236
November	115	74	26	215
December	83	60	16	159

It appears from this table that American like European auroras exhibit a maximum of frequency about the equinoxes.

91. Since auroras and magnetic disturbances go together, it is natural to imagine that we should have great auroral displays in years of maximum sun-spots. This is found to be the case, and in the following table (XXVIII.) Wolf's proportional numbers denoting sun-spot frequency are compared with the number of auroras witnessed in Europe and America as compiled by Loomis. It will be seen from this table that years of maximum auroras coincide very well with years of maximum sun-spots.

	Sun-Spot Number.	Auroral Number.		Sun-Spot Number.	Auroral Number.		Sun-Spot Number.	Auroral Number.

1792	59·9	37	1836	119·3	32	1879	7·7	
1793	47·3	23						

In fig. 39 a graphical representation is given of the likeness which subsists between the progress of auroral frequency, spot frequency, and declination ranges.

92. While the results now given leave little doubt as to the fact of a connexion of some sort subsisting between sun-spots on the one hand and magnetic disturbances and auroras on the other, yet it is desirable to obtain evidence as to the closeness of the connexion between auroras and sun-spots similar to that which was exhibited in § 82, and which showed the close connexion in point of time between sun-spots and disturbances. Loomis has with this view treated auroras in precisely the same way in which he treated disturbances, and has obtained the following table:—

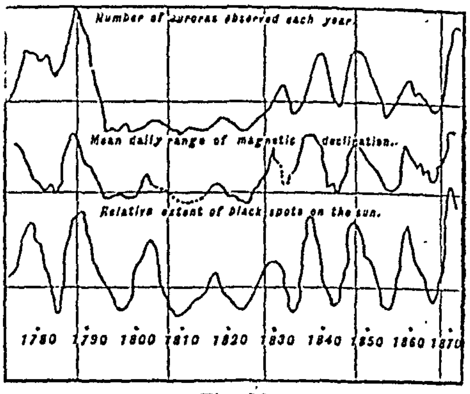

Fig. 39.

TABLE XXIX.—*Extent of Spotted Solar Surface.*

	Days before Aurora.						Aurora.	Days after Aurora.					
	6	5	4	3	2	1		1	2	3	4	5	6
Mean of 251 Days.	50·3	52·7	51·0	51·2	53·1	53·7	60·5	51·8	52·5	53·3	51·4	53·3	50·7

From which he concludes that "auroral observations in the middle latitudes of America are generally accompanied by a maximum disturbance of the sun's surface on the very day of the aurora."

93. *Earth Currents.*—These are electrical currents which take place in the moist crust of the earth, and were first detected by W. H. Barlow (*Phil. Trans.*, 1849). At a later period they were systematically observed and studied by C. V. Walker (*Phil. Trans.*, 1862). They are now continuously recorded by photography at the Royal Observatory, Greenwich. Earth currents are particularly strong during magnetic disturbances. Sir George Airy has graphically compared together certain magnetic disturbances as recorded by the Greenwich self-recording magnetographs and the simultaneous earth currents recorded by appropriate galvanometers (*Phil. Trans.*, 1868), and finds it almost impossible to avoid the conclusion that the magnetic disturbances are produced by terrestrial *galvanic currents below the magnets.* The likeness between the two systems of graphical representations is unquestionably very striking. But, while there is no doubt an intimate connexion between earth currents and magnetic disturbances, there is one circumstance which should make us pause before assigning the former as the complete and efficient cause of the latter. It is thus indicated by Lloyd:[1]—

"When we examine the curves in which Mr Barlow has represented the course of the galvanometric deflexions caused by the earth currents, we observe that the regularity of that course is continually interrupted by rapid reciprocating movements in which the needle oscillates from one side to the other of the zero alternately. These movements are similar to those of the magnetometers with which we are familiar; *but they are much more rapid*, and bear a larger proportion to the regular changes. . . . I have selected for calculation the observations made during the six hours commencing at 3 A.M. on May 29, 1848, that being a period of comparative disturbance. The sum of the changes of the galvanometer needle during that period, on the Derby and Rugby line, was *equivalent to 571 divisions of the instrument—the mean daily range* for the entire week being 11·4 divisions and the ratio=50. . . . The sum of the changes of the Greenwich declinometer during the same period was only 57 minutes, the mean daily range being 12·4 minutes. In like manner the sum of the changes of the horizontal force was ·0158 and the mean daily range ·0034. *The ratio is accordingly the same for the two magnetic elements*, and its amount is 4·6, or less than one-tenth of the corresponding ratio in the case of the galvanometrical changes. We learn therefore that the rapid changes of the earth currents are much greater in proportion to the regular daily changes than the corresponding movements of the magnetometers."

We shall return to this subject in a subsequent part of this article.

94. *Inequalities in Terrestrial Magnetism caused by the Moon.*—Kreil in 1841 was the first to point out that the moon has a small influence on the position of the declination needle, and shortly afterwards the same fact was independently discovered by John Allan Broun. The more recent observations of Sabine and of Broun, but especially those of the latter, have thrown much light upon the nature of this action. As the lunar influence is not generally large, it is necessary to free the observations from the results of other inequalities, and this has beendone by the two observers above mentioned. The results given in Table XXX. have been obtained by Sabine (see Walker's *Magnetism*).

95. Thus (1) the mean effect of the moon upon the declination needle is to cause in each lunar day a double oscillation, and Sabine has shown that the lunar influence upon the other magnetic elements is of a similar type. (2) The turning points for both hemispheres are in all cases not far removed from the lunar hours

[1] *Trans. Roy. Irish Acad.*, xxiv. 115.

TABLE XXX.—*Mean Lunar-Diurnal Variation in Declination.*

Lunar Hour.	Kew.	Toronto.	Peking.	St Helena.	Cape.	Hobart Town.

17	+ 5·1	+17·8	+5·0	−4·4	−10·3	−2·7
18	+ 8·5	+20·2	+4·8	−3·1	−10·1	−6·7
19	+ 9·8	+17·4	+3·5	−1·0	− 7·3	−9·1
20	+ 8·8	+10·2	+1·5	+1·5	− 2·7	−9·1
21	+ 7·4	+ 0·4	−0·8	+3·5	+ 2·4	−6·8
22	+ 2·4	− 9·3	−2·9	+4·4	+ 6·7	−2·8
23	− 1·6	−15·9	−4·1	+4·1	+ 9·2	+1·8

In this table + indicates that the north end of the magnet is to the east and − that it is to the west of its mean position.

0, 6, 12, 18. (3) In the northern stations we have a maximum westerly deflexion about the hours 0 and 12 and a maximum easterly deflexion about the hours 6 and 18, while in the southern stations the action is the reverse of this. (4) The oscillations would appear to be most decided at those stations, such as Toronto and Hobart Town, that are far removed from the equator.

96. *Annual Variation of Lunar Effect.*—Broun has recently studied with much success the peculiarities of the lunar influence at Trevandrum, and has obtained some very unexpected results. His first result was that the nature of the lunar influence upon the declination needle at Trevandrum depends upon the time of the year, and that the southern type of lunar action predominates at Trevandrum during the winter and the northern type during the summer months. If we take the mean of the whole year, then probably the southern type will be found to predominate.

97. *Mean Lunar-Diurnal Variation during the Day and during the Night.*—Broun has shown that the action of the moon on the declination needle at Trevandrum is greater in every month of the year during the day than during the night. The following table (XXXI.) gives the day and night ranges for the various months and their ratios:—

Range.	Jan.	Feb.	Mar.	April.	May.	June.	July.	Aug.	Sept.	Oct.	Nov.	Dec.
	′	′	′	′	′		′	′	′	′	′	′
Day	0·85	0·47	0·49	0·41	0·24	0·36	0·40	0·39	0·31	0·23	0·41	0·69
Night...	0·24	0·26	0·23	0·22	0·14	0·11	0·22	0·18	0·21	0·21	0·20	0·23
Ratio....	3·6	1·8	2·1	1·8	1·6	3·2	1·9	2·1	1·5	1·1	2·1	3·0

It would appear from Broun's observations that there is a difference of type as well as a difference of range.

98. *Lunar-Diurnal Variation with Reference to the Moon's Distance.*—Both Sabine and Broun have shown that this variation is greater for perigee than for apogee. Broun has found that the mean ratio of the apogee effect to the perigee effect is as 1 to 1·24 nearly. He remarks that "the ratio of the moon's mean distance from the earth in the half orbit about apogee is to that in the half orbit about perigee nearly as 1·07 is to 1; as the cube of 1·07 is 1·23 nearly, we see that the mean ranges of the curves for the two distances are in the approximate ratios of the inverse cubes of the moon's distance from the earth, as in the theory of the tides."

99. *Lunar-Diurnal Variation with Reference to the State of the Sun's Surface.*—Kreil in a memoir presented to the Imperial Academy of Science in 1852 considers that the observations at Prague and Milan tend to show the existence of a solar period in the lunar variations. Sabine (*Phil. Trans.*, 1856) has discussed the Toronto observations and also (*Phil. Trans.*, 1857) the Hobart Town observations with the view of deciding this important point, and has come to the conclusion that there is no systematic difference in the lunar-variation corresponding to the decennial period of the solar-diurnal variation, but merely such casual fluctuations as might be reasonably expected, considering the shortness of the periods which they represent.

We have made a preliminary discussion of Broun's Trevandrum observations with the view of throwing a little more light on this subject. For this purpose we have taken the ranges of the lunar-diurnal variations recorded by him for each month of each year. We have in the first place grouped these ranges together into threes, representing quarterly results, and have then compared together these quarterly results for years of small and for years of great sun-spot frequency,—assuming the years 1854–56 and 1863–64 to represent the former, and the years 1857–62 to represent the latter. We have thus obtained the following result:—

TABLE XXXII.—*Relation between Lunar-Diurnal-Ranges of Declination at Trevandrum and Sun-Spot Frequency.*

	Great Sun-Spot Frequency.	Small Sun-Spot Frequency.
	′	′
February, March, April..............................	0·501	0·493
May, June, July..............................	·461	·380
August, September, October..............................	·504	·419
November, December, January..............................	·641	·533

It would appear from this table that such ranges are greater at years of maximum than at years of minimum sun-spot frequency. Nevertheless the proof is not conclusive, inasmuch as associated with such lunar ranges we may have remnants of solar disturbance, the tendency of which might possibly be to increase the apparent range. Now such disturbances are more frequent at times of maximum sun-spots, and it might therefore be conjectured that this tendency would be to increase the apparent lunar range at such times above the range corresponding to years of minimum sun-spots. On the whole we are not disposed to think that the evidence already adduced is sufficient to decide this question as a matter of fact either in the one direction or in the other.

100. *Variation in the Diurnal Range of Declination depending upon the Age of the Moon.*—Capello (*Annals of Lisbon Observatory*, 1876) and Stewart (*Proc. Roy. Soc.*, 1877) have separately found that the range of declination is greatest about the times of new and full moon, a result recently confirmed by C. Chambers of Bombay. The following are the results recorded by Stewart derived from 197 lunations at the Kew Observatory:—

TABLE XXXIII.—*Variation of Diurnal Range of Declination with Moon's Age,* (0) *denoting New and* (4) *Full Moon.*

Phase of lunation........	(0)	(1)	(2)	(3)	(4)	(5)	(6)	(7)
Value of range............	519	512	499	499	507	508	499	503

101. *Earth Currents caused by Lunar Influence.*—Mr Alexander J. S. Adams (*Nature*, March 3, 1881) has made use of a telegraph wire the ends of which were connected with the earth, the one at Cardiff and the other at London. He observed the currents on this wire every quarter of an hour from March 28 to April 26, 1879. He believes that such are earth currents, and that they have a lunar-diurnal variation. There are during the lunar day, according to this observer, four electrical maxima, two positive and two negative, each maximum being divided from the next by a zero or point of no current. His results likewise exhibit a regular retardation or lagging of the earth-current variations behind the corresponding phase of the moon to the extent of nearly three hours, but these require confirmation from further observations.

THE EFFECT OF SOLAR VARIABILITY ON THE METEOROLOGY OF THE EARTH.

102. We may learn from the preceding paragraphs that the sun exercises a more powerful influence upon the magnetism of the earth at times of maximum than at times of minimum sun-spots. It remains now to find whether a similar variability obtains in the phenomena of terrestrial meteorology. For this purpose we may divide the meteorological elements into the four divisions of pressure, rainfall, wind, and temperature, inquiring in what manner these are affected by solar inequalities.

103. *Pressure.*—In 1871 Baxendell (*Memoirs of the Lit. and Phil. Society of Manchester*, 1871–72), from an analysis of eleven years of the Radcliffe observations, Oxford, came to the conclusion that in years of maximum sun-spots the maximum barometric pressure occurred under north-east winds and the minimum under south-west, while in years of minimum sun-spots the maximum and minimum pressures took place respectively under north and south-east winds. He came likewise to the conclusion that, besides this difference in distribution of the convection currents of the earth, the forces which give rise to the movements of the atmosphere appear to be more energetic in years of maximum than in years of minimum sun-spots.

104. A study of the isobaric lines would appear to be the best method of obtaining information upon this important point. It is well known that during summer the interiors of large continents have a peculiarly low and the surrounding oceans a peculiarly high atmospheric pressure; while a disposition exactly the reverse obtains during the winter months. All this is no doubt due to solar action, and we might therefore imagine that when the sun is peculiarly powerful these peculiarities of distribution will be found to be increased in prominence, while they will be diminished at times of comparatively weak solar influence.

The distribution of pressure has been studied with much success by the Indian meteorologists, including Messrs Archibald, Blanford,

Broun, Charles and Frederick Chambers, Eliot, and Hill, and the following conclusion is the result of their labours. We may assume that the Indo-Malayan region has for the mean of the year a barometric pressure probably below the general average of the earth. We might therefore imagine that during years of powerful solar influence this peculiarity would be increased. Now these observers have found that in this Indo-Malayan region the barometer is abnormally low during times of maximum sun-spots. Again, western Siberia is a district which in the winter season has a pressure decidedly above the average, and we should therefore imagine that during years of powerful solar influence this winter pressure should be peculiarly high. But this is what Blanford has found in his discussion of the Russian stations to correspond with years of maximum sun-spots.[1]

Again, Frederick Chambers has enunciated the following laws as resulting from his discussion of various meteorological records:—

(1) Variations of the sun-spot area are succeeded some months afterwards in the Indo-Malayan region by corresponding abnormal barometric variations, a high barometer corresponding to a minimum of sun-spots.[2]

(2) This lagging behind is greater for easterly than for westerly stations. In other words, this, like other meteorological phenomena, appears to travel from west to east.

We may therefore conclude that the barometric evidence as far as it goes is in favour of the hypothesis that the sun is most powerful at times of maximum sun-spots.

105. *Rainfall—Heights of Rivers and Lakes.*—In 1872 Meldrum of the Mauritius Observatory brought forward evidence showing that the rainfalls at Mauritius, Adelaide, and Brisbane were on the whole greater in years of maximum than in years of minimum sun-spots. Shortly afterwards it was shown by Lockyer (*Nature*, December 12, 1872) that the same law was observable in the rainfalls at the Cape of Good Hope and Madras.

Meldrum has since found that the law holds for a great number of stations, including eighteen out of twenty-two European observatories, with an average of thirty years' observations for each. The results are exhibited in the following table (XXXIV.):—

Name of Observatory.	Number of Years of Observation.	Excess (+) or defect (−) in maximum Sun-Spot years.
		Inches.
1. St Petersburg	41	+15·18
2. Christiania	31	+19·65
3. Edinburgh	31	+65·85
4. Königsberg	19	−22·79
5. Berlin	11	+10·85
6. Utrecht	11	+ 0·44
7. Munster	13	+22·72
8. Greenwich	22	−11·73
9. Breslau	33	+49·90
10. Bonn	11	+ 8·90
11. Brussels	41	−13·84
12. Prague	29	+23·37
13. Paris	64	−28·76
14. Vienna	11	+ 9·24
15. Kremsmünster	41	−18·55
16. Nicolaieff	11	− 6·44
17. Geneva	41	− 6·15
18. Milan	29	−11·81
19. Rome	18	+15·30
20. Lisbon	11	+ 3·65
21. Palermo	41	+ 4·35
22. Athens	11	+10·86

It would, however, appear from the observations of Governor Rawson that the rainfall in Barbados forms an exception to this rule, being greatest about the times of minimum sun-spots.

106. Gustav Wex in 1873[3] showed that the recorded depth of water in the rivers Elbe, Rhine, Oder, Danube, and Vistula for the six sun-spot periods from 1800 to 1867 was greater at times of maximum than at times of minimum sun-spot frequency. These conclusions have since been confirmed by Professor Fritz.[4]

Quite recently Stewart (*Proc. Lit. and Phil. Soc. of Manchester*, 1882) has treated the evidence given by Fritz as regards the Elbe and Seine in the following manner. He divides each sun period, without regard to its exact length, into twelve portions, and puts together the recorded river heights corresponding in time to similar portions of consecutive sun periods. He finds by this means residual differences from the average representing the same law whether we take the whole or either half of all the recorded observations, and whether we take the Elbe or the Seine. The law is that there is a maximum of river height about the time of maximum sun-spots and another subsidiary maximum about the time of minimum sun-spots. There is some reason too to think that the Nile and Thames agree with those rivers in exhibiting a maximum about the time of maximum sun-spots and a subsidiary maximum about the time of minimum sun-spots, only their subsidiary maximum is greater than it is for the Elbe and Seine.

107. In 1874 G. M. Dawson came to the conclusion that the levels of the great American lakes were highest about times of maximum sun-spots. In this investigation the value of the evidence derived from rivers and lakes is no doubt greater than that derived from any single rainfall station, inasmuch as in the former case the rainfall of a large district is integrated and irregularities due to local influence thus greatly avoided.

108. Dr Hunter, director-general of statistics in India, has recently shown (*Nineteenth Century*, November 1877) that the recorded famines have been most frequent at Madras about the years of minimum sun-spots—years likewise associated with a diminished rainfall.

109. *Winds and Storms.*—Meldrum of the Mauritius Observatory found in 1872, as the result of about thirty years' observations, that there are more cyclones in the Indian Ocean during years of maximum than during years of minimum sun-spots.[5] The connexion between the two is exhibited in the following table:—

TABLE XXXV.—*Comparison of the Yearly Number of Cyclones occurring in the Indian Ocean with the Yearly Number of Spots on the Sun.*

Character as regards Sun-Spots.		Number of Hurricanes.	Number of Storms.	Number of Whole Gales.	Number of Strong Gales.	Total Number of Cyclones.	Number of Cyclones in Max. and Min. Periods.
	1847	5	0	0	0	5	
Max.	1848	6	2	0	0	8	23
	1849	3	2	3	2	10	
	1850	4	3	1	0	8	
	1851	4	2	1	0	7	
	1852	5	0	3	0	8	
	1853	1	1	2	1	5	
	1854	3	1	0	0	4	
Min.	1855	3	2	0	0	5	13
	1856	1	0	2	1	4	
	1857	2	1	1	0	4	
	1858	3	1	3	2	9	
	1859	3	2	6	4	15	
Max.	1860	7	4	2	0	13	39
	1861	5	2	2	2	11

	1867	0	4	2	0	6	
	1868	3	2	2	0	7	
	1869	3	1	3	2	9	
Max.	1870	2	1	5	3	11	31
	1871	3	2	3	3	11	
	1872	6	5	1	1	13	
	1873*	4	5	3	0	12	

* Up to May 31.

In 1873 M. Poëy[6] found a similar connexion between the hurricanes of the West Indies and the years of maximum sun-spots. He enumerated three hundred and fifty-seven hurricanes between 1750 and 1873, and stated that out of twelve maxima ten agreed.

110. In 1877 Mr Henry Jeula, of Lloyd's, and Dr Hunter found that the casualties on the registered vessels of the United Kingdom were $17\frac{1}{2}$ per cent. greater during the two years about maximum than during the two years about minimum in the solar cycle.

111. *Temperature.*—Baxendell, in a memoir already quoted, was the first to conclude that the distribution of temperature under different winds, like that of barometric pressure, is sensibly influenced by the changes which take place in solar activity. In 1870 Piazzi Smyth published the results of an important series of observations made from 1837 to 1869 with thermometers sunk in the rock at the Royal Observatory, Edinburgh. He concluded from these that a heat wave occurs about every eleven years, its maximum being not far from the minimum of the sun-spot cycle. Sir G. B. Airy has obtained similar results from the Greenwich observations. In 1871 E. J. Stone examined the temperature observations recorded during thirty years at the Cape of Good Hope, and came to the conclusion that the same cause which leads to an excess of mean annual temperature at the Cape leads equally to a dissipation of sun-spots. Dr W. Köppen in 1873 discussed at great length the connexion between sun-spots and terrestrial temperature, and found that in the tropics the maximum temperature occurs fully a year before the minimum of sun-spots, while in the zones beyond the tropics it occurs two years after the minimum. The regularity and magnitude of the temperature wave are most strongly marked in the tropics.

112. The evidence now given appears at first sight to be antagonistic to that derived from the other elements both of magnetism and meteorology, and to lead us to conclude that the sun heats us most when there are fewest spots on its surface. This conclusion will not, however, be strengthened if we examine the subject with greater minuteness.

[6] A. Poëy, *Sur les Rapports entre les Taches Solaires et les Ouragans des Antilles de l'Atlantique-Nord, et de l'Océan Indien Sud.*

Scientifically we may regard the earth as an engine, of which the sun is the furnace, the equatorial regions the boiler, and the polar regions the condenser. Now this engine may be supposed to work in the following manner. Hot air and vapour are carried along the upper regions of the atmosphere from the equator to the poles by means of the anti-trade winds, while in return the cold polar air is carried along the surface of the earth from the poles to the equator, forming what is known as the trade-winds. Whenever the sun's heat is most powerful both trades and anti-trades should be most powerful likewise. But we live in the trades rather than in the anti-trades—in the surface currents, and not in the upper currents of the earth's atmosphere. When, therefore, the sun is most powerful is it not possible that we might have a particularly strong and cold polar current blowing about us? The same thing would happen in the case of a furnace-fire; the stronger the fire the more powerful the hot draught up the chimney, the more powerful also the cold draught from without along the floor of the room. It might thus follow that a man standing in the furnace-room near the door might be chilled rather than heated when the furnace itself was roaring loudest. In fact temperature is a phenomenon due to many causes. Thus a low temperature may be due (1) to a deficiency in solar power, (2) to a clouded sky, (3) to cold rain, (4) to cold winds, (5) to cold water and ice, (6) to cold produced by evaporation, (7) to cold produced by radiation into space.

Blanford has recently shown that at certain Indian stations a low mean temperature occurs when there is an unusually large rainfall and a great amount of clouds, a result in accordance with the conclusions previously enunciated by Professor Piazzi Smyth. Records of maximum and minimum temperature must not therefore be too closely associated with a maximum and minimum of solar power.

113. Considerations of this nature have induced Stewart to imagine (*Nature*, June 16, 1881) that the true connexion between sun-spots and terrestrial temperature is more likely to be discovered by a study of short-period inequalities of sun-spots than by that of the eleven-year period in which there is time enough to change the hygrometric state of the atmosphere and the whole convection system of the earth. He has accordingly discussed at some length two prominent sun-spot inequalities of short period (about twenty-four days), and endeavoured to see in what way they affect terrestrial temperature. From this it appears that a rapid increase of sun-spots is followed in a day or two by an increase of the diurnal temperature range at Toronto. Now an increase of diurnal temperature range most probably denotes an increase of solar energy, and we are thus led to associate an increase of solar heat with a large development of spots. This, however, is a point which requires further investigation.

114. *General Conclusion.*—On the whole we may conclude that the meteorological motions and processes of the earth are probably most active at times of maximum sun-spots, and that they agree with magnetical phenomena in representing the sun as most powerful on such occasions, although the evidence derived from meteorology is not so conclusive as that derived from magnetism.

Hypothetical Views regarding the Connexion between the State of the Sun and Terrestrial Magnetism.

115. *Principles of Discussion.*—In the following discussion we claim only to advance a working hypothesis, with the view of suggesting further inquiries into the subject of terrestrial magnetism. It seems therefore desirable that we should limit ourselves to such probable or possible causes as are known to exist and to operate on the earth. These various agents or causes will be described, and we shall endeavour to show that converging lines of evidence point in several cases to certain of these as being most likely to produce that particular type of effect which is exhibited in terrestrial magnetism. This course will in our view most readily suggest further inquiries with the view of confirming or disproving the various points of this working hypothesis. Believing that the introduction of any unknown cause can only be justified when known causes have been found insufficient to account for the phenomena in question, we have not advocated any direct magnetic action of the sun upon the earth. We have refrained from this for two reasons,—first, because from what we now know of the sun it appears to us unlikely that it should exercise an influence of this nature upon the earth, since a body at a high temperature possessing very strong magnetic properties is unknown to us; and, secondly, we shall see further on that such an influence will not explain the best-understood magnetic changes, nor is there in our opinion any magnetic phenomenon for the explanation of which it appears absolutely necessary to resort to this hypothesis. In fine, without presuming to deny the possibility of unknown influences of this nature, it does not appear to us that the time has yet arrived when we are called upon to resort to such as necessary aids to the discovery of further truth.

116. *Nature of Solar Variations.*—It is quite certain that there is a variability in the visible appearance of the sun's disk, which exhibits sometimes a comparatively large amount of spotted area while on other occasions it is entirely free from spots. Now it has been remarked by Thomson that were the sun an incandescent solid its surface would become cool in a few minutes. The astonishing property which our luminary possesses of pouring out continuously a vast amount of radiant energy must unquestionably depend upon machinery of great power by means of which fresh hot particles are rapidly brought from the interior to the surface, while those particles which have given out their light and heat are rapidly hurried downwards to be recruited from the great storehouse of heat in the sun's centre. In fine, a gigantic system of convection currents of this nature forms the essential condition without which the sun would not be able to continue shining as it does.

The mottled appearance of the sun's disk as seen through a telescope denotes no doubt the existence of a vast system of ascending and descending currents, the hot matter rising from beneath being denoted by the brighter portions and the cold matter descending from above by the darker portions of the structure. On certain occasions and in certain regions of the sun the scale of these phenomena is greatly increased, and we have a huge up-rush of bright and a corresponding down-rush of black matter—in fine, the well-known sun-spot with its bright faculous appendages. Whenever sun-spots are very frequent we should therefore expect the convection system of the sun to be particularly powerful, and the great velocity and size of the red flames or the higher portions of the convection system observed around the sun's limb on such occasions confirm us in this supposition. And if the convection system of the sun be particularly powerful when there are most spots on its surface, it would seem to follow that the radiation from our luminary should on such occasions be particularly powerful also. The spectroscope leads us to the same conclusion. It would appear from the observations of Lockyer and others that at times of maximum sun-spots certain definite regions of the sun when examined spectroscopically present all the appearances of a very high temperature.

We are unable to confirm these conclusions by direct observations of the sun's heating power. Actinometrical determinations have not yet been made with sufficient accuracy and persistence to decide this point experimentally. We have, however, evidence of an indirect nature derived from terrestrial magnetism and meteorology all tending to make us think that the sun is most powerful during times of maximum sun-spots. We have seen that on such occasions the solar influence upon the magnetism of the earth is peculiarly powerful in more than one way, and that its influence on meteorology is then peculiarly powerful also, although we are not so certain of this latter fact as of the former.

We may therefore take it to be most probable that the sun is most powerful at times of maximum sun-spots, and proceed from this basis to propound the two following questions:—in the first place, what is the nature of the solar influence upon terrestrial magnetism? and, secondly, why is this influence so much more easily perceived than certain forms of solar influence upon meteorology?

117. *Diurnal Magnetic Variations—Hypotheses regarding them.*—The various speculators on the cause of these phenomena have ranged over the whole field of likely explanations. (1) It has been supposed that the sun acts directly as a magnet upon the magnetism of the earth. (2) It has been imagined that convection currents established by the sun's heating influence in the upper regions of the atmosphere are to be regarded as conductors moving across lines of magnetic force, and are thus the vehicle of electric currents which act upon the magnet. (3) Faraday, reasoning from his discovery that oxygen is paramagnetic, and becomes weaker in its power when heated, and stronger when cooled, supposed that the sun by heating certain portions of the atmosphere renders them less magnetic while others, not subjected to any heating influence are rendered more magnetic. The action is equivalent to a displacement by means of the sun of the magnetic matter of the earth, and involves a displacement of the lines of force. Here too the solar action is associated with the great mass of the atmosphere. (4) It has been supposed by Christie and by De la Rive that the heat of the sun produces in the atmosphere and in the earth thermo-electric currents which produce the daily magnetic variations. It is not easy to perceive how we could have thermo-electric currents in the upper regions of the atmosphere, but there is no obvious objection to the generation of such currents in the crust of the earth. Thus the first hypothesis has no reference to the atmosphere whatever; the second deals with the upper atmospheric regions, the third with the great body of the atmosphere, while the fourth, as we have ventured to modify it, has reference to the crust of the earth.

118. *Discussion of these Hypotheses.*—Dr Lloyd and Mr C. Chambers[1] have both shown that direct solar magnetic action will not account for the peculiarities of the diurnal magnetic variation. Again (§ 48) we have strong evidence that changes in the range of the daily magnetic variation lag behind corresponding solar changes in point of time. Now this kind of behaviour is inconsistent with direct magnetic action, and points rather to an indirect magnetic effect caused by the radiant energy of the sun.

[1] *Proc. Royal Irish Academy*, February 22, 1858; *Phil. Trans.*, 1863.

119. Let us therefore dismiss the hypothesis of direct action and consider that of Faraday. We know both from observations of the declination and horizontal force (*Proc. Roy. Soc.*, March 22, 1877, and *Phil. Trans.*, 1880, p. 541) that the action of the sun in producing diurnal variations of these elements is one and a half times as powerful at epochs of maximum as it is at epochs of minimum sun-spot frequency. It is hardly credible that there should be such a great difference on these occasions in the sun's heating effect upon the great bulk of the atmosphere. Meteorologists have never observed such a difference, nor is there any marked corresponding inequality of diurnal temperature range. Meteorological evidence is thus against the diurnal magnetic changes being due to the heating up by the sun of the great mass of oxygen which constitutes the magnetic portion of the earth's atmosphere. Again, as there is a preponderance of hot oxygen in the northern hemisphere during the June and in the southern hemisphere during the December solstice, there ought according to this theory to be a well-marked annual variation of the magnetism of the earth, the northern hemisphere being at the same time differently affected from the southern. But there are no traces of such a phenomenon, the annual and semi-annual variations which we have already described (§§ 64–67) being of quite a different nature, and none of them very large.

120. Precisely the same objections apply with even greater force to the fourth hypothesis. It seems impossible to allow that any heating effect of the crust of the earth caused by the sun can be one and a half times as great at epochs of maximum as it is at epochs of minimum sun-spot frequency.

121. We are thus driven by the method of exhaustions to look to the upper regions of the earth's atmosphere as the most probable seat of the solar influence in producing diurnal magnetic changes, and it need hardly be said that the only conceivable magnetic cause capable of operating in such regions must be an electric current. Now we know from our study of the aurora that there are such currents in these regions—continuous near the pole and occasional in lower latitudes. A good deal has been said about the difficulty of imagining a daily set of currents to be generated in regions of such imperfect conductivity, but we shall see by and by (§ 134) that there seems ground for imagining that their conductivity may be much greater than has hitherto been supposed.

122. *Analogies between the Meteorological and Magnetical Systems of the Earth.*—We have in the first place a zone of maximum terrestrial temperature, the middle line of which is nearly coincident not only with the geographical but likewise with the magnetical equator. Again, there are possibly in the northern hemisphere two poles of greatest cold, which possibly do not greatly differ in position from those spots which we have called magnetic poles or foci. About the southern hemisphere we have no information.

Furthermore we believe that the hot air is carried from the zone of greatest heat to the place or places of greatest cold by means, no doubt, of the return trades which blow in the upper atmospheric regions. The hot air divides at this zone, one part blowing northwards in the northern and another southwards in the southern hemisphere. Now this zone, from which the anti-trades divide, has an annual motion of its own, being found farthest north at the June solstice and farthest south at that of December. Probably too the northern system is strongest in June and the southern system in December. If we now turn to the solar-diurnal variation of magnetic declination, we find here also a northern and a southern system (§ 41), the type of the one being antagonistic to that of the other. We find also that the northern system is strongest in June and the southern system in December.

Again, it seems probable from what we have now said that the anti-trades, strictly speaking, have reference not to the geographical equator and poles but to the zone of maximum and the poles of minimum temperature. Now, turning once more to the diurnal oscillations of the declination needle, it seems probable that the directions east and west must be interpreted as having a reference not to the geographical but to the magnetical pole (§ 45).

These analogies must be taken for what they are worth. Our object in introducing them has reference to the previous discussion, from which we concluded that the magnetic influence of the sun is probably due to currents in the upper region of the atmosphere—the cause of which we were content to leave in abeyance. Now these analogies would lead us to suggest that this cause, whatever it is, may perhaps be found to be related to the convection system of the earth on the one hand and to the magnetic system on the other.

123. *Analogies between Meteorological and Magnetical Weather.*—These remarks are borne out by the further analogy which appears to subsist betwixt what we have termed meteorological and magnetical weather. Let us take the solar-diurnal variation of declination. Not only is this variation similar in form to the diurnal variation of atmospheric temperature (§ 37), but the ranges of the two have a similar annual variation. And, as the element of meteorological weather affects the orderly march of the temperature range, just so the element of magnetical weather affects the orderly march of the declination range.

Furthermore, just as temperature-range weather progresses from west to east (§ 52), so declination-range weather would seem to progress in the same direction as the other (§ 52) although at a greater rate. It will doubtless require a more extended investigation to make us quite sure of this latter point; nevertheless we do not perceive the validity of the objection that is sometimes made to the hypothesis of progress in magnetic weather on the ground that magnetic influences are known to affect all portions of the globe simultaneously. It will, we think, be perceived that in the above statement no supposition whatever is made with respect to the rate of propagation of a magnetic influence through the earth; this may be instantaneous or it may not. It is supposed that we have here a travelling cause of excitement, say a travelling cause of currents in the upper regions of the atmosphere which progresses from west to east and always produces its most marked effect above those regions where it passes—just as the sun itself in passing from east to west produces a magnetic effect the various phases of which travel from east to west with the sun which causes them. We think too that this hypothesis of travelling causes of magnetic change is strengthened by the facts observed by Capello and described in § 97.

124. If, however, the objection made to this hypothesis refers to the fact disclosed by Broun (§ 85) that changes of horizontal force appear to take place simultaneously at distant parts of the earth's surface, then we think that analogy should lead us not to deny the possibility of a travelling magnetic excitement, but rather to suggest the possibility of there being some meteorological influence which, like the magnetical one above mentioned, may be found to take place simultaneously at different parts of the earth's surface. Now Broun (*Proc. Roy. Soc.*, May 11, 1876) has given us preliminary evidence for supposing that there are simultaneous barometric variations. For instance, there was a barometric maximum at Hobart Town, Peking, the Cape, St Helena, Makerstoun, Singapore, Madras, Simla, Ekaterinburg, and Bogoslovsk about the end of March or first day of April 1845. There appears to have been a simultaneous increase of the horizontal force of the earth at various stations much about the same time, and there also appears to have been a short-period maximum of spots on the solar surface. Broun has likewise registered simultaneous barometric variations at Singapore, Madras, and Simla, for the first three months of 1845. From these it would seem that simultaneous barometric maxima are possibly coincident with rapidly increasing sun-spot areas.

Again is it not absolutely certain that if there is a sudden increase of solar power this must mean an increase of heat communicated to the earth, although it may be difficult or even impossible to obtain experimental evidence of such a fact? All these are subjects which require further investigation.

125. *Further Remarks on the Solar-Diurnal Variation of Declination.*—In § 24 we have asked how far the action of the solar-diurnal force upon a freely-suspended magnet is due to currents acting directly upon the magnet and how far to a change produced in the magnetism of the earth. Some light appears to be thrown on this point by the behaviour of the needle at places near the magnetic pole where the dipping needle is nearly vertical. On opposite sides of this locality the declination needle points in opposite directions. Now suppose that we have a set of such needles placed all round this region. It seems a legitimate generalization from the observations described by Sabine (§ 45) to conclude that if we place ourselves above the centre of any of these needles at 8 A.M., and look towards its marked pole, we shall find it in every case deflected towards the right, while if we look towards the same pole at 2 P.M. we shall find it deflected to the left. Now if we imagine that at 8 A.M. there are above these magnets (in the upper atmospheric regions) electrical currents of which the horizontal components form a set of positive currents flowing from the pole on all sides, then by the known laws of such currents the marked pole of all these needles will be deflected towards the right. And if at 2 P.M. the resolved portions of such currents should be flowing towards the pole, then the marked poles of all these needles will be deflected towards the left. It thus appears that this peculiar magnetic behaviour might easily be explained by a hypothetical distribution of currents. And in fact in such regions we have indubitable evidence of the existence of currents in the upper regions of the atmosphere. On the other hand this behaviour could not easily be explained by the hypothesis of some definite temporary magnetic system set up by the solar influence in the earth, for in such a case we should imagine that similar poles of all the needles ought to be deflected towards the pole of this temporary system, which is not the case.

126. Another point for consideration is the possible complexity of the solar-diurnal variation. For we may imagine (1) that the sun acts in such a manner as to produce a diurnal variation; (2) it may also act like the moon (§ 94) and produce a semidiurnal variation; (3) these possible actions may be accompanied by induced currents in the upper regions of the atmosphere and in the crust of the earth; (4) it is possible that the sun's rays may affect these variations or some of them in the way in which Broun found that the lunar variation at Trevandrum was affected by the sun. It

was found by him that the lunar action was considerably increased when the sun was above the horizon of the place.

127. We have pointed out (§ 119) that, while there is a marked likeness in many respects between the diurnal variation of declination and that of atmospheric temperature, we have yet no long-period fluctuation of the diurnal range of temperature at all comparable in magnitude to the magnetic fluctuations. It does not, however, seem difficult to account for this difference if we imagine that the magnetic fluctuations take their origin in the upper atmospheric regions, while the temperature fluctuations are due to the lower regions of the earth's atmosphere. For, as the sun increases in power from times of minimum to times of maximum sun-spot frequency, we may imagine that a continuously increasing amount of aqueous vapour will be taken into the earth's atmosphere.

Now the experiments of Tyndall and others induce us to think that the air would under such circumstances become more and more opaque for certain rays of the sun, and thus a continuously decreasing proportion of the sun's heat would be able to penetrate into the lower atmospheric regions. This latter influence would therefore operate to cloak, perhaps to a considerable extent, the effect of the sun's increasing power; and this may very well be the reason why the temperature range at the earth's surface does not exhibit the same eleven-yearly inequality as the declination range.

128. There seems, however, reason to believe that if we go from long to short period inequalities there is a much greater similarity in the range of the magnetical and the meteorological changes (§ 113). The explanation seems to be that in the short-period changes the sun has not time to alter sensibly the constitution of the atmosphere, and hence the proportional increase of effect experienced in the upper atmospheric regions is more nearly the same as that experienced near the surface of the earth.

129. *Magnetic Disturbances.*—There is strong evidence that the most important disturbances break out very nearly simultaneously at widely different parts of the earth, and that they even affect both hemispheres at the same time. Very little, however, is known about the *modus operandi* of the forces concerned in producing such disturbances. For instance, it is not known whether a disturbance permanently affects the magnetic state of the earth, *e.g.*, whether one of the magnetic elements before a disturbance begins is sensibly different in value from what it is after the disturbance has ceased to exist. On the other hand we know (1) that disturbances break out on the very day when there are rapid changes taking place on the sun's surface (§ 83); (2) that they generally begin by momentarily increasing the horizontal force, but that the type quickly changes, so that during most disturbances the horizontal force is diminished (§ 86); (3) that large disturbances take place more particularly about the equinoxes, when, we have reason to believe, the horizontal force of the earth is at a minimum (§ 77). May we not possibly conclude from these habits of action that at times of disturbance the earth is magnetically in a delicate state of equilibrium, perhaps having more magnetism than its surroundings would strictly warrant, and being therefore inclined to part with some, and that a sudden increase of solar activity, tending, as such changes probably do, at first to exalt the magnetism of the earth, nevertheless destroys its magnetic balance and gives it ultimately the opportunity of parting with some of its magnetism? This can only be regarded as a speculation, inasmuch as we do not know whether or not a disturbance produces any permanent influence upon the magnetism of the earth.

130. *Auroras and Earth Currents.*—There is no doubt that these phenomena denote electric currents in the upper regions of the atmosphere and in the moist conducting crust of the earth. The point in dispute is with respect to the origin of such currents. Some are inclined to regard auroras as peculiar manifestations of atmospherical electricity in high latitudes, while others imagine that such displays are rather of the nature of induced currents generated by small but abrupt changes taking place in the magnetism of the earth. The advocates of the first view do not deny that currents taking place somehow in the upper atmospheric regions will have their conditions modified, to some extent at least, by the inducing influence of magnetic changes. Nor will the advocates of the induction hypothesis be disposed to deny the possibility or even the certainty that displays due to atmospherical electricity and not dissimilar to some kind of aurora take place in some region of the atmosphere. But the first party regard auroras rather as the cause than as the effect of magnetic changes, whereas the advocates of induction regard such displays rather as the effect than as the cause of changes somehow produced in the magnetism of the earth. And here it is desirable to remark that the advocates of the induction hypothesis take for granted the magnetism of the earth and the changes thereof as phenomena for which they do not profess to account, whereas unless we go to some absolutely unknown cause (and this is against our present programme) we must look to atmospherical electricity as likely to throw light upon the origin of terrestrial magnetism. We cannot therefore dispense with regarding atmospherical electricity as an agent which may have played an important part in the development of the present magnetical condition of the earth, but we are yet of opinion that, under the present state of things, the theory which holds by atmospheric electricity must largely be supplemented by the induction hypothesis if it is to explain the peculiarities in type or form of the phenomena which observation brings before us.

131. Professor Tait in his essay on thunderstorms attributes one kind of aurora to atmospherical electricity. Such an aurora is, he believes, the manifestation of almost continuous discharges, like those given by a Holtz machine in a vacuum tube. The cause is condensation of vapour going on very slowly in very large spaces of air. The electricity is due to previous contact of particles of air and vapour. The result is that the air-particles in the mixture in time acquire a definite difference of potential from those of vapour,—so that, when the latter aggregate, a misty region well charged is the result, and this discharges to the oppositely electrified air all round.

132. Again, Professor Stokes, without attempting to account for the origin of atmospherical electricity, has produced an hypothesis with the view of explaining the intimate connexion subsisting between auroral displays, earth currents, and magnetic changes on the one hand and outbursts of sun-spot activity on the other. His idea is that two somewhat distant atmospheric regions A and B are charged, let us say, with positive and negative electricity respectively; A induces in the ground below it a charge of negative, B a charge of positive electricity. At first things are held in this state: A cannot discharge either through the upper atmospheric regions to B or through the lower regions to the ground beneath it, while B is in a position precisely similar. Presently, however, an increase of the radiative power of the sun is produced. Such an increase would probably imply not merely an increase in general radiation but a particular increase in such actinic rays as are absorbed in the upper regions of the earth's atmosphere. The layer of atmosphere between A and B will therefore greedily absorb such rays, its temperature will rise, and, as is known to be the case for gases, the electrical conductivity of the stratum will be increased. A discharge will therefore ultimately take place in the upper regions between A and B; this will relieve the charges of negative and positive in the ground immediately beneath A and B, and these charges will therefore rush together through the ground, producing an earth current. This earth current will be in the opposite direction from the atmospheric current, and the two will combine to represent, virtually at least, if not absolutely, a closed circuit. This will of course affect the earth's magnetism and produce a disturbance.

133. This hypothesis certainly affords a good explanation of the promptness with which disturbances follow increased solar activity (§ 83). Unless we are to resort to some unknown cause it is difficult to think of any other possible explanation of this fact. Such an explanation appears too to receive corroboration from the fact (§ 97) that the lunar influence on the earth's magnetism as observed at Trevandrum is greater during the day than during the night,—greater possibly too at times of maximum than at times of minimum sun-spots. We are therefore disposed to accept this explanation of the way in which increased solar activity produces magnetic disturbance as the best that has been brought forward.

134. This does not, however, decide the disputed point how far these elevated currents are due to atmospherical electricity and how far to induction. The argument against the possibility of induced currents in these regions is derived from experiments with vacuum tubes, such as those recorded by Messrs De la Rue and Müller, which would seem to indicate that enormous differences of potential would be required to produce electrical currents in elevated regions, where the atmosphere is very rare.

Indeed, on account of these experiments, the measurements of the old observers, who sometimes assigned a height of more than 100 miles to the aurora, have been called in question, and it has been supposed against direct observation that these phenomena must always occur in regions much less elevated. It would appear too that such reasons were influential in determining Professor Stokes to regard the aurora as produced by atmospherical electricity which, as we know from ordinary lightning, presents us with enormous differences of potential; but it is to be remarked that he has carefully guarded himself against the possibility of laboratory experiments with vacuum tubes not being strictly analogous to that which takes place in the upper atmospheric regions. Now it would appear that recent experiments by Hittorf throw some doubt upon the strictness of this analogy. The high difference of potential required to force the current through vacuum tubes is, according to this observer, due in great part if not entirely to the passage of the fluid from the terminal to the residual air of the tube, so that the potential requisite to pass a current through a tube of double length is not sensibly greater than that required for a tube of single length. The whole subject is one which demands further investigation; meanwhile we are not disposed to assert the impossibility of induction currents taking place in the upper atmospheric regions.

135. Let us now consider whether the form or type of the earth currents observed during disturbances favours the presence of induction to any sensible extent. The remarks of Dr Lloyd already quoted (§ 93), which are confirmed by the Greenwich observations, seem to be decisive in this respect. These may be interpreted in

the following manner. In a magnetic disturbance we have frequently a general displacement of the various elements—the horizontal force, for instance; now on the curve which represents this slow but considerable displacement a large number of comparatively small but very abrupt changes are superimposed. These latter appearances are invariably accompanied by quick and strong alternations from positive to negative of the earth currents, while the former slow motion, although it may be of large range, hardly appears to have any galvanic equivalent at all. This would appear to favour the induction hypothesis, according to which small but abrupt magnetic changes should give rise to strong earth currents alternately positive and negative without reference to the position of the magnet above or below its normal at the time.

136. Another fact bearing upon this hypothesis is that mentioned in § 88. From this it would appear that on ordinary occasions the curves recording the progress of the declination needle at Kew and Stonyhurst are as nearly as possible identical, but on occasions of disturbance the range at Stonyhurst is greater than that at Kew by an amount not apparently depending so much on the magnitude of the disturbance as on its abruptness. The introduction of the element of abruptness would appear to be in favour of the mixing up to some extent of induced currents with the phenomena in question.

137. Sir George Airy has not been able to detect any resemblance in form between the regular diurnal progress of the magnet and that of the earth currents. It seems, however, possible that the peaks and hollows alluded to in § 73 may form an important and integral part of the daily magnetic movement, and there even appears to be some evidence that the diurnal progress of the earth currents bears a nearer resemblance to that of the peaks and hollows than it does to the progress of the smoother curve which is usually held to represent the diurnal variation. But this is a question which can only be decided by more prolonged investigations.

138. To conclude, there can be no doubt that at times of great magnetic disturbance we have currents in the upper atmospheric regions and in the crust of the earth which, so far as we can see, must either be due to atmospherical electricity or to induction, or to a mixture of both. The proportions of this mixture can only be decided by further inquiry and by the multiplication of stations where atmospherical electricity and earth currents may be observed. It ought to be mentioned that the experience of the Kew observers, as far as this extends, seems unfavourable to the hypothesis of a connexion between auroras and atmospheric electricity.

139. *Lunar-Semidiurnal Variation.*—From the fact observed by Broun (§ 98) that the moon's magnetic influence is as nearly as possible inversely proportional to the cube of the moon's distance from the earth, it is impossible to refrain from associating it either directly or indirectly with something having the type of tidal action, but in what way this influence operates we cannot tell. Is it possible that the earth currents observed by A. Adams (§ 101) are induction currents generated in the conducting crust of the earth by the magnetic change caused by the moon,—inasmuch as these currents were found by him to be strongest in one direction about the lunar hours 3 and 15, when the lunar-diurnal magnetic effect is changing most rapidly in one direction (§ 95), while they were found to be strongest in an opposite direction about the lunar hours 9 and 21, when the lunar-diurnal magnetic effect is changing most rapidly in an opposite direction?

140. We might perhaps expect from the analogy of the tides that the sun should possess a semidiurnal magnetic effect similar in type to that of the moon. Now Sir George Airy in his analysis of the earth currents observed at Greenwich (*Phil. Trans.*, 1870) during days of tranquil magnetism has detected in such currents a semidiurnal inequality having maxima in one direction at solar hours 3 and 15, while it has maxima in the opposite direction at solar hours 9 and 21. The reference to solar hours in this inequality is thus precisely similar to that which the inequality observed by Adams bears to lunar hours.

141. If there are induced currents of this nature in the crust of the earth, we might naturally suppose that there will be corresponding currents in the upper regions of the earth's atmosphere, and in accordance with the suggestion made by Professor Stokes (§ 132) we might perhaps suppose that these currents will be strongest when the upper atmospheric regions are heated by the sun and thereby rendered better conductors. Is it not possible to suppose that the influence of daylight upon the lunar magnetic effect discovered by Broun (§ 97) may be due to this cause, and may it not also induce us to recognize the possibility of a maximum lunar influence (§ 99) at times of maximum sun-spots, when there is reason to believe that solar radiation is most powerful?

142. *Secular Variation.*—Sabine and Walker are agreed in regarding this variation as cosmical in its origin, and they are apparently of opinion that it is caused by some change in the condition of the sun. It seems difficult if not impossible to attribute it to anything else, since the terella of Halley cannot be now regarded as having a physical existence. Again it is more than possible—it is probable—that there are solar variations of much longer period than eleven years. On the other hand the evidence given in § 81, tending to show that an access of sun-spots produces a change in the magnetic state of the earth consistent with the hypothesis that the magnetizing power of the sun has then been augmented, requires to be confirmed by more observations; and even then it is certain that this magnetic change produced by a considerable change in spotted area is extremely small. We cannot therefore regard the very large secular magnetic change as due to a non-cumulative magnetic influence of some long-continued solar variation; nor does it seem possible to attribute the change to solar influence at all unless we regard this influence as producing results of a cumulative nature.

It is possible, however, to regard solar influence as producing a cumulative effect in one of two ways, or by a combination of both. For (1) time is necessarily an element in any influence acting upon the hard-iron system of the earth—presuming the earth to possess such a system. There are in fact indications in the results of § 82 that a system of this kind is perhaps connected with the American pole; yet, even allowing the influence of time, it seems difficult to account for the peculiarities of the secular variation by an hypothesis of this nature. But (2) any long-continued variation of solar power would no doubt act cumulatively in producing an increase or diminution of the large ice-fields round the poles of the earth. In the course of time this cumulative change in the extent and disposition of these might perceptibly alter the distribution of the convection currents of the earth—and these, according to the views herein indicated, might in their turn perceptibly alter the earth's magnetic system.

143. *Concluding Remarks.*—If we agree to look for an explanation of terrestrial magnetism and its changes to strictly terrestrial processes, we may derive some assistance in our search from such considerations connected with symmetry as enable us, for example, at once to perceive that when two perfectly similar things are rubbed together we cannot have electrical separation, because there is no reason why the one should be positively and the other negatively electrified. Suppose then that an observer stands at the equator and looks towards the north, and then turns his back upon the north and looks towards the south. In the first position let him regard the northern system of meteorological processes and motions, and in the second the southern. Now if symmetry obtained absolutely in these systems—that is to say, if the observer, whether he regarded the northern or the southern system of things, had in either case precisely similar phenomena at his right hand and at his left—then we should see no reason why the earth should be a magnet, or why one hemisphere should be the seat of magnetism of the one kind rather than of the other. If then we regard meteorological processes and motions as being in some way the cause of terrestrial magnetism, we must direct our attention to that peculiar element which causes a want of perfect symmetry such as we have described in meteorological phenomena. This element can hardly be anything else than the rotation of the earth, which is from left to right to an observer facing the north, but from right to left to an observer facing the south.

144. Now if we look upon the terrestrial meteorological system modified by the earth's rotation as having produced somehow in the past the magnetic state of the earth, it seems most natural to regard the system which formerly produced this magnetic state as being likewise that which at present maintains it in its efficiency, and which also accounts for the various magnetic changes which take place. It would seem therefore that terrestrial meteorology and terrestrial magnetism are probably cognate subjects, and that they ought to be studied together in the well-founded hope that the phenomena of the one will help us to explain those of the other.

Furthermore, if these meteorological processes—deriving their one-sided character from the earth's rotation—are to be regarded as accounting not only for the origin but for the maintenance of the earth's magnetic system, we can hardly fail to imagine that these processes must derive part of the energy which they exhibit from that of the earth's rotation. Tidal energy we know is derived from this source; but we must likewise regard part of the energy displayed in convection currents whether in the air or in the ocean as derived no doubt from the same source. And we may perhaps allow that in the phenomena of tidal action, as well as in those of convection currents of the air and ocean, there may be, not merely a transmutation of actual energy directly through friction into heat, but likewise a transmutation of it, ultimately perhaps into heat, but first through the intermediate agency of electrical currents which serve to maintain the magnetic state of the earth and to produce magnetic changes.

Now if this be the case, if there be a large and complicated system of tidal and convection currents all tending to change the rotative energy of the earth ultimately into heat, whether directly through friction or indirectly through the medium of electricity, it is surely impossible with the present state of our knowledge to calculate with the smallest pretensions to accuracy at what rate this transmutation is taking place, and hence at what rate the velocity of the earth's rotation is being slowly diminished. (B. S.)

METHODISM

I. Wesleyan Methodism.

THE history of Wesleyan Methodism embraces—(1) the Methodism of Oxford, which was strictly Anglican and rigidly rubrical, though it was also more than rubrical; (2) the evangelical Methodism of the Wesleys after their conversion (in 1738), of which the Wesleyan doctrines of conversion and sanctification were the manifesto and inspiration, while preaching and the class-meeting were the great motive and organizing forces,—a movement which before Wesley's death had developed into a form containing, at least in embryo, all the elements of a distinct church organization, although in its general designation and deliberate claims it purported to be only an unattached spiritual society; and (3) Wesleyan Methodism since the death of Wesley, which, by steps at first rapid and afterwards, though leisurely, distinct and consecutive, assumed an independent position, and has grown into complete development as a church.

1. *Oxford Methodism.*—This began in November 1729, when John Wesley, returning to Oxford from Lincolnshire, where he had been serving his father as curate, found that his brother Charles, then at Christ Church, had induced a few other students to join him in observing weekly communion. John Wesley's accession lent weight and character to the infant association. Their first bond of association, besides the weekly communion, was the common study of the Greek Testament, with which they joined regular fasting, the observance of stated hours for private devotion, the visitation of the sick, of the poor, and of prisoners, and the instruction of neglected children. They never themselves adopted any common designation, but of the variety of derisive names they received from outsiders that of "Methodists" prevailed,—a sobriquet the fitness of which, indeed, as descriptive of one unchanging and inseparable feature of Wesley's character (which he impressed also on his followers), was undeniable.

This first Oxford Methodism was very churchly. Between 1733 and 1735, however, a new phase was developed. Its adherents became increasingly patristic in their sympathies and tendencies, and Wesley came much under the influence of William Law. In regard to this period of his history, Wesley himself says that he

> "Bent the bow too far, by making antiquity a coordinate, rather than a subordinate, rule with Scripture, by admitting several doubtful writings, by extending antiquity too far, by believing more practices to have been universal in the ancient church than ever were so, by not considering that the decrees of a provincial synod could bind only that province, and the decrees of a general synod only those provinces, whose representatives met therein, that most of those decrees were adapted to particular times and occasions, and, consequently, when those occasions ceased, must cease to bind even those provinces."

It was in 1736, during his residence in Georgia, whither he had gone as a missionary of the Propagation Society, that he learnt those lessons. Notwithstanding his ascetic severity and his rubrical punctilios, the foundations of his High-Churchmanship were gradually giving way. When he returned to England he had already accepted the doctrine of "salvation by faith," although he had not as yet learned that view of the nature of faith which he was afterwards to teach for half a century. He had, however, as in the journal of his homeward voyage he tells us, learned, "in the ends of the earth," that he "who went to America to convert others was never himself converted to God." In this result his Oxford Methodism came to an end.

The original Methodism of Oxford never at any one time seems to have numbered as many as thirty adherents. There was a set called "Methodists," but there was no organization, no common bond of special doctrine or of discipline; there were habits and usages mutually agreed upon, but there was no official authority, only personal influence. The general features of the fraternity, if fraternity it may be called, seem to suggest closer analogies with the "Tractarian" school in its earlier stages than with anything else in modern history, and the personal ascendency of John Wesley may remind us in some measure of the influence exercised a century later by J. H. Newman. There was no more any germ of permanent organization in the Oxford Methodism of 1735 than in the patristic and "Tractarian" school of Oxford of 1833.[1]

2. *Methodism after Wesley's Conversion.*—John Wesley landed at Deal, on his return from Georgia, on February 1, 1738. His journals on the homeward voyage, says Miss Wedgwood,[2] "chronicle for us that deep dissatisfaction which is felt whenever an earnest nature wakes up to the incompleteness of a traditional religion; and his after life, compared with his two years in Georgia, makes it evident that he passed at this time into a new spiritual region." . . . . . "By Peter Böhler,[3] in the hands of the great God," he writes in his journal, "I was, on March 5, fully convinced of the want of that faith whereby we are saved." This "conviction" was followed on March 24 of the same year (1738) by his "conversion."

Like most good men of that age in England, Wesley, before he came under the influence of his Moravian teacher, had regarded faith as a union of intellectual belief and of voluntary self-submission—the belief of the creeds and submission to the laws of Christ and to the rules and services of the church, acted out day by day and hour by hour, in all the prescribed means and services of the church and in the general duties of life. From this conception of faith the element of the supernatural was wanting, and equally that of personal trust for salvation on the atonement of Christ. The work of Böhler was to convince Wesley that such faith as this, even though there might be more or less of divine influence unconsciously mingling with its attainment and exercise, was essentially nothing else than an intellectual and moral act or habit, a natural operation and result altogether different from the true spiritual faith of a Christian. This conviction led him a few days afterwards to stand up at the house of the Rev. Mr Hutton, College Street, Westminster, and declare that five days before he had not been a Christian. When warned not thus to despise the benefits of sacramental grace, he rejoined, "When we renounce everything but faith and get into Christ, then, and not till then, have we reason to believe that we are Christians." It is true that for several years after this he remained High-Church in

[1] One evidence of this is to be found in the early and wide divergence of the various members of the Oxford Methodist company, after their brief association at the university came to an end. We know which way the Wesleys went; we know also the separate path that their friend Whitefield made for himself. John Clayton, the Jacobite churchman, settled at Manchester, renounced the Wesleys after they began their evangelical movement, and remained an unbending High-Churchman to the end. Benjamin Ingham became a great evangelist in Yorkshire, founded societies, and, with his societies or churches, took the decisive step of leaving the Church of England and embracing the position of avowed Dissent. The saintly Gambold, a poet as well as a theologian and preacher, became a Moravian bishop. James Hervey was in after life a famous evangelical clergyman, holding "Low" and Calvinistic views. These were the chief of the Methodists of Oxford.

[2] *John Wesley and the Evangelical Reaction of the 18th Century.*

[3] A disciple of Zinzendorf, then in England on his way to America.

some of his principles and opinions, but nevertheless his ritualism was dead at its roots.

This experience also made Wesley an evangelist. He had a forgotten gospel to preach,—the gospel by which men were to be converted, as he had been, and to be made "new creatures." And this result, this new birth, was not dependent on any churchly form or ordinance, on any priestly prerogative or service, or on any sacramental grace or influence. To raise up, accordingly, by his preaching and personal influence, a body of converted men, who should themselves become witnesses of the same truth by which he had been saved, was henceforth to be Wesley's life-work. This was the inspiration under which he became a great preacher; this also made him an organizer of his living witnesses into classes and societies. In the pulpit was the preaching power; in the class-room was the private and personal influence. The vital link between the pulpit and the class meeting was the doctrine and experience of "conversion." Thus Wesleyan Methodism is derived, not from Wesley the ritualist, but from Wesley the evangelist.

Wesley's doctrines offended the clergy. His popularity as a preacher alarmed them. The churches were soon shut against him. He attended the religious meetings—on a Church of England basis—which had existed in London and elsewhere for fifty years, so far as these were still open to him, the Moravian meetings, and meetings in the rooms of private friends, but these were quite insufficient for the zeal and energy of himself and his brother, who had been "converted" a few days before himself. Accordingly, in 1739, he followed the example set by Whitefield, and preached in the open air to immense crowds. In the same year also he yielded to the urgency of his followers and to the pressure of circumstances, and, becoming possessed of an old building called "the Foundery," in Moorfields, transformed it into a meeting-house. Here large congregations came together to hear the brothers. About the same time, in Bristol and the neighbouring colliery district of Kingswood, he found himself obliged, not a little against his will, to become the owner of premises for the purpose of public preaching and religious meetings. Here was the beginning of that vast growth of preaching-houses and meeting-rooms, all of them for nearly fifty years settled on Wesley himself, which, never having in any way belonged to the Church of England, became, through Wesley, the possession of the Methodist Connexion.

The religious societies through which the Wesleys, after their conversion, exercised at first their spiritual influence were in part, as has been intimated, Moravian,—that in Fetter Lane, of which the rules were drawn up by Wesley himself in 1738 (May 1), being the chief of these,—and in part societies in connexion with the Church of England, the successors of those which sprang up in the last years of the Stuarts, as if to compensate for the decay of Puritanism within the church. In 1739, however, a strong leaven of antinomian quietism gained entrance among the Moravians of England (Böhler himself having left for America in the spring of 1738); and Wesley, after vainly contending for a time against this corruption, found it necessary formally to separate from them, and to establish a society of his own, for which a place of meeting was already provided at the Foundery. This was the first society under the direct control of Wesley, and herein was the actual and vital beginning of the Wesleyan Methodist Society, that is, of Wesleyan Methodism. Hence the Wesleyans celebrated their centenary in 1839. It was not, however, till 1743 that Wesley published the Rules of his Society. By that time not a few other local societies had been added to that at the Foundry, the three chief centres being London, Bristol, and Newcastle. Hence Wesley called his Society, when he published the "Rules" in 1743, the "United Societies." His brother's name was joined with his own at the foot of these Rules, in their second edition, dated May 1, 1743, and so remained in all later editions while Charles Wesley lived. Those Rules are still the rules of Wesleyan Methodism. Since Wesley's death they have not been altered. During his life only one change was made of any importance. In 1743 the offerings given weekly in the classes were for the poor, there being at that time no Conference and no itinerant preachers except the two brothers; after a few years the rules prescribed that the weekly contributions were to go "towards the support of the gospel." The Society is described as "a company of men having the form, and seeking the power, of godliness, united in order to pray together, to receive the word of exhortation, and to watch over one another in love, that they may help each other to work out their salvation." "The only condition previously required of those who desire admission into these societies" is "a desire to flee from the wrath to come, and to be saved from their sins." The customary contribution was a minimum of a penny a week or a shilling a quarter.

In 1739 these societies were not divided into "classes." But in 1742 this further step in organization was taken, and the change is recognized in the rules of 1743. Leaders were appointed to these classes, and became an order of spiritual helpers and subpastors, not ordained like lay elders in the Presbyterian churches, but, like them, filling up the interval between the pastors that "labour in the word and doctrine" and the members generally, and furnishing the main elements of a council which, in after years, grew up to be the disciplinary authority in every "society." In every society there was from the beginning a "steward" to take and give account of moneys received and expended. After a few years there were two distinct stewards, one being specially appointed to take care of the poor and the "poor's money," the other being, in general, the "society steward." And, finally,—though hardly, perhaps, during Wesley's lifetime,—in the larger societies there came to be two stewards of each description. The leaders and stewards together constituted "the leaders' meeting," of which, however, the complete circle of functions grew into use and into recognition only by degrees. The Rules of the Society, which are strict and searching, relate to worship, to conduct, and to the religious life, but do not once mention or refer to the Church of England, the parish church, or the parish clergy. The only authority at first was the personal authority of the two brothers, exercised either directly or by their official delegates. After years had passed away the leaders' meeting came to have an important jurisdiction and authority, but its rights and powers were neither defined nor recognized until after Wesley's death. From first to last there is no trace or colour of any Anglican character in the organization. Moravians or Dissenters might have entered the fellowship, and before long many did enter it who had either been Dissenters or, at any rate, had seldom or never entered a church. What would to-day be called the "unsectarian" character of his society was, indeed, in Wesley's view, one of its chief glories. All the time, however, this "unsectarian" society was only another "sect" in process of formation. Wesley for many years before his death had seen that, unless the rulers of the church should come to adopt in regard to his society a policy of liberal recognition, this might be the outcome of his life-work. And it would seem as if in his private confidences with himself he had come in the end at times to acquiesce in this result.

Still more decisive, however, was the third step in the

development of Wesley's "Society." The clergy not only excluded the Wesleys from their pulpits, but often repelled them and their converts from the Lord's Supper. This was first done on a large scale, and with a systematic harshness and persistency, at Bristol in 1740. Under these circumstances the brothers took thedecisive step of administering the sacrament to their societies themselves, in their own meeting-rooms, both at Bristol and at Kingswood. This practice having thus been established at Bristol, it was not likely that the original society at the Foundery would rest content without the like privilege, especially as some of the clergy in London acted in the same manner as those at Bristol. There were therefore at the Foundery also separate administrations. Here then, in 1740, were two—if we include Kingswood, three—separate local churches, formed, it is true, and both served and governed by ordained clergymen of the Church of England, but not belonging to that church or in any respect within its government. As thereafter during Wesley's life one of the brothers, or some cooperative or friendly clergyman, was almost always present in London and in Bristol for the administration of the sacraments, these communions, when once begun, were afterwards steadily maintained, the Lord's Supper being, as a rule, administered weekly. Both on Sundays and on week days full provision was made for all the spiritual wants of these "societies," apart altogether from the services of the Church of England. The only link by which the societies were connected with that church—and this was a link of sentiment, not an organic one—was that the ministers who served them were numbered among its "priests."

In 1741 Wesley entered upon his course of calling out lay preachers, who itinerated under his directions. To the societies founded and sustained with the aid of these preachers, who were entirely and absolutely under Wesley's personal control, the two brothers, in their extensive journeys, administered the sacraments as they were able. The helpers only ranked as laymen, many of them, indeed, being men of humble attainments and of unpolished ways. For the ordinary reception of the sacraments the societies in general were dependent on the parish clergy, who, however, not seldom repelled them from the Lord's table. So also for the ordinary opportunities of public worship they often had no resource but the parish church. The simple service in their preaching-room was, as Wesley himself insisted, defective, as a service of public worship, in some important particulars; besides which, the visits of the itinerants were usually, at least at first, few and far between. Wesley accordingly was urgent in his advices and injunctions that his societies generally should keep to their parish churches; but long before his death, especially as the itinerant preachers improved in quality and increased in number, there was a growing desire among the societies to have their own full Sunday services, and to have the sacraments administered by their own preachers. The development of these preachers into ministers, and of the societies into fully organized churches, was, if not the inevitable, at any rate the natural, result of the steps which Wesley took in order to carry on the work that was continually opening up before him.

In 1744 Wesley held his first Conference. The early Conferences were chiefly useful for the settlement of points of doctrine and discipline and for the examination and accrediting of fellow-labourers. They met yearly. Conferences were a necessity for Wesley, and became increasingly so as his work continued to grow upon him. It was inevitable also that the powers of the Conference, although for many years the Conference itself only existed as it were on sufferance, and only exercised any authority by the permission of its creator and head, should continually increase. The result was that in 1784 Wesley could no longer delay the legal constitution of the Conference, and that he was compelled, if he would provide for the perpetuation of his work, to take measures for vesting in trustees, for the use of "the people called Methodists," under the jurisdiction of the Conference as to the appointment of ministers and preachers, all the preaching places and trust property of the Connexion. The legal Conference was defined as consisting of one hundred itinerant preachers named by Wesley, and power was given to the "legal hundred" continually from the first to fill up the vacancies in their own number, to admit and expel preachers, and to station them from year to year, no preacher being allowed to remain more than three years in one station.

By this measure Wesley's work was consolidated into a distinct religious organization, having a legally corporate character and large property rights. And yet Wesley would not allow this great organization to be styled a "church." It was only a "society"—the "United Society"—the Society of "the people called Methodists"—the "Methodist Society." And of its members all who were not professed Dissenters were by him reckoned as belonging to the Church of England, although a large and increasing proportion of them seldom or never attended the services of that church. The explanation of this apparent inconsistency is that Wesley admitted none to be Dissenters except such as were so in the eye of the law—those who, "for conscience sake, refused to join in the services of the church or partake of the sacraments administered therein"—and that he interpreted "the Church of England" to mean, as he wrote to his brother Charles, "all the believers in England, except Papists and Dissenters, who have the word of God and the sacraments administered among them."

But Wesley was to carry his Society to a yet higher pitch of development, and one which made it still more difficult to distinguish its character from that of a distinct and separate church. In 1738 Wesley had been theoretically a High-Churchman. For some time even after he had entered upon his course of irregular and independent evangelism he continued to hold, in the abstract, High-Church views. But in 1746 he abandoned once for all his ecclesiastical High-Churchmanship, although he never became either a political or a latitudinarian Low-Churchman after the standard and manner of the 18th century. He relates in his journal under date January 20, 1746, how his views were revolutionized by reading Lord (Chancellor) King's account of the primitive church. From this time forward he consistently maintained that the "uninterrupted succession was a fable which no man ever did or could prove." One of the things taught him by Lord King's book was that the office of bishop was originally one and the same with that of presbyter; and the practical inference which Wesley drew was that he himself was a "Scriptural Episcopos," and that he had as much right as any primitive or missionary bishop to ordain ministers, as his representatives and helpers, who should administer the sacraments, instead of himself, to the societies which had placed themselves under his spiritual charge. This right, as he conceived it to be, he held in abeyance for nearly forty years, but at length he was constrained to exercise it, and, by so doing, in effect led the way towards making his Society a distinct and independent church.

In 1784, the American colonies having won their independence, it became necessary to organize a separate Methodism for America, where Methodist societies had existed for many years. Wesley gave formal ordination and letters of ordination to Dr Coke, already a presbyter of the Church of England, as superintendent (or bishop) for America, where Coke ordained Francis Asbury as presbyter and superintendent (or bishop), and Coke and Asbury together ordained the American preachers as presbyters. From that ordination dates the ecclesiastical commencement of American Episcopal Methodism—in which the bishops are only chief among the presbyters whom they superintend, superior in office but of the same order. The Episcopal Methodism of America represents today the largest aggregate of Protestant communicants and worshippers of the same ecclesiastical name to be found in any one nation in the world.

The following year (1785) Wesley ordained ministers for Scotland. There his societies were quite outside of the established Presbyterianism of the day, with its lukewarm "moderatism"; while the fervid sects which had seceded from the state church would hold no terms with Arminians like Wesley and his followers. Hence Wesley was compelled to make special provision for the administration of the sacraments in Scotland. He therefore ordained some of his ablest and most dignified preachers, was careful to give them formally in his correspondence the style and title of "Reverend," and appointed them to administer the sacraments north of the Tweed.

At length, in 1788, Wesley ordained a number of preachers (Mr Tyerman says seven) to assist him in administering the sacraments to the societies in England; and of these he ordained one (Alexander Mather) to be superintendent (or bishop), his brother Charles being now dead, and Dr Coke sometimes absent for long periods in America. The number of societies which demanded to have the sacraments administered to them in their own places of worship continually increased, and their claims were often too strong to be resisted, especially when the parish priest was either a public

opponent of the Methodists or a man of disreputable conduct. Before Wesley's death (in 1791) it would seem that there were more than a dozen of his preachers who had at different times, in Scotland or in England, been ordained to administer the sacraments.

The foregoing view of the development of Methodism as an organization, during the lifetime of its founder, will have conveyed a general idea of its structure and polity. There is one cardinal, though variable, element in its organization, however, of which there has as yet been no occasion to speak. The societies of Methodism—each of these consisting of one or more "classes"—were themselves grouped into circuits, each of which was placed under the care of one or more of Wesley's Conference preachers, who were called his "assistants" or "helpers," the assistant being the chief preacher of a circuit, and the helper being a colleague and subordinate. The "assistants" were directly responsible to Wesley, who had absolute power over them, and exercised it between the Conferences. The same power he equally possessed in the Conference, at the yearly meetings, but he made it a rule, during his later life, to take counsel with the Conference as to all matters of importance affecting the permanent status of the preachers personally, or relating to the societies and their government. He thus prepared the Connexion, both preachers and people, to accept the government and the legislative control of the Conference after his death.

At the time of Wesley's death there were in Great Britain, the Isle of Man, and the Channel Islands, 19 circuits, 227 preachers, and 57,562 members. In Ireland there were 29 circuits, 67 preachers, and 14,006 members. There were also 11 mission circuits in the West Indies and British America, 19 preachers, and 5300 members. The number of members in the United States was returned as 43,265.

It has already been explained that in connexion with each society there was a leaders' meeting, of which society stewards and poor stewards as well as leaders were members. It must here be added that each circuit had its quarterly meeting, of which, at first, only the society stewards and the general steward (or treasurer) for the circuit, in conjunction with the itinerant preachers, were necessary members. Leaders, however, in some circuits were very early, if not from the first, associated with the stewards in the quarterly meeting, or at least had liberty to attend. The quarterly meeting was not defined in Wesleyan Methodism until the year 1852. The leaders' meeting had no defined authority until some years after Wesley's death. Discipline, including the admission and expulsion of members, lay absolutely with the "assistant," subject only to appeal to Mr Wesley. Many years, however, before Wesley's death it had become the usage for the "assistant," or, in his absence, the "helper," his colleague, to consult the leaders' meeting as to important questions either of appointment to office or of discipline. As the consolidated "society" approached towards the character of a "church," the leaders' meeting began to acquire the character and functions of a church court, and private members to be treated, in regard to matters of discipline, as having a status and rights which might be pleaded before such a "court." The rights, indeed, which, soon after Wesley's death, were guaranteed to leaders' meetings and members of society had, there can be no doubt, so far grown up, before his death, as to be generally recognized as undeniable.

"Bands" were a marked feature in early Methodism, but in later years were allowed, at least in their original form, to fall out of use. There is no reference to them in the "Minutes of Conference" after 1768, although till after Wesley's death they held a place in the oldest and largest societies. Originally there were usually in each considerable society four bands, the members of which were collected from the various society classes—one band composed of married and another of unmarried men, one of married and another of unmarried women. All the members of society, however, were not of necessity members of bands. Some maturity of experience was expected, and it was the responsibility of the "assistant" to admit into band or to exclude from band. After Mr Wesley's death, where "bands" so called were kept up, they lost their private character, and became weekly fellowship meetings for the society.

The "love-feast" was a meeting the idea of which was borrowed from the Moravians, but which was also regarded as reviving the primitive institute of the *agape*. In the love-feast the members of different societies come together for a collective fellowship meeting. One feature of the meeting—a memory of the primitive *agape*—is that all present eat a small portion of bread or cake and drink of water in common.

It may be supposed that in such a system as Methodism a large number of preachers and exhorters, from all the social grades included within the societies, could not but be continually raised up. These, during Wesley's life, acted entirely under the directions of the assistant, and were by him admitted or excluded, subject to an appeal to Wesley. Once a quarter—often in conjunction with the circuit quarterly meeting—a meeting of these local lay helpers, called "local preachers," was held for mutual consultation and arrangement, and to examine and accredit candidates for the office.

3. *Wesleyan Methodism after Wesley's Death* (1791).—When Wesley died the Conference remained as the bond of union and fountain of authority for the Connexion. But between the meetings of Conference Wesley had acted as patriarch and visitor with summary and supreme jurisdiction. The first need to be supplied after his death was an authority for the discharge of this particular function. In America Wesley had organized a system of bishops (presbyter-bishops), presbyters or elders, and deacons or ministers on probation. Among some of those preachers who had been most intimate with Wesley there was a conviction that his own judgment would have approved such a plan for England. No document, however, remains to show that such was his desire. The only request he left behind him for the Conference to respect was one which rather looked in another direction—the well-known letter produced before the Conference on its first meeting after his death by his friend and personal attendant, Mr Bradford, in which he begged the members of the legal hundred to assume no advantage over the other preachers in any respect. The preachers, accordingly, in their first Conference after Wesley's death, instead of appointing bishops, each with his diocese or province, divided the country into districts, and appointed district committees to have all power of discipline and direction within the districts, subject only to an appeal to the Conference, all the preachers exercising equal rights also in the Conference, the "legal hundred" merely confirming and validating *pro forma* the resolutions and decisions of the whole-assembly.

At first the preachers stationed in the districts were instructed to elect their own chairmen, one for each district. But the plan was speedily changed, and the chairmen were elected each year by the whole Conference; and this method has been maintained ever since. The "district meetings"—as they are generally called—are still "committees" of the Conference, and have *ad interim* its power and responsibilities as to discipline and administration. Originally, they were composed exclusively of preachers, but before many years had passed circuit stewards and district lay officers came to be associated with the preachers during the transaction of all the business except such as was regarded as properly pastoral.

The relation of the Conference to the government of the Connexion having thus been determined, the question which next arose, and which occupied and indeed convulsed the Connexion for several years (1792–95), was that of the administration of the sacraments, especially of the Lord's Supper, to the societies. The societies generally insisted on their right to have the sacraments from their own preachers. Many of the wealthier members, however, and in particular a large number of the trustees of chapels, opposed these demands. At length, between 1794 and 1795, after more than one attempt at compromise had been made by the Conference, the feeling of the societies as against the trustees became too strong to be longer resisted, and accordingly at the Conference of 1795 the "plan of pacification" was adopted, the leading provision being that, wherever the majority of the trustees of any chapel, on the one hand, and the majority of the stewards and leaders, on the other, consented to the administration of the sacraments, they should be administered, but not in opposition to either the one or the other of these authorities. In England the Lord's Supper was always to be administered after the Episcopal form; in Scotland it might still, if necessary, be administered, as it had commonly been before, after the Presbyterian form. In any case, however, "full liberty was to be left to give out hymns and to use exhortation and extemporary prayer." The result was that within a generation the administration of the sacraments

to the societies came to be the universal rule. By this legislation the preachers assumed the powers of pastors, in accordance, however, only and always with the desire and choice of their flocks. No formal service or act of ordination was brought into use till forty years afterwards. All preachers on probation for the ministry, after the completion of their probation, were "received into full connexion" with the Conference, this reception implying investment with all pastoral prerogatives. Modern Methodism has developed more fully and conspicuously the pastoral idea.

No sooner was the sacramental controversy settled than the further question as to the position and rights of the laity came to the front in great force. A comparatively small party, led by Alexander Kilham, imported into the discussion ideas of a republican complexion, and demanded that the members in their individual capacity should be recognized as the direct basis of all power, that they should freely elect the leaders and stewards, that all distinction in Conference between ministers and laymen should be done away (elected laymen being sent as delegates from the circuits in equal number with the ministers), that the ministry should possess no official authority or pastoral prerogative, but should merely carry into effect the decisions of majorities in the different meetings. In the course of a very violent controversy which ensued, pamphlets and broadsheets, chiefly anonymous, from Kilham's pen, advocating his views and containing gross imputations on the ministers generally, and in particular on some not named but distinctly indicated, were disseminated through the societies. The writer was tried at the Conference of 1796, condemned for the publication of injurious and unjustifiable charges against his brethren, and by a unanimous vote expelled from the Conference. In the following year he founded the "New Connexion," the earliest of the organized secessions from Wesleyan Methodism.

Views much more moderate than Kilham's prevailed in the Connexion at large. At the Leeds Conference of 1797 the basis was laid of that system of balance between the prerogatives of the ministers and the rights of the laity which has been maintained in its principles ever since, and which, in reality, has governed the recent provisions (1877-78) for the admission of lay-representatives into the Conference not less than the former developments of Wesleyan Methodism. The admission of members into the society had, up to 1797, been entirely in the hands of the itinerant preachers,—that is, the "assistant," henceforth to be styled the "superintendent," and his "helpers." The new regulations, without interfering with the power of the ministers to admit members on trial, declared that "the leaders' meeting shall have a right to declare any person on trial improper to be received into society, and after such declaration the superintendent shall not admit such person into society"; also that "no person shall be expelled from the society for immorality till such immorality be proved at a leaders' meeting."[1] For the appointment of church officers (leaders and stewards) the following regulations were made, the second based on recognized usage, the first on general but not invariable practice:—

"1. No person shall be appointed a leader or steward, or be removed from his office, but in conjunction with the leaders' meeting, the nomination to be in the superintendent, and the approbation or disapprobation in the leaders' meeting.

"2. The former rule concerning local preachers is confirmed,—viz., that no man shall receive a plan as a local preacher, without the approbation of a local preachers' meeting."

The Conference at the same time made several provisions for carrying out the process, which had been going on for some years, of denuding itself of direct responsibility in regard to the disbursement of the Connexional funds. The principle was established that such matters were to be administered by the district committees acting in correspondence with the quarterly meetings of the circuits. It was also provided that circuits were not to be divided without the consent of the respective quarterly meetings; and, finally, it was resolved that, in the case of any new rule made by the Conference for the Connexion, its action within a circuit might be suspended for a year by the quarterly meeting, if it disapproved of the rule. If, however, the Conference, after twelve months' interval, still adhered to the new rule, it was to be binding on the whole Connexion.

The powers of district committees, as defined by former Conferences, were in 1797 confirmed and enhanced, special powers being given to special meetings of these committees convened when necessary to settle the affairs of a distracted circuit. In the same Conference all the principal rules of Methodism, in regard both to the ministers and the laity, were collected and (in a sense) codified, including the new regulations adopted that same year; and the whole, under the title "Large Minutes," was accepted as binding by the Conference, each minister being required to sign his acceptance individually. This compendium, itself based on one which had been prepared by Wesley, is still accepted by every Wesleyan minister on his ordination as containing the rules and principles to which he subscribes. During the sitting of this critical Conference at Leeds an assembly of delegates from bodies of trustees throughout the kingdom was simultaneously held. The form of the regulations enacted by the Conference was, to a considerable extent, determined by the nature and form of the requests made by this body of trustees. There was one request, however, which the Conference distinctly declined to grant—namely, that for lay delegation to the Conference. The Conference replied that they could not admit any but regular travelling preachers into their body, and preserve the system of Methodism entire, particularly the "itinerant plan." It was not until many years afterwards that anything was heard again as to this matter.

By the settlement now described the outlines of Methodism as an organized church were fairly completed. Many details have since been filled in, and many changes have been made in secondary arrangements, but the principles of development have remained unchanged. The Connexion after 1797 had a long unbroken period of peaceful progress. The effect of the "Kilhamite" separation, indeed, was after 1797 not greatly felt by the parent body. The number of Methodists in the United Kingdom in 1796, the year of Kilham's expulsion, was 95,226; in 1797 it was 99,519; in 1798 the New Connexion held its first Conference, and reported 5037 members, the number of the parent body being 101,682. Nor was it till 1806 that the New Connexion reached 6000.

During the period of quiet growth and development which followed 1797 the influence of one superior mind (Dr Jabez Bunting, 1779-1858) was to prevail with increasing sway. This was to be the period of the gradual development of lay co-operation in the administration of the various departments of Connexional extension and enterprise—a development which prepared the way for the important legislation of 1852 and following years, and for the ultimate settlement of the respective provinces and powers

[1] In this regulation it was assumed that the old rule of society by which a member disqualifies and virtually expels himself by continued absence from class, without reason for such absence, still held good. The case provides only for expulsions for "immorality." Subsequent legislation has introduced a provision which ensures to any member before he ceases to be recognized on account of non-attendance the right of having his case brought before a leaders' meeting if he desires it. This rule of 1797 has always been understood by the Conference as constituting the leaders' meeting in effect a jury, leaving the superintendent with his colleague or colleagues as advisers to act as judge. Appeal has always lain from the leaders' meeting to the district meeting, and, finally, to the Conference.

of the ministers and laity which was made in 1877–78. It was also to be the period of the gradual completion of the pastoral idea, in its practical application to the ministers of the body. This period may be defined as extending from the revolutionary epoch of 1791–97 to the epoch of political and municipal reform agitation, 1828–35, which coincides with a second period of politico-ecclesiastical agitation in Wesleyan Methodism.

In 1797 the *Conference*, as already *mentioned*, had refused to allow elected laymen—or lay delegates—any place either in the Conference or in district committees. Within a few years after 1800, however, the practice grew up for the circuit stewards to attend the district committees during the transaction of financial business, and in 1815 this usage was recognized in the Minutes of Conference as an established "rule," and it was enacted that no general increase of the income of the ministers should be sanctioned by the Conference until approved by a majority of the district committees during the attendance of the circuit stewards. Since the adoption of this rule the lay element in the district committees has steadily increased and developed. Another characteristic and important feature in the organization of Wesleyan Methodism, which grew into distinct form and prominence during the period now under review, was that of the administration of all the Connexional departments, except such as were regarded as properly pastoral, by means of mixed departmental committees, appointed at each successive Conference. These committees made recommendations to the Conference in regard to such new legislation as they thought desirable and to the appointment of the members of committee; and, for each department, a large committee of review, of which the members of the ordinary committee of management formed the nucleus, came to be held each year immediately before the Conference. In these committees the numbers of ministers and of laymen were equal. On this principle, between 1811 and 1835, provision had been made for the management of all the funds of the Connexion and their corresponding departments of administration. The first mixed committee appointed by the Conference was the committee of privileges in 1803.

The development of the pastoral position and character of the ministers of the body after 1797 could not but advance on a line parallel to the development of the position and claims of the laity. In 1818 the usage of the Conference was conformed to what had long been the ordinary unofficial custom, and the preachers began to be styled in the *Wesleyan Methodist Magazine* and in other official publications "Reverend," a fact which may seem trivial, but which in reality was of important significance.

In 1834, after the idea had been long entertained and the project had been repeatedly discussed, it was determined to establish a theological institution for the training of ministerial candidates. There are now four colleges, with two hundred and fifty students. In 1836 the practice of ordination by imposition of hands was adopted.

Such advances, however, as these in the general organization and development of the Connexion, and especially in the status and professional training of the ministers, could not be made in such a body without offence being given to some, whose tendencies were to disallow any official distinction between the ministry and the laity, and who also objected to the use of the organ. This levelling element was strong in the West Riding of Yorkshire, and in 1828, on the placing of an organ in Brunswick Chapel, Leeds, by the trustees, with the consent of the Conference, a violent agitation broke out. The consequence was a disruption, the first since 1798, under the title "Protestant Methodists." But this was absorbed, some years later, in a more considerable secession.

In fact, the Connexion was in 1828 entering on a period of agitation. The current of political affairs was approaching the rapids of which the Reform Act marked the centre and the point of maximum movement. A body like Wesleyan Methodism could not but feel in great force the sweep of this movement. It is true that Wesleyan Methodism as such has never been political, that few of its numbers cultivated extreme politics, and that the ministers and the better classes of the "Society" were strongly Conservative in their general tone. Nevertheless the mass of the community shared in the general movement of the times, and the Conservative tone of the ministers and of most of the well-to-do laity was not in full harmony with the sympathies of the people generally. Accordingly the elements of disturbance, which only partially exploded in the "Protestant Methodist" secession, continued to make themselves felt, in different parts of the Connexion, during the following years of political controversy. The decision of the Conference in 1834 to provide a college for the training of ministerial candidates gave special offence to the malcontents. Such an occasion was all that was wanting for the various discontents of the Connexion to gather to a head. The demands made by the agitators proceeded on a basis of democratic ecclesiasticism such as it is very difficult to apply successfully to a system of associated churches. The result was a third secession, based on the same general ground of ecclesiastical principles as the two preceding, which was organized in 1836, and with which the "Protestant Methodists" eventually coalesced. This new secession was known first as the "Wesleyan Methodist Association"; but for a number of years past it has been merged in a still larger body of seceders designated "The Methodist Free Churches." Its leader at the first was the Rev. Dr Warren, who left it, however, not many months after it was formed, and took orders in the Church of England.[1]

The controversies of 1835–36 left their mark on the legislation and official documents of the Connexion. The principles of 1797 remained intact, some further guards only being added to prevent any danger of hasty or irresponsible action on the part of superintendents, and at the same time "minor district meetings" being organized in order to facilitate appeals. One error was, however, committed by the Conference. In 1797 no provision had been made for bringing the circuit, through its quarterly meeting, into direct relations with the Conference. In 1836 a right of direct memorial to the Conference was given to the circuit quarterly meeting; but it was so fenced round with conditions and limitations as to make it practically inoperative, and at the same time provocative of suspicion and irritation.

The effect of the secession of 1836 on the general progress of the Connexion was not great. The number of members reported in 1835 in Great Britain and Ireland was 371,251 (there being a decrease in England of 951), in 1836 381,369, in 1837 384,723. For the next ten years the advance of the Connexion in numbers and in general prosperity was apparently unprecedented. The Centenary Fund of 1839–40 amounted to £221,000. In the midst, however, of all the outward prosperity of Methodism—partly perhaps in consequence of it—very perilous elements were at work. The revolutionary ideas of the Chartist period (1840–48) and of Continental politics (1848–49) reacted on Wesleyan Methodism as the political ideas of 1791 and of 1831 had done at those epochs. The embers of old controversies—ecclesiastical, quasi-political, and personal—still smouldered, and at length burst into fresh flame. From 1844 a strong spirit of opposition to the leaders of the Connexion, and especially to Dr Bunting, was fanned by the circulation of anonymous "fly leaves" of a very scurrilous character. At the same time the policy of the Conference and of the ministers in their circuits had proceeded more than was wise on the old lines. The general administration relied too much on the footing of implicit confidence on the part of the people and on the power of official prerogative in the hands of the minister. The memorial law of 1836 was indicative of the too exclusive spirit of pastoral government which had prevailed. The wisdom of Dr Bunting had for five and twenty years led the way in gradually liberalizing both the polity and the policy of Methodism, and adapting them to the changing conditions of the times. But this wisdom seems to have found its limits before 1849, when the internal dissensions reached their climax. In that year James Everett, the chief author of the fly sheets, and two other ministers, Samuel Dunn and William Griffith, who had identified themselves with him, were expelled. A disastrous agitation followed. No distinct secession took place till after the Conference of 1850. The union of the "Methodist Free Churches," in which was incorporated the "Wesleyan Association" (of 1836), was formed by the seceders. The "New Connexion" also received some thousands of the seceders into its ranks. But by far the greatest part of those who left went with neither of these bodies.

Between 1850 and 1855 the Connexion in Great Britain and Ireland lost 100,000 members, and not till 1856 did it begin to recover. In that year the numbers were returned as 282,787, showing a small increase over the preceding year. Since then peace and unity have prevailed unbroken.

The convulsion of 1849–52 taught the Connexion, and in particular the Conference, lessons of the highest importance. In 1852 the quarterly meeting was so defined as to make it the great representative meeting of the circuit, including stewards, leaders, local preachers, and trustees. The right of memorial to the Conference was given to it in the widest and freest sense. These powerful bodies invite ministers to the circuits, or decline so to do, determine and pay their "allowances," as salaries to ministers are still called in the Connexion, and review all the interests of the circuits, spiritual or financial. They had also conferred upon them in 1852 the right to appoint a circuit jury of appeal from the verdict and findings of a leaders' meeting in certain cases of discipline. Since 1852 Conference legislation has still proceeded in the direction of recognizing and enlarging the functions and rights of the laity. The committee of review system, already spoken of, had been considerably developed between 1835 and 1849, and included every department of ordinary administration. In 1861, however, whilst a representation of the departmental executive committees formed still the leading element in each committee of review, a great improvement was made in their constitution by giving to each of the districts of British Methodism the right to send a lay representative

[1] This "Warrenite" secession, as at first it was commonly called, gave rise to a lawsuit which led to the judicial recognition by the Court of Chancery of the Conference Deed Poll of 1784, and the "Large Minutes" of 1797, as documents having the force of public law in the administration of Wesleyan Methodism.

to attend these preparatory Conference committees. In 1877 and 1878 the final and natural consummation of the whole course of advance since 1791 was effected in the constitution of the united Conference of ministers and lay representatives. The ministers meet by themselves to discharge the functions which belong to them as the common pastorate of the Connexion. As to all the points involved in their specific character and common responsibility, as the mutually exchanging and itinerating pastors in common of a vast common flock, they take mutual counsel in a separate assembly. The Conference, in its ministerial-and-lay or representative session, meets after the pastoral business is completed, and occupies a full week between Sundays in discussing and settling the business of all the funds and the general administrative departments of the body. The Conference in its pastoral session assembles on the last Tuesday in July, that session closing on the Friday or Saturday week following; the representative session occupies the following week. It is legally necessary that the decisions of the Conference in both its sessions should be confirmed and validated by the vote of the "legal hundred." This confirmation is, however, given as a matter of course.

The Conference in its pastoral session is not formally representative. To each district is assigned by the preceding Conference a certain amount of representation, there being at present thirty-five districts. The numbers allocated to the districts vary according to circumstances. The total number of ministers and laymen composing the Conference in its representative session is 480, or 240 ministers and 240 laymen. The basis of the lay representation in the Conference is the constituency of lay officials in the district committees. The Connexion at large is represented by the lay officials of the general Connexional departments. The business transacted in the Conference during its representative session relates to all the Connexional departments of general administration, viz., the committee of privileges, foreign missions, the maintenance and education fund (and the schools) for ministers' children, chapel affairs (general, metropolitan, and provincial), the home mission and contingent fund, district sustentation funds, army and navy evangelization, lay mission work, the worn-out ministers' and ministers' widows' fund, the theological institution with its four colleges, Sunday and day schools and the children's home and orphanage, higher education, the extension fund of Methodism, alterations and divisions of circuits and districts, and the Lord's Day observance and temperance questions.

The president of the Conference is chosen by the ministers by ballot on the opening of the pastoral session. After the election of president follows that of secretary. These elections, however, cannot take place until the vacancies in the hundred have been filled up. Such vacancies are caused by death, by absence for two years together without a dispensation, by expulsion, or by superannuation, which takes place ordinarily after two years' retirement from the full work of the ministry.

The principal statistics of the denomination at the last Conference (1882) were as follows:—

	Members.	On Trial.	Ministers.	On Trial.	Retired or Supernumerary Ministers.	Sunday Scholars.
Great Britain	393,754	40,653	1,549	81	279	829,666
Ireland	24,475	776	200	18	43	
Foreign missions.[1]	89,363	12,934	343	198	16	

Of the Sunday scholars in Great Britain, 177,965 were over fifteen years of age, and 93,127 were members of society or on trial as members.

Wesleyan Methodism in Ireland has always been part and parcel of British Methodism, but since 1732 it has had a branch Conference of its own. The acts of this Conference are, in accordance with a provision in the Conference Deed Poll, made valid by the concurrence with them of a delegate from the British Conference, who is to the Irish Conference what the legal Conference is to the British Conference. Ten ministers of the Irish Conference are members of the "legal hundred" of the British Conference. The "plan of pacification" of 1795 was not carried out at the time by the Irish Conference. In the year 1816, however, it was adopted in Ireland. The result was a secession which assumed the designation "Primitive Wesleyans," a very different body from the Primitive Methodists of England. In 1878 the Primitive Wesleyans were reunited to the parent Connexion. The number of members in Ireland has, owing to emigration, not increased of late years. The last return showed 24,475 members.

Affiliated Conferences.—For more than twenty years there were several "affiliated Conferences" of British Methodism. But there are now only two—the *French Methodist* Conference, and that of *South Africa*,—the latter constituted quite recently (1882). Since 1852 French Methodism has been under an affiliated Conference. The dimensions of the French Connexion, however, are very small, and it is dependent to a considerable extent on pecuniary aid furnished by the Wesleyan Missionary Society. The last statistical return showed 1769 members, 126 members on trial, 27 ministers, 1 minister on trial, and 3 supernumerary or retired ministers. The British Conference has a right of veto as to certain points of legislation in the case of affiliated Conferences.

Australasian Methodism was for more than twenty years under an affiliated Conference, dating from 1854. Since 1876, however, the Australasian Conference has been independent. The General Conference meets once in three years, having under it our annual Conferences—one for New South Wales and Queensland, another for Victoria and Tasmania, a third for South Australia, and a fourth for New Zealand. These Conferences—the general and the annual—are all mixed and representative after the same general pattern as the British Conference. They have also under their charge, and as part of their Connexion, the Wesleyan missions in Tonga and Fiji, which were begun by the parent body before the original affiliated yearly Conference for Australasia was organized. The numbers in 1881 were for the Methodism of Australia 28,310 members with 362 ministers, and for the South Sea missions 33,411 members with 16 missionaries of European blood and a very large number of native ministers and assistant ministers.

Canadian Methodism was also affiliated till 1873, when it became an independent Connexion. It includes six provincial annual Conferences and one General Conference which meets every three years. The General Conference is mixed and representative; the annual Conferences are purely ministerial. Canadian Methodism occupies a powerful position in the Dominion. It numbers as nearly as can be ascertained about 116,000 members, and is strongest in Upper Canada. It possesses a university—the Victoria University in Upper Canada.

The Doctrines of Methodism.—In doctrine all branches of Methodism are substantially identical. Wesley's doctrines are contained in fifty-three sermons known as the "four volumes" and in his *Notes on the New Testament*. The Conference has, however, published two catechisms, one for younger the other for older children, of which a new and carefully revised edition has lately been completed.[2] In general, Wesleyan theology is to be described as a system of evangelical Arminianism. In particular, Wesleyan divines insist on the doctrines of original sin, general redemption, repentance, justification by faith, the witness of the Spirit, and Christian perfection,—or, as it has been customary for Methodists to say, the doctrines of a "present, free, and full salvation." By the witness of the Spirit is meant a consciousness of the Divine favour through the atonement of Jesus Christ. Wesleyans have often been represented as holding the Calvinistic doctrine of "assurance." The word, however, is not a Wesleyan phrase, and assurance, so far as it may be said to be taught by Methodists, signifies, not any certainty of final salvation, but merely a "sense of sin forgiven."[3]

II. American Episcopal Methodism.

The beginnings of American Methodism are traceable to the year 1766, when a few pious emigrants from Ireland introduced Methodism into New York. On receiving an appeal in 1768 from the New York Methodists, who were engaged in building a preaching-house, Wesley laid the case of America before the Conference at Leeds in 1769, and two preachers, Boardman and Pilmoor, volunteered to go to the colonies. Boardman went to New York, Pilmoor to Philadelphia. In 1771 two other Methodist itinerants, Francis Asbury—the most famous name in American Methodism—and Richard Wright, went out to America. In 1773 Thomas Rankin, a preacher of experience sent out

[1] Chiefly in the West Indies, Africa, India, and China.

[2] Besides Wesley's *Sermons* and *Notes*, his *Appeals* and his treatise on *Original Sin*, in reply to Dr Taylor of Norwich, should be read in order to appreciate his theological views. After these may be particularly noted Joseph Benson's *Commentary*, Watson's *Institutes* (3 vols.), Dr Pope's *Compendium of Theology* (3 vols.), the series of *Fernley Lectures*, especially that by the Rev. B. Gregory on "The Holy Catholic Church," and Dr Rigg's *Discourses and Addresses*.

[3] For the history and constitution of Wesleyan Methodism the following works may be consulted;—Wesley's Works, especially his *Journals*; Southey's *Wesley*; Tyerman's *Wesley*; Rigg's *Living Wesley*, and *Churchmanship of John Wesley*; Jackson's *Life of Charles Wesley*; *Minutes of Conference*, vol. i., 1744-98; Dr George Smith, *History of Wesleyan Methodism*, 3 vols.; Dr Abel Stevens, *History of Methodism*, 3 vols.; Pierce, *Polity of Methodism*; Dr Williams, *Constitution and Polity of Wesleyan Methodism*; Rigg, *Connexional Economy*; and the *Minutes*, 1877 to 1881.

by Wesley, held the first Conference in Philadelphia, when there were 10 itinerant preachers and 1160 members. After the breaking out of the War of Independence the English Methodist preachers were unpopular, and all but Francis Asbury went back to England. At the end of the war, however, in 1784, Wesley sent out Dr Coke, and American Methodism was organized as an independent church, with Dr Coke and Francis Asbury as its presbyter-bishops. The history of American Methodism since that period is too vast and complicated for any attempt to be made to summarize it here. Methodism is more properly national in its character as an American church than any church in the States. In Massachusetts and some other of the New England States it is less powerful than Congregationalism, which still retains there much of its ancient predominance; in the city of New York it is less powerful than Presbyterianism, and, indeed, occupies a position less generally influential than might have been expected. But in Philadelphia it is very powerful; so also in Baltimore and in Cincinnati; if not strong in New York city, it is very strong in the State; and generally throughout the western and mid-western States it is the prevalent form of faith and worship. In the south, also, it is more powerful than any other church.

American Methodism is Episcopal. But its Episcopacy is neither prelatical nor diocesan. The bishops are superintending presbyters, and they visit the whole territory of Methodism in rotation, holding (presiding over) the annual Conferences. These Conferences are purely ministerial. But the General Conference, which meets once in four years, and which is the Conference of legislation and final appeal, is mixed and representative. The first General Conference was held in 1792, the first delegated or representative Conference in 1812, the first mixed or ministerial-and-lay General Conference in 1872. There were till lately no district assemblies in the Episcopal Methodism of America, and now there are but few. The bishops maintain the unity of the Connexion in the interval between the General Conferences, by their visitation and by their conjoint council. A sub-episcopal class of ministers also, called presiding elders, supplement the action and superintendency of the bishops. These preside over districts, holding all the circuit quarterly meetings, and holding the district meetings, if any such meetings have been organized.

American Episcopal Methodism is distributed into five distinct sections or churches, which, however, differ from each other in no points of any importance as respects organization or discipline, still less doctrine. The American Methodist Episcopal Church South became a separate organization in 1847 by reason of the slavery controversy. The coloured churches, of which there are three, sprang up distinctly from local causes. The following are the latest available statistics:—

	Itinerant Ministers.	Local Preachers.	Lay Members.
Methodist Episcopal Church	12,142	12,323	1,717,567
" " " South	4,004	5,868	837,831
African " "	1,832	9,760	391,044
Methodist Episcopal Zion Church	1,650	3,750	300,000
Coloured Methodist Episcopal Church	638	683	112,000
	20,266	32,384	3,358,442

In the Methodist Episcopal Church alone there are one hundred annual Conferences, visited by twelve bishops. This church has more than twenty universities, of which some are distinguished schools of learning. Boston University is one of the most recent and one of the chief. The principal foreign missions are in India, China, and Japan. The Methodist Church South also has some influential universities, particularly that at Nashville, and has missions, in particular in Japan and China.

Besides these Methodist Episcopal churches, with their total of 3,358,000 church members, there are two other churches which do not assume the name at all, but are yet essentially Methodist in doctrine and discipline, not varying in any important particulars from the Episcopal Methodism of America. Of these one is called the United Brethren, with 157,000 members, the other the Evangelical Association, with 113,000 members.[1]

Non-Episcopal American Methodism.—The bodies included under this head are chiefly secessions from the original stock of American Methodism, founded on principles of democratic church government, analogous to those of the English Methodist secessions. The only considerable body, however, is the Methodist Protestant Church, with 125,000 members. The minor bodies, four in number, count altogether less than 60,000 members, the principal being the American Wesleyan Church, with 25,000 members.

III. Other Methodist Bodies in Britain.

The bodies still to be noticed, while differing as to points of church government, agree as to doctrine and in general as to the means of grace and as to inner spiritual fellowship with the parent "Connexion." They all maintain class-meetings and love-feasts, have leaders' meetings and quarterly meetings, and largely employ local preachers.

The Methodist New Connexion was founded in 1797–98 by Alexander Kilham, who died in 1798. Its general principles are indicated above. Its statistics for 1881 were as follows:—183 ministers and 27,770 members (including those on mission stations, besides 3882 on trial), and 74,744 Sunday scholars.[2]

United Methodist Free Churches.—This organization in its original form must be identified with the Wesleyan Methodist Association of 1836. That body first absorbed into itself, in great part, the "Protestant Methodists" of 1828. It was afterwards greatly increased, and its organization in some points modified, when a large number of the seceders from the parent Connexion in 1850–52 joined its ranks. The main body of its Conference does not consist, like that of the New Connexion, of an equal number of circuit ministers and elected circuit lay delegates, but of circuit delegates, whether ministerial or lay, elected without any respect to office, ministerial or other. Its circuits also are independent of the control of the Conference. The Connexional bond, accordingly, in this denomination is weak, and the itinerancy is not universal or uniform in its rules or its operation. The amalgamation between the Wesleyan Methodist Association and the "Wesleyan Methodist Reformers" of 1850 took place in 1857. At that time the combined churches numbered 41,000. At present (1881–82) they number 72,839, including 7772 members on the mission stations, besides 7824 on trial. The number of ministers is 392, with 40 retired or "supernumerary" ministers. The number of Sunday scholars is 190,957.[3]

Primitive Methodism.—In this earnest and hard-working denomination the ministers, of whom some are women, are very literally "the servants of all." The Conference is composed, in addition to twelve permanent members, of four members appointed by the preceding Conference, and of delegates from district meetings. The principle of proportion is that there should be two laymen to one minister or "travelling preacher," and the "travelling preachers" have no pastoral prerogative whatever. The Conference is supreme, and the Connexional bond is strong. This body was founded by Hugh Bourne and William Clowes, local preachers who were separated from the Wesleyan Connexion, the former in 1808, the latter in 1810, because of their violation of Conference regulations as to camp meetings and other questions of order. The Conference had, in 1807, pronounced its judgment against camp meetings, which had been introduced into the country from America, whereas Bourne and Clowes were determined to hold such meetings. Founded thus by zealous and "irregular" lay preachers, "Primitive" Methodism, as the resulting new body called itself, bears still in its organization, its spirit, and its customs strong traces of its origin. It has been a very successful body, aiming simply at doing evangelistic work, and is now numerous and powerful, numbering among its ministers, not only many useful preachers, but some of marked originality and power and also of superior cultivation. There has for many years past, if not from the beginning, been a very friendly feeling between the old Wesleyan Connexion and the Primitive Methodists. Its latest statistics (1881–2) show 1149 travelling preachers, 185,312 members, and 383,350 Sunday scholars.[4]

Bible Christians.—The Primitive Methodists sprang up in the midland counties, the Bible Christians in Cornwall. These closely resemble the "Primitives" in their character and spirit. Their founder was a Cornish local preacher called O'Bryan. Hence the Connexion is often known as the Bryanites, and Cornish emigrants have propagated this denomination widely in the colonies. The Conference is composed of ten superintendents of districts, the president and secretary of the preceding Conference, lay delegates, one from each district meeting, and as many of the travelling preachers as are allowed by their respective district meetings to attend. In general it may be said that the ministerial and lay members of the Conference are about equal in number. The returns for 1881–82 showed in England (chiefly the west and south of Eng-

[1] The best authority as to American Methodism is Dr Abel Stevens's *History*, in 5 vols. The statistics are given in the *Methodist Year Book*, New York, 1882.

land) and in the Channel Islands 136 itinerant preachers, 21,209 members (besides 690 on trial), and 36,335 Sunday scholars. In Canada the number of members was 6652, and in Australia and New Zealand 3671.[1]

The Wesleyan Reform Union is an aggregate of local Methodist secession churches, loosely held together by a Conference, and is one of the results of the great Methodist disruption of 1851-52. The returns for 1881-82 showed 18 ministers and 7728 members.

Œcumenical Methodist Conference.—This Conference was held in City Road Chapel, London, in September 1881. Representatives were present from all the Methodist bodies throughout the world, and it was estimated that these represented not less than 5,000,000 of members and 20,000,000 of population. Whilst in church organization these bodies differed, as has been shown above, in doctrine and in respect of their purely spiritual discipline and means of grace, they were all agreed in principal matters. The Conference was entirely practical in character. The object was to promote zeal and union among the constituent bodies as to all practical points of Christian sympathy and activity, at home and abroad, and especially as to home mission work, general philanthropy, Christian education, and a Christian use of the press. There were 100 representatives present from the Methodist bodies in all parts of the world.[2]

Welsh Calvinistic Methodists.—Between the Methodism of Wales and that of England there was never any other than incidental connexion. Indeed, although the name of the Welsh movement was borrowed from the English, not only was Welsh Methodism quite independent in its origin, but in reality its beginning, as an evangelical movement, was earlier than that of English Methodism. From Wesleyan Methodism, furthermore, Welsh Methodism was throughout distinguished by the fact that it was Calvinistic in its doctrine. For some years Whitefield's name was placed by the leaders of Welsh Methodism at the head of their movement, but the connexion was not at any time much more than nominal, Whitefield being, indeed, too often and too long together in America to exercise any real presidency over the Methodism of the Principality.

Distinction, however, must be made between Welsh Methodism as an evangelistic movement and as an organization. In its later and distinctly organized form, its main elements date from 1811, while the actual unity and the final consolidation of the organization date from so recent a period as 1864. At that date we find the Calvinistic Methodism of North and of South Wales for the first time united in a common organization and government, and brought under the supreme control of one "General Assembly."

The spiritual awakening from which Welsh Calvinistic Methodism derived its earliest inspiration and impulse began in 1735 and 1736, almost contemporaneously and quite independently, in three different counties of South Wales. Howell Harris, a gentleman of some position, born and bred at Trevecca in the parish of Talgarth, county of Brecon, is the most prominent name connected with early Welsh Methodism. His first strong religious convictions and impulses date from 1735. He was sent to Oxford in the autumn of that year to "cure him of his fanaticism," but remained only one term. On his return to Wales he began to exhort and preach in private houses and in such buildings as he could obtain the use of, being then and throughout his life a simple layman. Of learning or theology he had but little; but he was an extemporary preacher of prodigious vehemence, and often of overwhelming power and pathos. While Harris was thus preaching in the county of Brecon, Daniel Rowlands had been spiritually awakened at Llangeitho in Cardiganshire, the two men knowing nothing whatever of each other. Rowlands was an ordained clergyman, of some learning and of great eloquence. He was a pulpit orator, and carefully prepared his powerful discourses. In Pembrokeshire, again, in that same year 1735-36, Howell Davies began to preach the same doctrine in the same spirit as the other two preachers, and with effects scarcely, if at all, less remarkable. The work thus begun in three distinct centres within the space of one year was in strict connexion with the Established Church, and so continued to be throughout the last century. These single-minded preachers pursued their work in Wales knowing nothing of the parallel work which Whitefield had just begun in England. In 1738, however, Whitefield, in the west of England, heard of Howell Harris, and in that year the two revivalists met in Cardiff. In 1739 Howell Harris had begun to extend his preaching tours far and wide, visiting not only South but North Wales, and, wherever he went, founding religious societies in connexion with the Church of England, of a character resembling those called Dr Woodward's societies, which had long been in existence throughout England, the chief difference being that the Welsh societies were "evangelical," Calvinistic, and revivalist. It was in the same year that Wesley founded his society in England. In 1742 the clergymen connected with the Welsh movement were ten in number, and there were labouring in concert with these forty lay "exhorters," as they were called. In that year the first "association" of Welsh Calvinistic Methodists was held at Waterford or Watford, in Glamorganshire. Whitefield consented to preside, and joined his preaching to that of the Welsh evangelists. The first Calvinistic Methodist Conference was held at Waterford, under Whitefield's presidency, on January 5, 1743, eighteen months earlier than Wesley's first Conference. For a short time the Calvinistic Methodism of Wales was linked to that of England. After 1748, however, Whitefield ceased to act as in any sense the official head of the Calvinistic Methodists of England, and their organization, always loose, was gradually dissolved.

There was no Wesley in Welsh Methodism, and accordingly there was no organic unity among the societies of earlier Welsh Methodism. Each local society was under the care of an "exhorter," an unpaid layman. A number of these local societies were grouped together into a district, over which an "overseer" had charge. He also was usually an unpaid layman, although exercising many of the functions of a spiritual pastor. Sometimes, however, as in the case of Rowlands, he was a parish clergyman. The societies attended their parish churches and there received the sacraments. The meeting- or preaching-houses for the societies were vaguely called "houses for religious purposes."

In 1751 Howell Harris ceased to itinerate and retired to Trevecca. From this time his leadership in the Methodist movement seems to have come to an end, and the movement languished for many years after. Not till 1762 is any "revival" chronicled. In 1763 Rowlands was obliged to quit his curacy at Llangeitho and leave the Established Church. His people built him a chapel. He thus, after 1763, became a Dissenting minister; and, retaining his fame and much of his power to the end of his course, he died in 1790.

Fifty years had now passed since the first societies of Welsh Methodism had been established by Howell Harris, and the movement, instead of having grown to strength and maturity, appeared to have spent its force, almost in all directions, at least so far as any outward signs could show. But the Rev. Thomas Charles of Bala was to be one of the chief means of reviving it. He, like the earlier Methodists, was a churchman; he had taken his degree at Oxford and served a curacy in Somersetshire. The doors of the Established Church having been closed against him because of his style of preaching, he joined the Welsh Methodists in 1785, and his first sphere of marked influence was in North Wales. In 1791 he took a leading part in a great revival of which Bala was the centre. From this period may be dated the second spring of Welsh Calvinistic Methodism, from which its later successes were to grow. Charles zealously and successfully promoted the establishment of "circulating schools" and of Sabbath schools. He was, in fact, the soul of the great Christian educating movement in Wales which began in the last decade of the 18th century; and it was through his earnest zeal in seeking to provide Bibles for his Welsh schools, especially the Sunday schools, that the British and Foreign Bible Society was established. Though Methodism came then to be effectually rooted in the soil of the Principality, it was not till 1811 that the Welsh Calvinists took that step in the direction of ecclesiastical independence which the English Wesleyans had taken sixteen years before by calling their preachers to the official position of pastors and ordaining them to administer the sacraments.

From 1790 till almost the present time the work of gradually moulding the constitution of Welsh Calvinistic Methodism has proceeded. The "rules regarding the proper mode of conducting the quarterly association" were drawn up by Charles and agreed upon in 1790. In 1801 the *Order and Form of Church Government and Rules of Discipline* were published. In 1811, as has been shown, ministerial ordination was initiated. In 1823 the *Confession of Faith* was promulgated. And in 1864, as has been already mentioned, the first "General Assembly" was held, and the two associations of North and South Wales respectively were united into one body. The constitution is now a modified Presbyterianism, each church managing its own affairs subject to successive appeal to the monthly meeting of the county and the quarterly association of the province, while the latter body may refer the decision to the annual General Assembly.

The Welsh Methodists (or Welsh Presbyterians, as they are now often called) have two theological colleges, one at Bala and the other at Trevecca. They have also a foreign missionary society, with missions in Brittany, among their congeners of the Celtic race, and in Bengal.

In recent years this church has made great progress. In 1850 the number of members was 58,678, in 1870 it was 92,735, and in 1880 the returns showed 1174 churches, 118,979 communicants, 185,635 Sunday scholars. The number of ministers is not officially given, but is estimated at 600. The North and South Wales associations are now also known as synods.[3] (J. H. RI.)

is never made synthetically, but simply extracted from wood-spirit, a commercial substance which is produced industrially in the dry distillation of wood. The wood-spirit is contained in the aqueous portion of the tar produced in this operation, along with acetic acid. To recover both, the tar-water is neutralized with lime and distilled, when the acetate remains, while the spirit distils over, along with a deal of water, which, however, is easily removed, as far as necessary, by redistillation and rejection of the less volatile parts. The "crude" wood-spirit, as thus obtained, is not unlike in its general properties to ordinary spirit of wine, from which, however, it is easily distinguished by its abominable smell. The ordinary commercial article, besides a variable percentage of water, contains from 35 to 80 per cent. of methyl-alcohol; the rest consists chiefly of acetone, but besides includes dimethyl-acetal, $C_2H_4(OCH_3)_2$, acetate of methyl, and numerous other minor components. In Great Britain large quantities of wood-spirit are used for the making of methylated spirit, a mixture of ordinary spirit of wine with one-ninth of its volume of wood-spirit, which is allowed to be sold duty free for the preparation of varnishes, and for other industrial purposes. In former times, here as elsewhere, wood-spirit itself used to be employed as a cheap substitute for spiritus vini; but this is no longer so, since the aniline-colour industry has created a large demand for pure methyl-alcohol. Hence in some Continental works the wood-spirit, instead of being sent out as such, is being worked up for its components, by the following sequence of operations:—(1) dehydration by lime; (2) heating, under an inverted condenser, with caustic soda, to convert the acetate into hydrate of methyl; (3) destruction of the bad smells by mild oxidation; (4) distillation in a kind of Coffey's still, whereby it is split up into approximately pure alcohol, acetone, and "tails."

The new industry led to the invention of the following technical methods for the determination, in a given spirit, of the percentages of real methyl-alcohol and of acetone.

The alcohol is determined by saturating 5 c.c. of the spirit with hydriodic acid (volatilization of alcohol and iodide of methyl being avoided by means of a cold-water bath and an inverted condenser), and the product poured into water. Iodide of methyl separates out as a heavy oil, which is measured as it is. According to direct trials 5 c.c. of pure methyl-alcohol yields 7·15 c.c. of crude iodide (Krell, Kramer and Grodzky).

For the determination of the acetone the following reagents are required (Kramer):—(1) a solution of iodine, prepared by dissolving $I_2 = 254$ grammes of iodine, by means of (say) 500 grammes of iodide of potassium, in water, and diluting to 1 litre; (2) a solution of caustic soda containing twice (NaOH) grammes per litre; (3) alcohol-free ether. Ten c.c. of the soda are placed in a graduated cylinder and mixed intimately, first with 1 c.c. of the spirit, then with 5 c.c. of the iodine solution. Iodoform separates out (if acetone is present) in minute yellow crystal plates; this product is "shaken out" by means of 10 c.c. of ether, and determined by evaporating an aliquot part of the ethereal layer in a tared watch-glass to dryness and weighing the residue. C_3H_6O yields CHI_3; hence 1 part of iodoform indicates 0·28 parts of acetone.

The formula of methyl-alcohol and its true chemical character were correctly ascertained by Dumas and Péligot as early as 1834; yet pure methyl-alcohol may be said to have been an unknown substance until 1852, when Wöhler taught us to prepare it, by first extracting the CH_3 of the CH_3OH in the wood-spirit as oxalate of methyl, and then decomposing the (purified) oxalate with water.

The most convenient raw material to use nowadays is the commercial "pure" alcohol; if wood-spirit is employed it had better first be purified by distillation over caustic soda (vide supra). The formation of the oxalate then is best effected (according to Alexander Watt) as follows:—500 grammes of oxalic acid crystals are mixed with 200 c.c. of oil of vitriol; then 500 c.c. of the spirit are added, the whole kept for a time at 80° C., and then allowed to stand cold for twenty-four hours.

The large crop of oxalate crystals—partly $(CH_3)_2C_2O_4$, partly $CH_3 . H . C_2O_4$—is separated from the liquor by pressure and subsequent drying over vitriol, and then decomposed by distillation with water.

The aqueous alcohol thus obtained is dehydrated by the well-known methods used in the preparation of ordinary absolute alcohol.

According to Krämer, a purer preparation than Wöhler's is obtained by extracting the methyl as formiate instead of as oxalate, which is easily effected by digesting the wood-spirit with a formic acid of 1·22 specific gravity, and purifying the formic ether by fractional distillation. This ether boils at 32°, the oxalate at 161° C., hence a proper combination of the two methods should be infinitely superior to either. What now follows must, in general, be understood to refer to Wöhler's preparation.

Pure methyl-alcohol is a colourless liquid similar in its general properties, in its behaviour to other chemically inert liquids, and in its action as a solvent to ordinary absolute alcohol, from which, however, it differs by the entire absence from it of all spirituous odour. A preparation which smells of wood-spirit may be condemned at once as impure. According to H. Kopp, its specific gravity is 0·8142 at 0° C. and 0·7997 at 16°·4. If the volume at $t°$ be V, then (from 0° to 61°)

$$V = 1 + \cdot 0011342t + 1\cdot 3635 \times 10^{-6}t^2 + 8\cdot 741 \times 10^{-9}t^3.$$

The boiling point is 64°·6 to 65°·2. The tension-curve was determined by Regnault and by Landolt; but the results of the two observers do not agree except (approximately) at $P = 760$ mm. Methyl-alcohol has quite a characteristic tendency to "bump" badly on distillation, which, however, can be prevented by addition of a small fragment of tin-sodium, which produces a feeble but sufficient current of hydrogen. Its specific heat is ·6713; latent heat of vapour, 264; combustion heat, 5307 per unit weight (Favre and Silbermann). The refractive index for the D (sodium) ray is 1·3379 ± ·0013 for 10° ∓ 5° C. (Dale and Gladstone).

Methyl-alcohol mixes with water in all proportions with contraction.

Since Wöhler's discovery a table for the specific gravities of aqueous methyl-alcohols has been constructed experimentally by A. Dupré; but unfortunately his alcohol boiled at 58°·7, and consequently must have been something different from what generally goes by this name.

In its chemical reactions methyl-alcohol, $CH_3 . OH$, is very similar to ordinary (ethyl) alcohol, $C_2H_5 . OH$, and consequently, in the same sense as the latter, analogous to water, $H . OH$. Thus, for instance, metallic sodium and potassium dissolve in either alcohol with evolution of hydrogen and formation of ethylates or methylates of the alkali metals. Example—

$$CH_3OH + Na = CH_3 . ONa + \tfrac{1}{2}H_2.$$

The two methylates crystallize from the solution with crystal-alcohol, which can be driven off in an atmosphere of hydrogen by heat, without decomposition of the salts themselves. Water at once decomposes them into caustic alkali and alcohol, $CH_3 . ONa + H . OH = NaOH + CH_3OH$. Yet the reverse reaction takes place when the alcohol is treated with a large excess of caustic soda.

The action of acids on methyl-alcohol is in general quite analogous to that on, for instance, caustic soda, with this important difference, however, that what in the case of NaHO goes on so readily in aqueous solutions with $CH_3 . OH$ succeeds only under circumstances precluding the accumulation of water. In these circumstances we have, for instance,

$$(1)\ Cl\overline{H + OH} . CH_3 = H_2O + Cl . CH_3;$$

$$(2)\ \underset{\text{Acetic acid.}}{(C_2H_3O_2)}\overline{H + OH} . CH_3 = H_2O + \underset{\text{Acetic ether}}{C_2H_3O_2 . CH_3};$$

and so on with all monobasic acids. A dibasic acid XHH may act as $(X)H_2$ or as $(XH) . H$; thus, for instance,

$$(3)\ \underset{\text{Oxalic acid.}}{(C_2O_4H)}\overline{H + OH} . CH_3 = H_2O + \underset{\text{Methyl oxalic acid.}}{C_2O_4 . HCH_3};$$

$$(4)\ (C_2O_4)H_2 + 2OH . CH_3 = 2H_2O + \underset{\text{Methyl oxalate.}}{C_2O_4 . (CH_3)_2};$$

A tribasic acid forms two methyl acids and one neutral ether; we have, for instance,

(5) (From PO_4H_3); $PO_4(CH_3)H_2$; $PO_4(CH_3)_2H$; $PO_4(CH_3)_3$.

It would, however, be a great mistake to suppose that whether, for instance (Ex. 3 and 4), the monomethyl or the dimethyl compound is formed depends on the quantity of methyl-alcohol employed per unit of acid. This depends far more largely on other conditions, as will be illustrated in next paragraph. The methyl-salts of oxygen acids are called esters, in opposition to the chloride, bromide, iodide, sulphide, and oxide, which are set apart as ethers. Broadly speaking, ethers are not, while esters are, readily decomposed by water into their cogeners; but the nitrate $CH_3 . NO_3$ behaves in this respect like an ether.

Action with Sulphuric Acid.—Methyl-alcohol mixes with oil of vitriol with considerable evolution of heat and (always only partial) conversion of the two ingredients into methyl-sulphuric acid. Equal volumes of acid and alcohol give a good yield. To prepare pure methyl sulphates, dilute the mixture largely with water, avoiding elevation of temperature (which would regenerate the ingredients), and saturate with carbonate of baryta. Filter off the sulphate of baryta to obtain a solution of the pure methyl sulphate $SO_4 . CH_3 . ba$ (where $ba = \frac{1}{2}Ba = 1$ *eq.*), from which this salt is easily obtained in crystals. From the baryta salt any other methyl sulphate is readily obtained by double decomposition with a solution of the respective sulphate; the acid itself, for instance, by means of sulphuric acid. At higher temperatures the reaction between vitriol and methyl-alcohol results in the formation of methyl-ether, $(CH_3)_2O$, or of normal sulphate of methyl, $(CH_3)_2SO_4$. The ether is a gas condensable into a liquid which, under pressure of one atmosphere, boils at $-21°$ C.

The gas dissolves in about one thirty-seventh of its volume of water; far more largely in alcohol and in ether; most abundantly in oil of vitriol, which dissolves about six hundred times its volume of methyl-ether gas, thus affording a very handy means for storing up the gas for use. The solution needs only be diluted with its own volume of water to be broken up into its components (Erlenmeyer).

Liquefied oxide of methyl is now being produced on the manufacturing scale, and sold as a powerful refrigerating agent. One part of sulphuric acid is mixed with a little over one part of dehydrated wood-spirit, and the mixture heated to 125° to 128° C. (130° being carefully avoided), when methyl-ether goes off. When the mixture is exhausted, more wood-spirit is added to the residue so as to re-establish the original specific gravity (of 1·29), and the heating resumed, which again furnishes a supply of the gas, and so on. This proves that the process is not, as used to be supposed, one of mere dehydration, but a cycle of reactions analogous to those in the ordinary process of etherification, as shown by the equations:—

(1) $SO_4H_2 + CH_3OH = SO_4 . HCH_3 + H_2O$.

(2) $SO_4 . H . CH_3 + H . O . CH_3 = SO_4HH + CH_3 . O . CH_3$.

The ester, $SO_4(CH_3)$, though obtainable by distillation of the alcohol with 10 parts of vitriol, is more conveniently prepared from pure methyl-sulphuric acid by distillation in vacuum at 130°–140° C; thus:—$2SO_4CH_3 . H = SO_4H_2 + SO_4(CH_3)_2$. It is a colourless liquid, smelling like peppermint, specific gravity 1·327 at 18°; it boils at 187° to 188° C.

Chloride of methyl, CH_3Cl, readily produced by the action of hydrochloric acid gas and hot methyl-alcohol (preferably in the presence of chloride of zinc as an auxiliary dehydrator), is a gas which, under ordinary pressure, condenses into a liquid at $-23°$ C. The gas, at ordinary temperatures (though very readily soluble in alcohol), is only sparingly absorbed by water, which, however, at 6° unites with it into a solid hydrate. Condensed methyl chloride has become an article of commerce, being largely produced from trimethylamine (*vide infra*) and used as a powerful frigorific agent, as well as for the extraction of perfumes from flowers. Regarding nitrite of methyl, $NO—O—CH_3$, its interesting isomeride nitromethane, $O_2N—CH_3$, and nitrate of methyl, NO_3CH_3, we must refer to the handbooks of organic chemistry.

Iodide of methyl, CH_3, is obtained by distilling methyl-alcohol with hydriodic acid, which latter is best produced off-hand by addition to the alcohol of iodine and amorphous phosphorus. It is a colourless liquid of 2·269 specific gravity, boiling at 42°·5 C., insoluble in water.

Organic Methyl-Esters.—The more volatile ones are in general easily obtained by distillation of the respective acid with methyl-alcohol, or with methyl-alcohol and oil of vitriol (virtually $SO_4 . H . CH_3$); the less volatile ones more conveniently by passing hydrochloric acid gas into a methyl-alcoholic solution of the acid. We have no space for the individual substances; but the salicylate $C_7H_5O_3 . CH_3$ may just be named as being the principal component of the essential oil of *Gaultheria procumbens* (wintergreen oil).

Methylamines.—The general result of the action of ammonia on an ester is the formation of alcohol and acid amide. Example—

$$\underbrace{(C_2H_3O)-\overline{O-CH_3}}_{\text{Acetate of methyl.}} + HNH_2 = CH_3 . OH + \underbrace{C_2H_3O . NH_2}_{\text{Acetamide.}}.$$

With iodide of methyl this reaction is an obvious impossibility; what really takes place (as A. W. Hofmann has shown for this and all analogous cases) is that the iodide unites with the ammonia into the HI compound $HI . NH_2CH_3$ of a base NH_2CH_3, which can be separated from the acid by distillation with caustic potash, and when thus liberated presents itself as a gas surprisingly similar (almost to identity) to ammonia. The analogy extends to the action on iodide of methyl, which, in the case of methylamine, NH_2CH_3, leads to the formation of dimethylamine, $NH . (CH_3)_2$; and from the latter again trimethylamine, $N(CH_3)_3$, can be prepared by a simple repetition of the operation. These three amines are closely analogous in their chemical character to ammonia, the points of difference becoming the more marked the greater the number of (CH_3)'s in the molecule. Trimethylamine, having lost all its ammonia-hydrogen, cannot possibly act upon iodide of methyl like its analogues. What it really does is to unite with the iodide into "iodide of tetramethyl-ammonium," $I . N(CH_3)_4$, analogous to iodide of ammonium, INH_4, we should say, if it were not the reverse, because the organic iodide (unlike its prototype, which is an ammonium compound only in theory), when treated with moist oxide of silver (virtually with AgOH), really does yield a solution of a true analogue of caustic potash in the shape of hydroxide of tetramethyl-ammonium, $N(CH_3)_4 . OH$.

In regard to the actual preparation of these several bodies, which is not so simple as might appear from our exposition of their mutual relations, we must refer to the handbooks of organic chemistry. But we must not omit to state that trimethylamine, which only the other day was never seen outside a chemical museum, is now being manufactured on a large scale, and promises to play an important part in industrial chemistry. The waste liquors obtained in the distillation of alcohol from fermented beet-root molasses serve as a raw material for its preparation. These liquors, when evaporated to dryness and subjected to dry distillation, yield, besides tar and gases, an aqueous liquid containing large quantities of ammonia, acetonitrile, methyl-alcohol, and trimethylamine. This liquor is neutralized with sulphuric acid, and distilled, when the nitrile and the methyl-alcohol distil over, to be recovered by proper methods. From the mixed solution of the sulphates of ammonia and trimethylamine the former is separated out as far as possible by crystallization; the mother-liquor

is distilled with lime; the volatile bases are absorbed in hydrochloric acid; the hydrochloric solution is evaporated; and the sal-ammoniac which comes out at first is, as far as possible, fished out. The last mother-liquor is evaporated to dryness, and in this form represents commercial trimethylamine hydrochlorate. It is this product which serves for the preparation of methyl chloride (*vide supra*), the process being founded upon the fact that a concentrated solution of the salt, when heated, breaks up $3HCl \,.\, N(CH_3)_3$ into $2N(CH_3)_3$ of free trimethylamine + $NH_2 \,.\, CH_3HCl$ of hydrochlorate of monomethylamine and $2CH_3Cl$ of methyl chloride.

These processes are being carried out industrially by Vincent in France. But this base trimethylamine seems destined to do more than provide us with a new refrigerating agent. The attempt has been made—it would appear, with success—to utilize it for the preparation of pure carbonate of potash from native chloride of potassium, just as ordinary ammonia, in the famous ammonia-soda process, serves for the conversion of common salt into soda-ash.

Methyl Cyanides.—There are two distinct bodies which, by composition and by synthesis, are both $CH_3 + NC$; they are named "acetonitrile" (formerly called simply cyanide of methyl) and isocyanide of methyl or methylcarbamine respectively.

Acetonitrile was discovered by Dumas in 1847. It may be prepared by the distillation of a mixture of methylsulphate and of cyanide of potassium; but is obtained more easily and in a purer state by distilling acetamide with phosphoric anhydride. Acetate of ammonia may be used instead of the amide, but it does not work so well.

$CH_3 \,.\, CO \,.\, O(NH_4)$	$CH_3 \,.\, CO \,.\, (NH_2)$	$CH_3 \,.\, CN$
Acetate of NH_3	Acetamide	Nitrile
$= A$ (say).	$= A - H_2O$.	$= A - 2H_2O$.

It is a colourless liquid of a pungent aromatic odour, with specific gravity ·805 at 0°, and boils at 82° C. When heated with aqueous potash (at the wrong end of a condenser) it breaks up with formation of ammonia and acetate of potash. Whence we conclude that the methyl is combined more directly with the carbon of the cyanogen, thus:

$$N\{\overline{C—CH_3}\} + 2H_2O = NH_3 + \underset{\text{Acetic acid.}}{CH_3 \,.\, COOH} \,.$$

This conclusion is supported by the action on the nitrile of nascent hydrogen, which leads to the formation of ethylamine, thus (Mendius):—

$$NC—CH_3 + 4H = \underset{\text{Ethylamine.}}{H_2N—CH_2CH_3} \,.$$

In either case we pass from a monocarbon to a dicarbon body, virtually from methyl to ethyl alcohol.

The isocyanide is prepared by heating iodide of methyl with cyanide of silver (CH_3I; $2NCAg$) and ether in a sealed-up tube to 130° to 140°, to produce the crystalline body $AgNC + NCCH_3$ (and AgI). The double cyanide, when distilled with some water and cyanide of potassium, breaks up into its components,—the $NCAg$ forming $(NC)_2AgK$; and the cyanide of methyl distils over. It is a colourless liquid, characterized by quite an unbearably irritating and sickening smell. The specific gravity is ·756 at 14°, the boiling point 59° C. It combines with hydrochloric acid into a crystalline salt which is readily decomposed by water into methylamine and formic acid. Whence we conclude that in this case the cyanogen is tied to the methyl by its nitrogen; thus:—

$$C\{N—CH_3\} + 2H_2O = \underset{\text{Formic acid.}}{H \,.\, COOH} + \underset{\text{Methylamine.}}{NH_2 \,.\, CH_3} \,.$$

The methyl here remains methyl, being separated by an N from the cyanogen-carbon, which latter passes into formic acid.

We must not close this section without at least referring to the *methylphosphines*, as being a set of bodies related to PH_3 (phosphine) as the methylamines are to NH_3 (ammonia), and similar to these in their chemical character, in so far as they are bases. The points of difference between the two series are of pretty much the same sense as those between the two prototypes. Thus, for instance, while trimethylamine $N(CH_3)_3$ is a strong base, but inert to oxygen gas, trimethylphosphine is a relatively feeble base, but in contact with air greedily absorbs oxygen with formation of an oxide $P(CH_3)_3O$, the like of which in the nitrogen series has no existence.

Sulphur Compounds of Methyl.—Substances analogous to methyl-alcohol and methyl-ether respectively can be obtained by the distillation of methyl sulphate of potassium with strong solutions of the potassium sulphides KHS and K_2S respectively. The body $CH_3 \,.\, SH$ is known as methyl-mercaptane, the other $(CH_3)_2S$ as sulphide of methyl. Both are very volatile stinking liquids. Sulphide of methyl claims a special interest as being the starting point for the preparation of an important class of bodies called trymethyl sulphine compounds. The sulphide $(CH_3)_2S$ readily unites with the iodide CH_3I into crystals of iodide of trimethyl sulphine, $(CH_3)_3S \,.\, I$, a substance which is closely analogous in its chemical character to the iodide of tetramethyl-ammonium. Moist oxide of silver, for instance, converts it into a strongly basic hydrate, $S(CH_3)_3 \,.\, OH$, which in its avidity for acids almost beats its analogon in the nitrogen family. An investigation of its salts was published by Crum Brown and Blaikie.

Methyl Arsenides.—Arseniferous bases constituted like mono- or di-methylamine (bodies such as AsH_2CH_3, analogous to $NH_2 \,.\, CH_3$) do not seem to exist. What we do know of are—(1) a trimethylarsine and the iodide and the hydroxide of tetramethylarsonium, —$As(CH_3)_3$, $As(CH_3)_4I$, and $As(CH_3)_4OH$,—bodies discovered by Cahours and Riche; (2) a whole series of monomethylic bodies, $As(CH_3)X_2$ (where $X = Cl$, Br, or $X_2 = O, S$), discovered by Baeyer in 1857; (3) the kakodyle compounds, a series of bodies, $As(CH_3)_2 \,.\, X$ or $As(CH_3)_2 \,.\, X_3$, which were discovered and investigated by R. Bunsen in 1842. This great investigation marks an epoch in the history of organic chemistry, and our article would not be complete without at least a short summary of its results. Bunsen started in his investigation with a liquid which had been obtained by Cadet as early as 1760, by the dry distillation of equal parts of white arsenic and anhydrous acetate of potash, and which nobody cared to investigate because it emits fumes which have an indescribably sickening smell and an intensity of poisonous action, compared with which that of white arsenic itself appears insignificant. It was reserved for Bunsen to attack this awful substance and force it to give an account of itself. According to Bunsen, Cadet's liquid is substantially an oxide, $(AsC_2H_6)_2O$, which has strongly basic properties, readily exchanging its O for Cl_2, &c. To obtain the pure substance, the liquor is distilled with corrosive sublimate and hydrochloric acid, which in the first instance yields the pure muriate of the base $As(CH_3)_2Cl$, in the form of a liquid volatile above 100° into vapours which take fire spontaneously in air. From this chloride of kakodyle the pure oxide is obtained by distillation with caustic potash. The pure oxide emits no fumes; its specific gravity is 1·462; it boils near 150°. A mixture of its vapour with air detonates at 50° C. From the chloride again, Bunsen obtained the free radical *kakodyle*, $(AsC_2H_6)_2$, by treatment with metallic zinc in a special apparatus, so constructed that all the several operations involved could be carried out without bringing the contents in contact with air,—a necessary precaution, because kakodyle is a liquid which takes fire in air spontaneously even at ordinary temperatures. Pure kakodyle is a heavy colourless liquid boiling at about 170° C., and freezing at −6°. When exposed to oxygen or chlorine it suffers destructive combustion; but on slow access of air it is oxidized into its oxide, $(AsC_2H_6)_2O$, and kakodylic acid; with chlorine water it unites into the chloride which it came from; it also unites directly with sulphur and other elements; in short, it is exactly to kakodyle compounds what potassium is to potash and potash salts, "a true organic element," as Bunsen himself put it. This discovery of Bunsen's was greeted with an enthusiasm which it is difficult in these days to realize. With us now, a radical is intrinsically a fiction; it was different in 1842. By the isolation of kakodyle the "radical" notion suddenly rose from an unproved hypothesis to the rank of a theory based on experiment. Still, however much our theoretical notions may shift, Bunsen's research will stand as a piece of monumental scientific work.

Kakodylic acid, $As \,.\, O \,.\, (CH_3)_2 \,.\, OH$, is most conveniently prepared from the oxide by addition of water and oxide of mercury,—$H_2O + 2HgO$ supplying the $H_2 + O_3$ required for $1(AsC_2H_6)_2O$. This is a crystalline monobasic acid, soluble in water. Unlike the kakodylides of the $As \,.\, X_3$ type, it has no smell, and is no very violent poison. It takes six grains of it to kill a rabbit.

Metallic Methides.—Examples of these are—$Sb(CH_3)_3$; $Sb(CH_3)_5$; $Mg(CH_3)_2$; $Zn(CH_3)_2$; $Pb(CH_3)_4$; $Al(CH_3)_3$; $Sn(CH_3)_4$. To give an idea of the chemical character of this interesting class of bodies we choose *zinc-methyl* as a representative example, and state briefly the chief points of its chemical history. This body was discovered by Frankland in 1849. It is prepared by boiling iodide of methyl over granulated zinc in a flask connected with an inverted condenser, and so contrived otherwise that the contents are protected against access of moisture and oxygen. Under these circumstances the two ingredients gradually unite into a non-volatile and solid compound $IZn \,.\, (CH_3)$. When this body is heated with more of iodide of methyl, it undergoes decomposition, with formation of iodide of zinc and of dimethyl gas, $I—Zn—CH_3 + CH_3I = ZnI_2 + (CH_3)_2$, which reaction to some extent takes place unavoidably in the preparation of the zinc salt, however great an excess of metal may be taken. What survives needs only to be subjected to dry distillation (in the absence of air) to yield a distillate of zinc-methyl:—

$$2I—Zn—CH_3 = ZnI_2 + Zn(CH_3)_2 \,.$$

Zinc-methyl is a colourless liquid of 1·386 specific gravity at 10°·5, which boils at 46° C.; in contact with air it takes fire. Water decomposes it at once into hydrate of oxide of zinc and marsh gas, $Zn(CH_3)_2 = Zn(OH)_2 + 2CH_3H$. Of other reactions the following may be named. (1) When digested with sodium, it yields a precipitate of metallic zinc, and a double compound of itself and sodium-methyl. This latter unites readily with carbonic acid into acetate of soda, $NaCH_3 + CO_2 = CH_3{-}CO{-}ONa$ (Wanklyn). (2) With chloride of acetyl it forms acetone, $Zn(CH_3)_2 + 2CH_3 . CO . Cl = ZnCl_2 + 2CO(CH_3)_2$ (Freund). (3) Under somewhat different conditions, including the presence of an excess of $Zn(CH_3)_2$, a compound is produced which with water, yields tertiary butyl-alcohol (Boutlerow):

$$CO(CH_3)_2 + Zn(CH_3)_2 = C(CH_3)_3 . O . ZnCH_3 = A;$$
$$A + 2H . OH = Zn(OH)_2 + CH_4 + \underbrace{C(CH_3)_3 - OH}_{\text{Tertiary alcohol.}}$$

(W. D.)

METRONOME, an instrument for denoting the speed at which a musical composition is to be performed. Its invention is generally, but falsely, ascribed to Johann Nepomuk Maelzel, a native of Ratisbon (1772–1838). It consists of a pendulum swung on a pivot; below the pivot is a fixed weight, and above it is a sliding weight that regulates the velocity of the oscillations by the greater or less distance from the pivot to which it is adjusted. The silent metronome is impelled by the touch, and ceases to beat when this impulse dies; it has a scale of numbers marked on the pendulum, and the upper part of the sliding weight is placed under that number which is to indicate the quickness of a stated note, as M.M. (Maelzel's Metronome) 𝅗𝅥 = 60, or ♩ = 72, or ♪ = 108, or the like. The number 60 implies a second of time for each single oscillation of the pendulum,—numbers lower than this denoting slower, and higher numbers quicker beats. The scale at first extended from 50 to 160, but now ranges from 40 to 208. A more complicated metronome is impelled by clock-work, makes a ticking sound at each beat, and continues its action till the works run down; a still more intricate machine has also a bell which is struck at the first of any number of beats willed by the person who regulates it, and so signifies the accent as well as the time.

The earliest instrument of the kind, a weighted pendulum of variable length, is described in a paper by Étienne Loulié (Paris, 1696; Amsterdam, 1698). Attempts were also made by Enbrayg (1732) and Gabory (1771). Harrison, who gained the prize awarded by the English Government for his chronometer, published a description of an instrument for the purpose in 1775. Davaux (1784), Pelletier, Abel Burja (1790), and Weiske (also 1790) described their various experiments for measuring musical time. In 1813 Gottfried Weber, the composer, theorist, and essayist, proposed a weighted ribbon graduated by inches or smaller divisions, which might be held or otherwise fixed at any desired length, and would infallibly oscillate at the same speed so long as the impulse lasted; this, the simplest, is also the surest, the most enduring, the most portable, and the cheapest invention that has come before the world, and one can but wonder that it has not been universally accepted. Stöckel and Zmeskall produced each an instrument; and Maelzel made some slight modification of that by the former, about the end of 1812, which he announced as a new invention of his own, and exhibited from city to city on the Continent. It was, as nearly as can be ascertained, in 1812 that Winkel, a mechanician of Amsterdam, devised a plan for reducing the inconvenient length of all existing instruments, on the principle of the double pendulum, rocking on both sides of a centre and balanced by a fixed and a variable weight. He spent three years in completing it, and it is described and commended in the *Report of the Netherlands Academy of Sciences*, August 14, 1815. Maelzel thereupon went to Amsterdam, saw Winkel and inspected his invention, and, recognizing its great superiority to what he called his own, offered to buy all right and title to it. Winkel refused, and so Maelzel constructed a copy of the instrument, to which he added nothing but the scale of numbers, took this copy to Paris, obtained a patent for it, and in 1816 established there, in his own name, a manufactory for metronomes. When the impostor revisited Amsterdam, the inventor instituted proceedings against him for his piracy, and the Academy of Sciences decided in Winkel's favour, declaring that the graduated scale was the only point in which the instrument of Maelzel differed from his. Maelzel's scale was needlessly and arbitrarily complicated, proceeding by twos from 40 to 60, by threes from 60 to 72, by fours from 72 to 120, by sixes from 120 to 144, and by eights from 144 to 208. Dr Crotch constructed a time-measurer, and Henry Smart (the violinist, and father of the composer of the same name) made another in 1821, both before that received as Maelzel's was known in England. In 1882 James Mitchell, a Scotsman, made an ingenious amplification of the Maelzel clock-work, reducing to mechanical demonstration what formerly rested wholly on the feeling of the performer. Although "Maelzel's metronome" has universal acceptance, the silent metronome and still more Weber's graduated ribbon are greatly to be preferred, for the clock-work of the other is liable to be out of order, and needs a nicety of regulation which is almost impossible; for instance, when Sir George Smart had to mark the traditional times of the several pieces in the Dettingen Te Deum, he tested them by twelve metronomes, no two of which beat together. The value of the machine is exaggerated, for no living performer could execute a piece in unvaried time throughout, and no student could practise under the tyranny of its beat; and conductors of music, nay, composers themselves, will give the same piece slightly slower or quicker on different occasions, according to the circumstances of performance.

METSU, Gabriel, a Dutch painter of celebrity (born in 1630, died after 1667), is one of the few artists of renown in Holland whose life has remained obscure. Houbraken, who eagerly collected anecdotes of painters in the 18th century, was unable to gather more from the gossip of his contemporaries than that, as early as 1658, Metsu, at the age of forty-three, submitted to a dangerous surgical operation. The inference drawn by superficial readers from this statement has been that death immediately ensued. A more careful perusal would have shown that Houbraken knew that Metsu had given lessons to De Musscher in 1665. Local records now reveal that Gabriel was the son of Jacques Metsu, who lived most of his days at Leyden, where he was three times married. The last of these marriages was celebrated in 1625, and Jacomina Garnijers, herself the widow of a painter, gave birth to Gabriel in 1630. Connected by both his parents with art, Metsu was probably taught first by his father and then by Gerard Dow. He probably finished his training under Rembrandt. So far back as 1648, but a few days earlier than Jan Steen, who is said to have painted his portrait, Metsu was registered in the painters' corporation at Leyden; and the books of the guild also tell us that he remained a member in 1649. In 1650 he ceased to subscribe, and works bearing his name and the date of 1653 give countenance to the belief that he had then settled at Amsterdam, where he continued his studies under Rembrandt. His companions at the time would naturally be De Hooch and Van der Meer, whose example he soon followed when it came to his turn to select the class of subjects for which his genius fitted him. Under the influence of Rembrandt he produced the Woman Taken in Adultery, a large picture with the date of 1653, in the Louvre, in which no one would suspect the painter of high life or taverns were it not that his name is written at full length on the canvas. The artist who thus repeated the gospel subjects familiar to

general rising throughout Germany, he expressed in his despatches no distrust of the power of Austria to cope with Napoleon. This is the more singular because, after the disastrous issue of the campaign of 1809, Metternich seems to have taken credit for having opposed the policy of war. Napoleon again captured Vienna; the battle of Wagram was lost; and after a long negotiation Austria had to purchase peace by the cession of part of Austrian Poland and of its Illyrian provinces. Metternich, who had virtually taken Count Stadion's place immediately after the battle of Wagram, was now installed as minister of foreign affairs. The first striking event that took place under his administration was the marriage of Marie Louise, daughter of the emperor Francis, to his conqueror Napoleon. To do justice to Metternich's policy it must be remembered that the alliance of Tilsit between France and Russia was still in existence, and that Austria was quite as much threatened by the czar's designs upon Turkey as by Napoleon's own aggressions. Metternich himself seems, in spite of his denials, to have been the real author of the family union between the houses of Hapsburg and Bonaparte,—a most politic, if not a high-spirited measure, which guaranteed Austria against danger from the east, at the same time that it gave it at least some prospect of security from attack by Napoleon, and enabled Metternich to mature his plans for the contingency of an ultimate breach between France and Russia. In 1812 this event occurred. Metternich, in nominal alliance with Napoleon, sent a small army into southern Russia, allowing it to be understood by the czar that the attack was not serious. Then followed the annihilation of the French invaders. While Prussia, led by its patriots, declared war against Napoleon, Metternich, with rare and provoking coolness, held his hand, merely stating that Austria would no longer regard itself as a subordinate ally, but would act with all its force on one side or the other. The result of this reserve was that Metternich could impose what terms he pleased on Russia and Prussia as the price of his support. The armies of these two powers, advancing into central Germany, proved no match for the forces with which Napoleon took the field in the spring of 1813; and the hard-fought battles of Lützen and Bautzen resulted in the retreat of the allies. After the combatants had made an armistice, Metternich tendered Austria's armed mediation, requiring Prussia to content itself with the restoration of its territory east of the Elbe, and leaving Napoleon's ascendency in Germany almost untouched. Napoleon, after a celebrated interview with Metternich, madly rejected terms so favourable that every Prussian writer has denounced Metternich's proposal of them as an act of bitter enmity to Prussia. On the night of the 10th of August the congress of Prague, at which Austria, as armed mediator, laid down conditions of peace, was dissolved. Metternich himself gave orders for the lighting of the watch-fires which signalled to the armies in Silesia that Austria had declared war against Napoleon. The battle of Leipsic and the campaign of 1814 in France followed, Metternich steadily pursuing the policy of offering the most favourable terms possible to Napoleon, and retarding the advance of the allied armies upon the French capital. Metternich had nothing of that personal hatred towards the great conqueror which was dominant both in Prussia and in England; on the contrary, though he saw with perfect clearness that, until Napoleon's resources were much diminished, no one could be safe in Europe, he held it possible to keep him in check without destroying him, and looked for the security of Austria in the establishment of a balance of power in which neither Russia nor France should preponderate, while Prussia should be strictly confined within its own limits in northern Germany. The assistance of the Austrian army, which was no doubt necessary to the allies, had, so far as related to Prussia, been dearly purchased. When, at the beginning of 1813, Prussia struck for the freedom of Germany, its leading statesmen and patriots had hoped that the result of the war of liberation would be the establishment of German unity, and that the minor German princes, who had been Napoleon's vassals since 1806, would be forced to surrender part of their rights as sovereigns, and submit to a central authority. This dream, however, vanished as soon as Austria entered the field as an ally. It was no part of Metternich's policy to allow anything so revolutionary as German unity to be established, least of all under the influence of Prussian innovators. He made treaties with the king of Bavaria and Napoleon's other German vassals, guaranteeing them, in return for their support against France, separate independence and sovereignty when Germany should be reconstructed. Accordingly, though the war resulted, through Napoleon's obstinate refusal of the terms successively offered to him, in the limitation of France to its earlier boundaries and in a large extension of Prussia's territory, the settlement of Germany outside Prussia proceeded upon the lines laid down by Metternich, and the hopes of unity raised in 1813 were disappointed. A German confederation was formed, in which the minor sovereigns retained supreme power within their own states, while the central authority, the federal diet, represented, not the German nation, but the host of governments under which the nation was divided. Metternich even advised the emperor Francis of Austria to decline the old title of German emperor, disliking any open embodiment of the idea of German unity, and preferring to maintain the ascendency of Austria by a gentle pressure at the minor courts rather than by the avowed exercise of imperial rights. In this unprogressive German policy Metternich was completely successful. His great opponent, Stein, the champion of German unity and of constitutional systems, abandoned his work in despair, and refused the useless post of president of the diet, which Metternich, with a kind of gentle irony, offered to him.

The second branch of Metternich's policy in 1813–14 was that which related to Italy. Following the old maxims of Austrian statesmanship, Metternich aimed not only at securing a large territory beyond the Alps but at making the influence of Austria predominant throughout the Italian peninsula. The promises of national independence which had been made to the Italians when they were called upon to rise against Napoleon were disregarded. In the secret clauses of the first treaty of Paris the annexation of both Lombardy and Venetia was guaranteed to Austria, and the rest of Italy was divided into small states as of old. Napoleon's return from Elba led to the downfall of Murat, who had been allowed to retain the kingdom of Naples, and to the reunion of this country with Sicily, under the Bourbon Ferdinand. After the second overthrow of Napoleon, Metternich endeavoured to make every Italian sovereign enter into a league under Austria's presidency. Ferdinand of Naples accepted the position of vassal, but the pope and the king of Sardinia successfully maintained their independence. With the construction of the German federation, and the partial construction of an Italian federation, both under Austria's guidance, the first part of Metternich's career closes. He had guarded Austria's interests with great skill during the crisis of 1813 and 1814. It was not his own fault, but the fault of ages, that Austria's interests were in antagonism to those of German and of Italian nationality. He thought as an Austrian, and as nothing else; his task was to serve the house of Hapsburg, and this he did with signal ability and success. To denounce Metternich as a kind of criminal, according to the practice

have absolute monarchy restored. The proceedings of the congress at Laibach were a farce. A letter was concocted by Metternich for King Ferdinand to send to his subjects, informing them that the powers would not permit the constitution to exist, and that, in default of their submission, the allied courts would employ force. The British Government, while protesting against the joint action of the three powers as an assumption of international sovereignty, was perfectly willing that Austria, as a state endangered by the Neapolitan revolution, should act on its own account. Metternich, however, continued to treat the Neapolitan question as the affair of Europe, and maintained his concert with Russia and Prussia. Early in 1821 an Austrian force, acting in the name of the allies, entered central Italy. The armies opposed to it collapsed, and the Austrians entered Naples on March 24. But in the meantime a revolution broke out in Piedmont, which threatened to cut off the Austrians from their supports, and to raise all Italy against them. For a moment the bold action of Metternich seemed to have resulted in immense danger both to his own conservative policy and to the peace of Europe; for it was believed that the Piedmontese revolution would be answered, not only by a general Italian movement, but by a rising against the Bourbons in France. The cloud, however, passed away. Order was quickly restored in Piedmont; Lombardy was safely held by Austrian garrisons; and the conclusion of the Italian difficulties, in which Metternich had played a very difficult part with great resolution and dexterity, was his complete and brilliant personal triumph. No statesman in Europe at this moment held a position that could compare with his own.

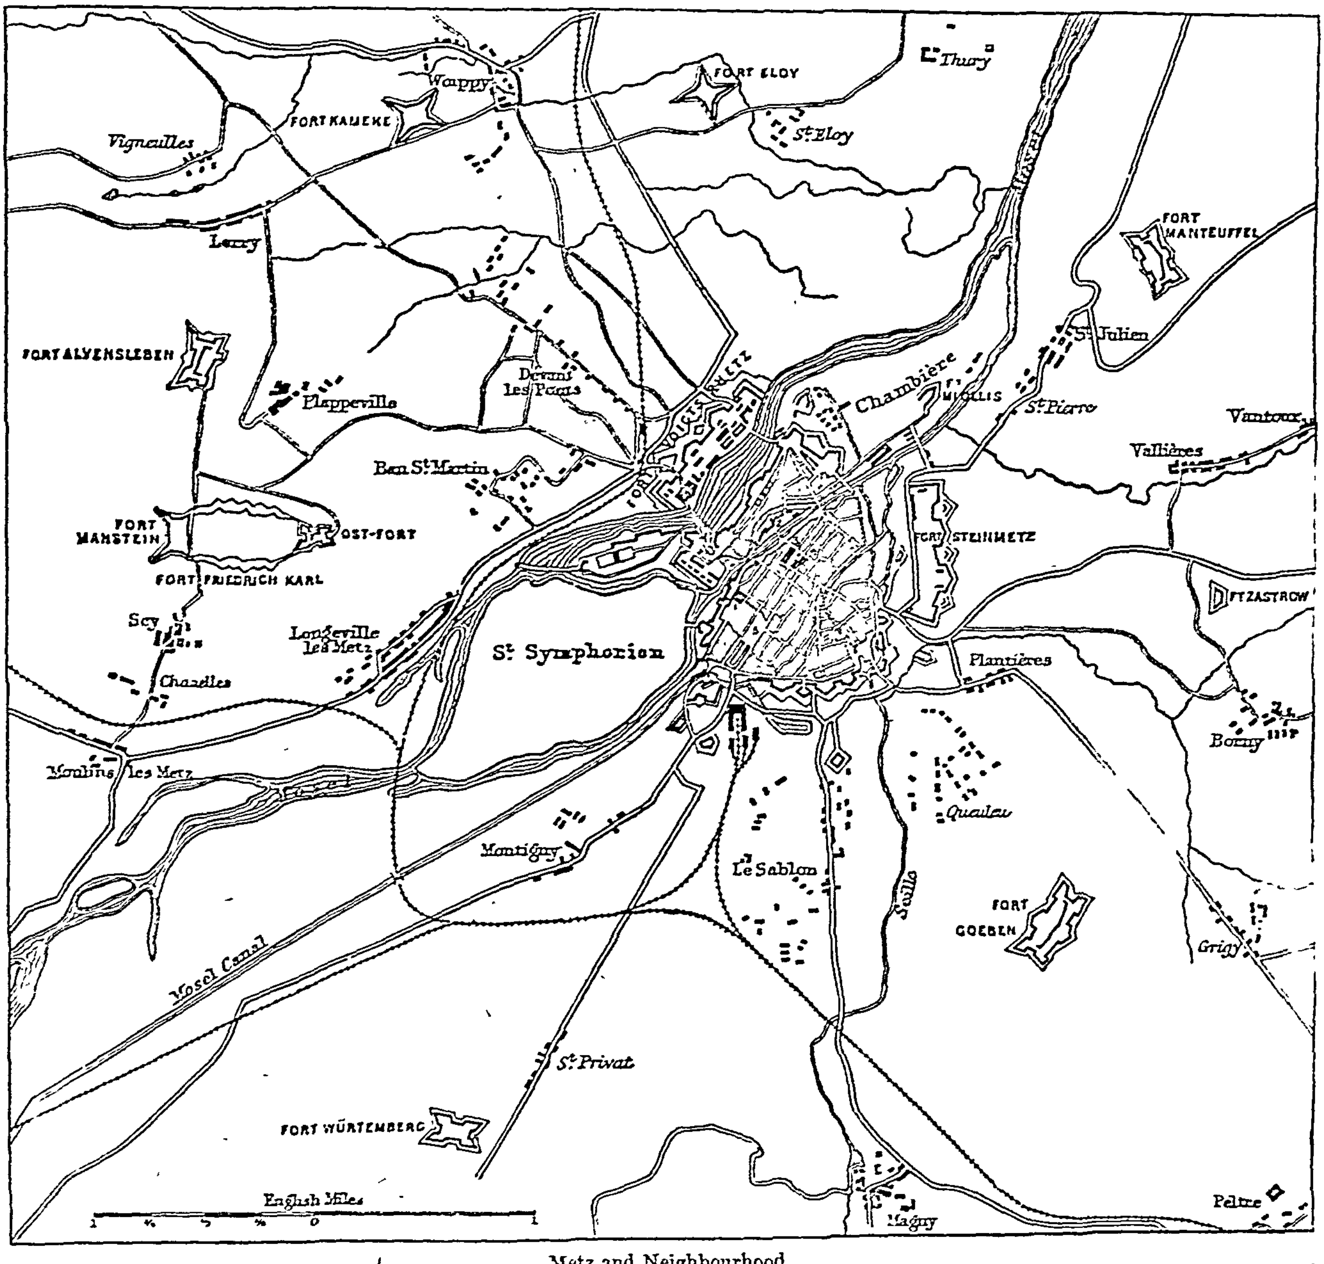
At the congress of Verona, held in 1822, the affairs of Spain were considered by the powers. In the end, the Spanish constitution was overthrown by a French invading army; but, though the arm employed was that of France, the principle of absolutism which animated the crusade was that which Metternich had made his own. A severe check, however, now met him in another quarter. Greece had risen against Turkish rule in 1821. The movement was essentially a national and a religious one, but Metternich treated it as a Jacobinical revolt against lawful authority,—confusing, or affecting to confuse, the struggle for national independence with the shallow and abortive efforts of political liberalism in Italy and Spain. Metternich's attitude towards the Greeks was for some time one of unqualified hostility. If, under the pressure of the Tilsit alliance, he had once been willing that Austria should join Russia in dismembering Turkey, he had now reverted to the principle of maintaining Turkey at all costs against a Russian advance southwards; and he attributed the Greek movement to the efforts of Russian agitators unauthorized by the czar. His desire was that the sultan should deprive Russia of all possible cause for complaint as regarded its own separate interests, and so gain freedom to deal summarily with the Greeks. Metternich's hopes failed, partly through the obstinacy of the Turks, partly through the wavering conduct of Alexander, and partly through the death of Castlereagh and the accession of Canning to power. It was in great part owing to Canning's moral support that Greece ultimately became an independent state; and the extraordinary violence of Metternich's language whenever he mentions this English statesman marks only too well the opposite character of his aims. No politician has left a more damning record against himself than Metternich in his bigoted abuse of Canning. The Greek question, however, was only the first on which the judgment of events was now beginning to declare itself against Metternich and all his principles. The French revolution of 1830 shattered the moral fabric which he had so proudly inaugurated, and in great part himself raised, in 1815. The accord that grew up between England and France now made any revival of the kind of presidency that he had once held in Europe impossible. He was indeed bold and rapid in throwing troops into the papal territory when revolutionary movements broke out there in 1831 and 1832, though war with France seemed likely to result from this step. He was as unsparing as he had been in 1819 in suppressing the agitation which after 1830 spread from France to Germany; and the union of the three eastern courts was once more exhibited in the meeting of the monarchs which took place at Münchengrätz in 1833, and in a declaration delivered at Paris, insisting on their right of intervention against revolution in other countries. It was, however, the new czar of Russia, Nicholas, who was now the real head of European conservatism; and the stubborn character, the narrow, unimaginative mind, of this prince made it impossible for Metternich to shape his purposes by that delicate touch which had been so effective with his predecessor. But in Austria itself Metternich continued without a rival. In 1835 the emperor Francis, with whom he had worked for nearly thirty years, died. Metternich, himself falling into the mental habits of old age, remained at the head of the state till 1848. The revolution of that year ended his political career. He resigned office with the dignity of demeanour which had never failed him; his life was scarcely safe in Vienna, and the old man came for a while to England, which he had not visited since 1794. Living on till June 1859, he saw every great figure of his earlier life, and many that had appeared on the horizon since his own prime, pass away; and a few more months of life would have enabled him to see the end of that political order which it had been his lifework to uphold; for the army of Napoleon III. was crossing the Sardinian frontier at the moment when he died, and before a second summer had gone Victor Emmanuel had been proclaimed king of Italy.

Metternich was a diplomatist rather than a statesman. His influence was that of an expert manager of individuals, not of a man of great ideas. All his greatest work was done before fifty; and at an age when most statesmen are in the maturity of their powers he had become tedious and pedantic. His private character was very lovable. He was an affectionate if not a faithful husband, a delightful friend, and a most tender father. The excessive egotism which runs through his writings gives perhaps an impression of weakness which did not really belong to his nature. Drawn by a firmer pen, the scene in which he describes himself labouring in the German conferences of 1820, while his favourite daughter was dying in an adjoining room, would have been one of the most affecting things in political biography. The man who could so have worked and felt together must have possessed no ordinary strength of character, no common force of self-control.

The collection of Metternich's writings published by his family under the title of *Denkwurdigkeiten*, along with French and English editions, contains letters and despatches of great value. The autobiography is not always trustworthy, and must be read with caution. Gentz's correspondence is of first-rate importance for the years 1813–30. Original papers are also contained in various German works upon particular events or movements, as in Oncken for the negotiations of 1813; Welcker, Aegidi, Nauwerck for German affairs in 1819 and following years; Prokesch von Osten for Eastern affairs. (C. A. F.)

METZ, the capital of German Lorraine, and one of the strongest fortresses in Europe, is situated at the confluence of the Moselle and the Seille, 80 miles to the north-west of Strasburg, and 190 miles to the east of Paris. It is the seat of a military governor, the judicial and administrative authorities of Lorraine, a Roman Catholic bishop,

Protestant and Jewish consistories, and a chamber of commerce. The general appearance of the town is quaint and irregular, but there are also many handsome modern streets. The Moselle flows through it in several arms, crossed by fourteen or fifteen bridges. In the south-west corner of the town is the esplanade, an extensive open space commanding a fine view of the fertile "Pays Messin" around Metz. The most interesting of the ten city gates is the Porte d'Allemagne or Deutsches Thor, a castellated structure erected in 1445, and still bearing traces of the siege of Charles V. Metz contains seven Roman Catholic churches, two Protestant churches, and a synagogue. The cathedral, with huge pointed windows, slender columns, and numerous flying buttresses, was begun in the 13th century, and finished in 1546, and belongs to the decadence of the Gothic style. The Gothic churches of St Vincent and St Eucharius, and the handsome garrison-church, completed in 1881, also deserve mention. Among secular buildings the most important are the large covered market, the town-hall, the palace of justice, the theatre, the governor's house, and the various buildings for military purposes. The public library contains 35,000 volumes, including an



Metz and Neighbourhood.

1. Palace of Justice. 2. Prefecture. 3. Cathedral. 4. Town-Hall and Governor's House.

extensive collection of works relating to the history of Lorraine. In the same building is the museum, which contains a picture gallery, a numismatic cabinet, and a collection of specimens of natural history. Metz also possesses several learned societies and charitable institutions, a gymnasium, three seminaries, and a military academy. The cemetery of Chambière contains the graves of 8400 French soldiers who died here in 1870.

The commerce and industry of Metz have not yet entirely recovered from the blow inflicted by the withdrawal of French capital in 1871. The principal articles of manufacture are leather, coarse cloth and canvas, gunpowder, arms, needles, billiard tables, hats, and artificial flowers. There are several large iron-works in the neighbourhood. The trade of Metz is chiefly carried on in leather, timber, wine, brandy, liqueurs, beer, preserved fruits, and hardwares. A large annual fair is held here. The civil population of Metz, which in 1869 amounted to 48,066, sank in 1872 to 33,134. Since then it has steadily increased, and in 1881 was 43,275, about half of whom were Germans. The garrison of Metz consists of 10,000 men, or including the surrounding forts nearly 16,000. The total of 58,813 includes 17,000 Protestants and 1600 Jews.

History.—Metz, the Gallic Divodurum, was the chief town of the Mediomatrici, and was also called by the Romans Mediomatrica, a name from which the present form has been derived by contraction. Cæsar describes it as one of the oldest and most important towns in Gaul. The Romans, recognizing its strategical importance, fortified it and supplied it with water by an imposing aqueduct, the remains of which still exist. Under the Roman emperors Metz was connected by military roads with Toul, Langres, Lyons, Strasburg, Verdun, Rheims, and Treves. Christianity was introduced in the 3d century of our era. In the middle of the 5th century the town was plundered by the Huns under Attila; subsequently it came into the possession of the Franks; and in 512 it was made the capital of Austrasia. On the partition of the Carolingian realms in 843 Metz fell to the share of the western kingdom as the capital of Lorraine. Its bishops, whose creation reaches back to the 4th century, now began to be very powerful. Metz acquired the privileges of a free imperial town in the 12th century, and attained great commercial prosperity. In 1552 it fell into the hands of the French through treachery, and was heroically and successfully defended against Charles V. by the young duke of Guise. It now sank to the level of a French provincial town, and its population dwindled from 60,000 to 22,000 (1698). At the peace of Westphalia Metz, with Toul and Verdun, was formally ceded to France, in whose possession it remained for upwards of two centuries. In August 1870 the successes of the German troops compelled Marshal Bazaine and the French army of the Rhine to seek shelter behind the fortifications of Metz, which was forthwith subjected by the Germans to a rigorous blockade. After an investment of ten weeks, during which not a single shot was fired at the town, Bazaine capitulated, surrendering to the victors an army of nearly 180,000 men, several hundred cannon, and an immense quantity of military stores of all kinds. By the peace of Frankfort in 1871 Metz was again united to the German empire. Marshal Fabert and Generals Custine and Kellermann were natives of Metz.

As a fortress Metz has always been of the highest importance, and it now ranks with Strasburg as one of the two great bulwarks of the west frontier of Germany. The original town-walls were replaced by ramparts in 1550, and the citadel was built in 1566. In 1674 the works were reconstructed by the celebrated military engineer Vauban. Under Napoleon III. the fortress was strengthened to meet the demands of modern warfare, and since 1871 the Germans have spared neither time nor money in completing and supplementing his plans. The present fortifications of Metz consist of two lines—an inner circle of bastions and ramparts enclosing the city itself, and an outer circle of large detached forts on the surrounding hills. The inner line is strengthened by two citadels, one of which is advanced as a tête-de-pont on the left bank of the Moselle. The outer circle consists of nine or ten large forts, connected with each other by smaller fortifications and commanding all the approaches to the city. They form a large fortified camp with a circumference of 15 miles, within which are twelve villages and numerous country-houses and farms. The most distant of the outlying forts is about 3½ miles from the cathedral. Their names and positions may be seen on the annexed plan. Previous to 1870 the fortress of Metz had never succumbed to an enemy.

Sources of Information.—Westphal, *Geschichte der Stadt Metz*, 1875-78; Georg Lang, *Metz und seine Umgebungen*, 1883, and *Statistisch-topographisches Handbuch für Lothringen*. The official German account of the blockade of Metz in 1870 will be found in the history of the Franco-German war issued by the general staff at Berlin, 1872 *sq.* A succinct account is given by Georg Lang, *Die Kriegsoperationen um Metz im Jahr* 1870, 2d ed., Metz, 1880.

MEULEN, Antony Francis van der (1634–1690), was called to Paris about 1666 by Colbert, at the instance of Le Brun, to fill the post of battle painter to Louis XIV. Born in 1634 at Brussels, he had at an early age eclipsed his master Peter Snayers, and the works executed by him for the king of France during the campaigns of Flanders (1667) so delighted Louis that from that date Van der Meulen was ordered to accompany him in all his expeditions. In 1673 he was received into the French Academy, and attained the grade of councillor in 1681. Lodged in the Gobelins, richly pensioned, and loaded with honours, he died at Paris in 1690. Detached works from his hand are to be seen in various collections, but he is best represented by the series of twenty-three paintings, mostly executed for Louis XIV., now in the Louvre. They show that he always retained his Flemish predilections in point of colour, although in other respects his style was modified by that of the French school.

See *Mém. inédit. Acad. de Peinture*, 1854; Descamps, *Vies des Peintres Flamands*.

MEURTHE-ET-MOSELLE, a department in the north-east of France, formed in 1871 out of those parts of the old departments of Meurthe and Moselle which continued French, and deriving its name from the two principal rivers which water it. Prior to 1790 it belonged to ancient Lorraine, or to one or other of the bishoprics of Toul, Metz, and Verdun. It lies between 5° 25′ and 7° 5′ E. long. and 48° 25′ and 49° 5′ N. lat., and is bounded on the E. by Alsace-Lorraine, on the N. by Belgium and the grand-duchy of Luxemburg, on the W. by the department of Meuse, and on the S. by that of Vosges. The superficial area is 2020 square miles. Geologically Meurthe-et-Moselle has five well-marked regions following each other in regular succession from east to north-west. On the frontier of Alsace are the Vosges mountains, of Trias sandstone (*grès Vosgiens*), with a maximum elevation of 3000 feet. A narrow band of variegated sandstone divides the Vosges from the second region, formed of shelly limestone, which extends as far as the Meurthe on the north and the Moselle on the west. The third region is formed by the variegated marls which cover the rich saline strata of the neighbourhood of Nancy. The Jura limestones of the Lias and Oolite, to the north-west and west of the department, form the last two regions. Here there is a maximum elevation of 1400 feet, and the plateau of Briey stretches out towards that of the Ardennes. Between the Vosges and the Ardennes the valley of the Moselle runs from south to north, forming the main artery of the department; the lowest level (570 feet) occurs where the river leaves it. Only a small part of the drainage of Meurthe-et-Moselle flows into the Meuse. The Moselle runs north-west from its entrance into the department as far as Toul; north-east from Toul to Frouard, where it receives its principal affluent, the Meurthe, and becomes navigable; north from Frouard to Pagny-sur-Moselle, passing to Pont à Mousson. The principal affluents of the Moselle are the Madon and the Orne on the left, and on the right, besides the Meurthe, the Seille, which in one part of its course forms the boundary of Alsace-Lorraine. The Meurthe, which flows to the north-west from Raon l'Étape to Frouard, passes on to Baccarat, Lunéville, St Nicholas, and Nancy, and is swelled on the right by the Vezouse and the Sanon, and on the left by the Mortagne. The principal tributary of the Meuse within the department is the Chiers, which takes its course by Longwy and Longuyon. Climatologically Meurthe-et-Moselle belongs to the Vosgian region. Its mean annual temperature is 52° Fahr., being 2° Fahr. lower than that of Paris (which has the same latitude). The thermometer in severe winters falls to 13° Fahr., while in summer it reaches 100° Fahr. This is to be accounted for by the general elevation of the department, the proximity of the mountains, the arrangement of the valleys (which lie open towards the north), and the distance from the sea.

More than half of the department consists of culturable land, one-fourth of forests, and one-tenth of meadow land. In 1878 there were 54,346 horses, more than 100,000 sheep, 85,000 pigs, 74,000 cattle, 15,000 goats, 21,000 dogs, and 17,000 hives of bees. The crops for the same year amounted to 454,192 quarters of wheat, 37,500 quarters of barley, 35,078 quarters of rye, 570,884 quarters of oats, 9,079,125 bushels of potatoes, and 76,868 tons of beet-root. Hops, tobacco, colza, hemp, and flax also occupy a considerable area. The annual yield of the vineyards (56 square miles in extent) exceeds £900,000; the wines of Toul are the best. The most common fruit trees are the pear, the apple, the walnut, the cherry, and the plum. Of forest trees the oak and the wych-elm are most frequent in the west of the department, the beech and the fir in the Vosges. The French school of forestry has its seat at Nancy. The metallurgic industry is highly developed, and has made very rapid progress within the last few years. Even in 1872 there was a consumption of 350,000 tons of coal, four-fifths of which came from Saarbruck, and the remaining fifth from Belgium. In 1877 the iron ore obtained amounted to 1,000,000 tons, of which two-thirds came from the beds near Nancy, the remainder from the neighbourhood of Longwy. In 1880 the department produced a third of the pig-iron made in France (more than 500,000 tons).

In 1877 the yield was 43,000 tons. Besides blast-furnaces, forges, and rolling-mills, there are manufactories of files and boring tools, agricultural implements, and furniture. In the production of salt the department holds the first rank in France; the salt-bearing tracts cover more than 150 square miles, the beds having a mean thickness of 65 feet. The principal salt-working centres (St Nicolas, Varangeville, and Rosières-aux-Salines) lie between Nancy and Lunéville; the annual value of rock-salt and refined salt produced exceeds £500,000; subsidiary to this production is an important manufacture of soda salts. The other chemical products are prussiate of potash, bone-black, wax-candles, soap, and matches. Stone quarrying and the manufacture of plaster and lime are also important branches of industry. The flint-glass manufactory of Baccarat, which employs nearly 1500 workmen, is well known; that of plate-glass at Cirey (with 1000 workmen) produces plates of great size. The faience manufactories of Lunéville, Toul, and Longwy are important. Mention may also be made of the manufacture of window-glass, watch-glasses, and drinking-glasses. The tobacco manufacture at Nancy employs 1000 workmen; tanning, glove-making, hat-making in felt and straw, wool-spinning, and the manufacture of army clothing are also carried on. Nancy is renowned for its embroidery, which is, however, diminishing in importance. It also possesses factories for cotton spinning and cotton stuffs, and for hosiery. The starch manufactories and the breweries, especially that of Tantonville, the largest in France, are highly productive. Nancy also carries on distilleries, grain-mills, paper-mills, manufactories of pasteboard objects, and a large printing establishment. The commerce of the department is effectively served by 300 miles of railway (the principal line being that from Paris to Strasburg through Nancy), by a number of good roads, and by several navigable rivers and canals. The main waterway is formed by the canal between the Marne and the Rhine, which runs by Toul and Nancy, and traverses the department from west to east. This canal communicates with the Moselle, which is navigable from Frouard downwards, and with the new eastern canal, which reascends the Moselle as far as Épinal, and which is intended to unite the Meuse and the Moselle with the Saône and the Rhone. The population of Meurthe-et-Moselle in 1881 was 419,317 inhabitants. It constitutes the diocese of Nancy, has its court of appeal at Nancy, and forms a part of the district of the 6th army corps (Châlons-sur-Marne). There are 4 arrondissements (Nancy, Briey, Lunéville, and Toul), 29 cantons, and 597 communes. The capital is Nancy, and the other principal towns are Pont à Mousson, formerly the seat of a university; Longwy (5064), a fortified place; and Baccarat (6013), celebrated for its glass-works.

MEUSE, MAESE, or MAAS, a river of France, Belgium, and Holland, discharging into the North Sea or German Ocean, has a course (variously measured) of some 500 or 550 miles, about 300 miles lying within France. Rising in the department of Haute-Marne (1342 feet), at a point where the plateau of Langres borders on the Monts Faucilles, it follows a winding course, first from south to north, then to north-west, and afterwards to north, across the departments of Vosges, Meuse, and Ardennes, passing by Neufchateau, Vaucouleurs, Commercy, St Mihiel, Verdun, Sedan, Mézières, and Givet. Naturally navigable below Verdun, it has been made so from Troussey, where it meets the canal which unites the Marne to the Rhine, and from this point to Liége it admits vessels of from 6 to 7 feet draught. After traversing a wide valley covered by green meadows, the Meuse, below Mézières, flows through narrow gorges confined between rocky walls 200 or 300 feet high, formed by the plateau of the Ardennes. The hills of the Argonne, by which it is hemmed in on its upper course, prevent its receiving any important affluent before the Chiers and the Semoy, which both fall into it on the right in the Ardennes. At the point where it leaves France its ordinary volume is about 1000 cubic feet. In Belgium it runs picturesquely between the districts of Famenne and Condroz on the right, and those of Les Fagnes and Hesbaye on the left. Above Dinant it receives the Lesse, whose valley is celebrated for its wonderful grottoes, and at the foot of the citadel of Namur it is joined on the left by its principal affluent, the Sambre, whose north-easterly direction it takes. It then takes its course through the busy valley in which Huy, Seraing, and Liége are situated, receiving the Ourthe on its right. Resuming a northerly direction, then taking one to the north-west, and finally one to the west, the Meuse passes in front of the Dutch citadel of Maestricht to Roermonde, so called from its confluence there with the Roer, and to Venlo, where the canal between the Meuse and the Scheldt begins. Flowing thence through an absolutely unbroken plain, it finally joins the Rhine, to which it gives its own name, although the volume of its waters is twenty times less than that of the German river. It is at Gorcum that the Waal, the first separate arm of the Rhine, brings to the Meuse two-thirds of the waters of that river. The Meuse soon after divides into two branches. While the Merwede flows due west, the southern arm falls into the Biesbosch, an estuary of the sea, formed four hundred and fifty years ago by an irruption of the sea over a country then cultivated and thickly peopled, and now the subject of attempts at reclamation. On reaching Dordrecht, where the river navigation and sea navigation meet, and where the rafts which come down from the Black Forest are broken up, the Meuse again divides into two arms. The Old Meuse flows due west, while the northern arm joins the Lek, a second branch of the Rhine, and continues its course to Rotterdam. This is the most important branch of the estuary of the Meuse, and efforts are being made to regulate and deepen its channel by constructing one of those grand canals in which the Dutch are so skilful. Schiedam and Vlardingen, both on the right, are the last places of importance on the banks of the river.

MEUSE, a department in the north-east of France, formed out of a part of Lorraine and portions of the Three Bishoprics, the Clermontais, and Champagne, derives its name from the river by which it is traversed from south to north. It lies between 4° 52′ and 5° 50′ E. long., and between 48° 25′ and 49° 38′ N. lat., and is bounded on the N. by Belgium and the department of Ardennes, on the E. by that of Meurthe-et-Moselle, on the S. by those of Vosges and Haute-Marne, and on the W. by those of Marne and Ardennes. Of its superficial area (2405 square miles), about one-half belongs to the basin of the Meuse, which is enclosed to the east and west by the eastern and western Argonnes. On the north-east it is watered by the Orne, a tributary of the Moselle, and the Chiers, which runs by Montmédy, and joins the Meuse a little beyond the northern limit of the department. The other half sends its waters to the Seine through the Aire, a tributary of the Aisne, both of which take their rise here, and by the Ornain, an affluent of the Saux, these two last being tributary to the Marne. The Meuse receives no important river in its course through this department. The highest elevation (1388 feet) occurs to the south-west, on the line of the ridge which separates the basin of the Meuse from that of the Seine. The heights gradually sink from south to north, but seldom fall below 1000 feet. The hills of the western Argonne similarly sink rapidly down to the valley of the Saux, where the lowest level of the department (377 feet) is reached. The climate of Meuse is transitional between the region of the Seine and that of the Vosges; its winters are less severe than those of the latter, but it is not so temperate as the former. The mean annual temperature is 52° Fahr. As at Paris, the maximum cold is 9° Fahr.; the greatest heat rarely exceeds 95° Fahr.

More than half the surface of the department consists of culturable lands, one-fourth of forest, one-tenth of meadow land. The proportion of horses is larger than in any other French department, except La Manche. There are 53,800 horses, 90,000 cattle, 145,000 sheep, 125,000 pigs, and nearly 30,000 beehives. Cereals, potatoes, and beet-root are the chief crops (in 1877 465,966 quarters of wheat, 104,660 quarters of barley, 585,355 quarters of oats, 7,677,374 bushels of potatoes, besides pulse, hemp, and colza). The vineyards produced more than 6,600,000 gallons of wine of good quality. The forests, which are principally of oak, are rich in game, as are the rivers in fish. The mineral wealth of the depart-

ment includes iron ore, good freestone, and fossil phosphates of lime. There are blast-furnaces, iron, copper, and bell foundries, wire-works, and manufactories of files, hardware, and edge tools. The cotton-spinning factories employ 15,000 spindles and 32,000 frames; the woollen manufacture employs 5000 spindles, and some hundreds of persons are employed in the spinning and weaving of hemp, flax, and jute. The glass-works (particularly the manufactory of painted window-glass, transferred after the war of 1870 from Metz to Bar-le-Duc), paper-mills, saw-mills, and flour-mills, as well as the manufactures of lime, tiles, and fire-bricks, are worthy of mention. Hosiery and embroidery also give occupation to a great number of workshops, and the department is celebrated for its confectionery. Meuse contains more than 300 miles of railway,—the principal lines being that from Paris to Strasburg through Bar-le-Duc and Commercy, that from Paris to Metz through Verdun, and the branch line to the Meuse. The chief waterways are the canal connecting the Marne with the Rhine, and the canal of the Meuse; the two together have a length of 146 miles. The population of the department in 1881 was 289,861,—a small number in proportion to its extent, and with a tendency to decrease. Ecclesiastically it forms the diocese of Verdun; it has its court of appeal at Nancy, and constitutes part of the district of the army corps of Châlons-sur-Marne. There are 4 arrondissements,—Bar-le-Duc, Commercy, Montmédy, and Verdun,—28 cantons, and 586 communes. Bar-le-Duc (population in 1881, 17,485) is the capital; Commercy has 5260 inhabitants and Montmédy 3000; St Mihiel (5915), on the Meuse, has good churches and some remarkable rocks, and is the seat of the departmental assize court.

MEXICO

I. ANCIENT MEXICO.

THE name Mexico is connected with the name of the group of American tribes calling themselves *Mexica* (sing. *Mexicatl*), or *Azteca*. The word is related to or derived from the name of the Mexican national war-god Mexitl, better known as Huitzilopochtli. The Aztecs from the 12th century appear to have migrated from place to place over the mountain-walled plateau of *Anahuac*, the country "by the water," so called from its salt lagoons, and which is now known as the valley of Mexico. About 1325 they founded on the lake of Tezcuco the permanent settlement of Mexico Tenochtitlan, which is still represented by the capital city Mexico. The name Mexico was given by the Spanish conquerors to the group of countries over which the Aztec power more or less prevailed at the time of the European invasion. Clavigero (*Storia Antica del Messico*, vol. i.) gives a map of the so-called "Mexican empire," which may be roughly described as reaching from the present Zacatecas to beyond Guatemala; it is noticeable that both these names are of Mexican origin, derived respectively from words for "straw" and "wood." Eventually Mexico and New Mexico came to designate the still vaster region of Spanish North America, which (till cut down by changes which have limited the modern republic of Mexico) reached as far as the Isthmus of Panama on the south and took in California and Texas on the north. Mexico in this wide sense is of high interest to the anthropologist, from the several native American civilizations which appear within its limits, and which conveniently if loosely group themselves round two centres, the Mexican proper and the Central American.

When early in the 16th century the Spaniards found their way from the West India Islands to this part of the mainland of America, they came in view of nations cultured high above the level they had hitherto met with in the New World. Here were not rude and simple tribes like the islanders of the Antilles, but nations with organized armies, official administrators, courts of justice, high agriculture and mechanical arts, and, what struck the white men especially, stone buildings whose architecture and sculpture were often of dimensions and elaborateness to astonish the builders and sculptors of Europe. How a population of millions could inhabit a world whose very existence had been till then unknown to geographers and historians, and how its nations could have reached so high a grade of barbaric industry and grandeur, was a problem which naturally excited the liveliest curiosity of scholars, and gave rise to a whole literature. Hernandez and Acosta shared the opinion of their time that the great fossil bones found in Mexico were remains of giants, and it was argued that, as before the deluge there were giants on the earth, therefore Mexico was peopled from the Old World in antediluvian times. On the other hand the multitude of native American languages suggested that the migration to America took place after the building of the tower of Babel, and Siguenza arrived at the curiously definite result that the Mexicans were descended from Naphtuhim, son of Mizraim and grandson of Noah, who left Egypt for Mexico shortly after the confusion of tongues. Although such speculations have fallen out of date, it is to be remembered in their favour that they were stepping-stones to more valid argument; especially they induced the collection of native traditions and invaluable records of races, languages, and customs, which otherwise would have been lost for ever. Even in the present century Lord Kingsborough was led to spend a fortune in printing a magnificent compilation of Mexican picture-writings and documents in his *Antiquities of Mexico* by his zeal to prove the theory advocated by Garcia a century earlier, that the Mexicans were the lost tribes of Israel.

Real information as to the nations of Mexico before Spanish times is very imperfect, but not altogether wanting. It is derived partly from inspection of the natives themselves, their languages and customs, which may be now briefly considered, before going on to the recollections handed down in the native picture-writings and oral traditions. The remarks made by the accurate and experienced observer Alexander von Humboldt, who had seen more American tribes than almost any traveller, are still entitled to the greatest weight. He considered the native Americans of both continents to be substantially similar in race-characters. Such a generalization will become sounder if, as is now generally done by anthropologists, the Eskimo with their pyramidal skulls, dull complexion, and flat noses are removed into a division by themselves. Apart from these polar nomads, the American indigenes group roughly into a single race or division of mankind, of course with local variations. If our attention is turned to the natives of Mexico especially, the unity of type will be found particularly close. The native population of the plateau of Mexico, mainly Aztecs, may still be seen by thousands without any trace of mixture of European blood; and the following description may give a fair idea of their appearance.[1] Their stature is somewhat low, estimated about 5 feet 3 inches, but they are of muscular and sturdy build. Measurements of their skulls show them mesocephalic (index about 78), or intermediate between the dolichocephalic and brachycephalic (narrow and wide skulled) types of mankind. The face is oval, with low forehead, high cheek-bones, long eyes sloping outward towards the temples, fleshy lips, nose wide and in some cases flattish but in others aquiline, coarsely moulded features, with a somewhat stolid and gloomy expression. Thickness of skin, masking the muscles, has been thought the cause of a peculiar heaviness in the outlines of body and face; the complexion varies from yellow-brown to chocolate (about 40 to 43 in the anthropological

[1] References may be found in Bancroft, *Native Races of the Pacific States*, vol. i. pp. 24, 573, 618, 646.

scale); eyes black; straight coarse glossy black hair; beard and moustache scanty. Among variations from this type may be mentioned higher stature in some districts, and lighter complexion in Tehuantepec and elsewhere. If now the native Americans be compared with the races of the regions across the oceans to their east and west, it will be seen that their unlikeness is extreme to the races eastward of them, whether white Europeans or black Africans. On the other hand they are considerably like the Mongoloid peoples of North and East Asia (less so to the Polynesians); so that the tendency among anthropologists is now generally to admit a common origin, however remote, between the tribes of Tartary and of America. This original connexion, if it may be accepted, would seem to belong to a long-past period, to judge from the failure of all attempts to discover an affinity between the languages of America and Asia. At whatever date the Americans began to people America, they must have had time to import or develop the numerous families of languages actually found there, in none of which has community of origin been satisfactorily proved with any other language-group, at home or abroad. In Mexico itself the languages of the Nahua nations, of which the Aztec is the best-known dialect, show no connexion of origin with the language of the Otomi tribes, nor either of these with the languages of the regions of the ruined cities of Central America, the Quiché of Guatemala and the Maya of Yucatan. Indeed, within the Mexican limits, there are various other languages which, so far as philological research can at present decide, are independent of one another. The remarkable phenomenon of nations so similar in bodily make but so distinct in language can hardly be met except by supposing a long period to have elapsed since the country was first inhabited by the ancestors of peoples whose language has since passed into so different forms. The original peopling of America may well date from the time when there was continuous land between it and Asia.

It would not follow, however, that between these remote ages and the time of the discovery of the New World by Columbus no fresh immigrants can have reached America. We may put out of the question the Scandinavian searovers who sailed to Greenland about the 10th century, and appear afterwards to have coasted New England (see AMERICA, vol. i. p. 706), but do not seem to have found their way far enough southward for their visit to have any effect on Mexico. But at all times communication has been open from East Asia and even the South Sea islands to the west coast of America. The importance of this is evident when we consider that Japanese junks now drift over by the ocean current to California at the rate of about one a year, often with some of the crew still alive (see C. W. Brooks in Bancroft, vol. v. p. 51; *Overland Monthly*, San Francisco, 1872, p. 353). Further north, the Aleutian islands offer a line of easy sea passage, while in north-east Asia, near Behring's Strait, live Chukchi tribes who carry on intercourse with the American side; the presence of Eskimo in this part of Asia (see Nordenskiöld, *Voy. of Vega*, vol. ii. pp. 13, 81) is so plainly due to local migration that it is neglected in comparing the languages of the two continents. Asiatics such as Japanese or Kurile Islanders, if they found their way in small numbers to America and merged into native tribes, might hardly leave descendants distinguishable from the rest of the population even in the first generation, nor introduce their own language. Such assertions as that the Guatusos of Costa Rica are a tribe with fair skin and flaxen hair, and that Japanese words may be detected among the Indians of British Columbia, are examples of evidence which may be worth further sifting; but in an account like the present no proofs can be admitted unless far better authenticated than these. What gives a more solid interest to the question of Asiatic influence in America, is that, though neither the evidence of features nor of language has substantiated it, there are details of Mexican civilization which are most easily accounted for on the supposition that they were borrowed from Asia. They do not seem ancient enough to have to do with a remote Asiatic origin of the nations of America, but rather to be results of comparatively modern intercourse between Asia and America, probably since the Christian era. Humboldt (*Vues des Cordillères*, pl. xxiii.) compared the Mexican calendar with that in use in eastern Asia. The Mongols, Tibetans, Chinese, and other neighbouring nations have a cycle or series of twelve animals, viz., rat, bull, tiger, hare, dragon, serpent, horse, goat, ape, cock, dog, pig, which may possibly be an imitation of the ordinary Babylonian-Greek zodiac familiar to ourselves. The Mongolian peoples not only count their lunar months by these signs, but they reckon the successive days by them, rat-day, bull-day, tiger-day, &c., and also, by combining the twelve signs in rotation with the elements, they obtain a means of marking each year in the sixty-year cycle, as the wood-rat year, the fire-tiger year, &c. This method is highly artificial, consisting, not in mere numbering, but in combining series of different terms so that the same combination does not recur till the end of the period. Thus the reappearance of its principle in the Mexican and Central-American calendar (see p 212) is suggestive of importation from Asia. Humboldt also discussed the Mexican doctrine, represented in the native pictures, of four ages of the world belonging to water, earth, air, and fire, and ending respectively by deluge, earthquake, tempest, and conflagration. The resemblance of this to some versions of the Hindu doctrine of the four ages or yuga is of so remarkable a closeness as hardly to be accounted for except on the hypothesis that the Mexican theology contains ideas learnt from Asiatics. Among Asiatic points of resemblance to which attention has since been called is the Mexican belief in the nine stages of heaven and hell, an idea which nothing in nature would suggest directly to a barbaric people, but which corresponds to the idea of successive heavens and hells among Brahmans and Buddhists, who apparently learnt it (in common with our own ancestors) from the Babylonian-Greek astronomical theory of successive stages or concentric planetary spheres belonging to the planets, &c. The Spanish chronicles also give accounts of a Mexican game called *patolli*, played at the time of the conquest with coloured stones moved on the squares of a cross-shaped figure, according to the throws of beans marked on one side; the descriptions of this rather complicated game correspond closely with the Hindu backgammon called *pachisi* (see Tylor in *Jour. Anthrop. Inst.*, vol. viii. p. 116).[1]

The native history of Mexico and Central America is entitled to more respect than the mere recollections of savage tribes, inasmuch as here memory was aided by something like written record. The Mexican pictures so far approached writing proper as to set down legibly the names of persons and places and the dates of events, while the rude drawings which accompanied these at least helped the professional historians to remember the traditions repeated orally from generation to generation. Thus actual documents of native Aztec history, or copies of

[1] The appendix to Prescott's *Conquest of Mexico* contains an interesting summary of analogies between the civilization of Mexico and that of the Old World, but some of the arguments are very inconclusive. One which has been often cited turns on the likeness alleged by Nazera between the Chinese language and that of the Otomi nation of Mexico (whose name survives in that of their town Otompan, now Otumba). The examination of an Otomi grammar (such as *Éléments de la Grammaire Othomi*, Paris, 1863) will, however, convince the philological reader that the resemblance is hardly of an amount to found a theory of a Chinese connexion upon.

them, are still open to the study of scholars, while after the conquest interpretations of these were drawn up in writing by Spanish-educated Mexicans, and histories founded on them with the aid of traditional memory were written by Ixtlilxochitl and Tezozomoc; the most important of these picture-writings, interpretations, and histories may be found in Kingsborough's *Antiquities of Mexico*. In Central America the rows of complex hieroglyphs to be seen sculptured on the ruined temples probably served a similar purpose up to the time of the Spanish invasion. The documents purporting to be histories, written down by natives in later times, thus more or less represent real records of the past, but the task of separating the preponderant mythical part from what is real history is of the utmost difficulty. Among the most curious documents of early America is the *Popol-Vuh* or national book of the Quiché kingdom of Guatemala, a compilation of traditions written down by native scribes, found and translated by Father Ximenez about 1700, and published by Scherzer (Vienna, 1857) and Brasseur de Bourbourg (Paris, 1861). This book, composed in a picturesque barbaric style, begins with the time when there was only the heaven with its boundaries towards the four winds, but as yet there was no body, nothing that clung to anything else, nothing that balanced itself or rubbed together or made a sound; there was nought below but the calm sea alone in the silent darkness. Alone were the Creator, the Former, the Ruler, the Feathered Serpent, they who give being and whose name is Gucumatz. Then follows the creation, when the creators said "Earth," and the earth was formed like a cloud or a fog, and the mountains appeared like lobsters from the water, cypress and pine covered the hills and valleys, and their forests were peopled with beasts and birds, but these could not speak the name of their creators, but could only chatter and croak. So man was made first of clay, but he was strengthless and senseless and melted in the water; then they made a race of wooden mannikins, but these were useless creatures without heart or mind, and they were destroyed by a great flood, and pitch poured down on them from heaven, those who were left of them being turned into the apes still to be seen in the woods. After this comes the creation of the four men and their wives who are the ancestors of the Quichés, and the tradition records the migrations of the nation to Tulan, otherwise called the Seven Caves, and thence across the sea, whose waters were divided for their passage. It is worth while to mention these few early incidents of the national legend of Guatemala, because their Biblical incidents show how native tradition incorporated matter learnt from the white men. Moreover, this Central-American document, mythical as it is, has an historical importance from its bringing in names belonging also to the traditions of Mexico proper. Thus Gucumatz, "Feathered Serpent," corresponds in name to the Mexican deity Quetzalcoatl; Tulan and the Seven Caves are familiar words in the Aztec migration-traditions, and there is even mention of a chief of Toltecat, a name plainly referring to the famed Toltecs, of whom further account will be given in their place in Mexican history. Thus the legends of the *Popol-Vuh* confirm what is learnt from comparing the culture of Central America and Mexico proper, that, though the nations of these districts were not connected by language, the intercourse and mixture between them had been sufficient to implant in them much common civilization, and to justify the anthropologist in including both districts in one region. Historical value of the ordinary kind may be found in the latter part of the *Popol-Vuh*, which gives names of chiefs down to the time when they began to bear Spanish names, and the great city of Quiché became the deserted ruin of Santa Cruz. The Maya district of Yucatan has also some vestiges of native traditions in the manuscript translated by D. Pio Perez (in Stephens, *Incidents of Travel in Yucatan*) and in the remarkable 16th century *Relacion de las Cosas de Yucatan* by Diego de Landa, published by Brasseur de Bourbourg (Paris, 1864). As in the Guatemala traditions, we hear of ancient migration from the Mexican legendary region of Tula; and here the leaders are four famous chiefs or ancestors who bear the Aztec name of the Tutul-Xiu, which interpreted means "Bird-Tree." Unfortunately for the historical standing of these four ancestors, there are in the Aztec picture-writings representations of four trees each with a bird perched on it, and placed facing the four quarters, which make it probable that the four Tutul-Xiu of tradition, in spite of the circumstantial detail of their wars and migrations, may be only mythic personifications of the four cardinal points (see Schultz-Sellack in *Zeitsch. f. Ethn.*, 1879, p. 209). Nevertheless, part of the later Maya records may be genuine,—for instance, when they relate the war about three centuries before the Spanish conquest, when the king of Chichen-Itza destroyed the great city of Mayapan. Though the names and dates of Central-American native kings have too little interest to general readers for traditions of them to be dwelt on here, they bring into view one important historical point, that the wondrous ruined cities of this region are not to be thought monuments of a perished race in a forgotten past, but that at least some of them belong to history, having been inhabited up to the conquest, apparently by the very nations who built them.

Turning now to the native chronicles of the Mexican nations, these are found to be substantial dated records going back to the 12th or 13th century, with some vague but not worthless recollections of national events from times some centuries earlier. These last-mentioned traditions, in some measure borne out by linguistic evidence of names of places, tribes, and persons, point to the immigration of detachments or branches of a widespread race speaking a common language, which is represented to us by the Aztec, still a spoken language in Mexico. This language was called *nahuatl*, and one who spoke it as his native tongue was called *nahuatlacatl*, so that modern anthropologists are following native precedent when they use the term *Nahua* for the whole series of peoples now under consideration.[1] Earliest of the Nahua nations, the Toltecs are traditionally related to have left their northern home of Huehuetlapallan in the 6th century; and, though this remote date cannot be treated as belonging to genuine history, there is other evidence of the real existence of the nation. Their name *Toltecatl* signifies an inhabitant of *Tollan*, "land of reeds," a place which, as has been already pointed out, appears elsewhere in the national traditions of this region, and has a definite geographical site in the present Tulan or Tula, north of the valley of Anahuac, where a Toltec kingdom of some extent seems to have had its centre. To this nation is ascribed not only the oldest but the highest culture of the Nahua nations; to them was due the introduction of maize and cotton into Mexico, the skilful workmanship in gold and silver, the art of building on a scale of vastness still witnessed to by the mound of Cholula, said to be Toltec work; the Mexican hieroglyphic writing and calendar are also declared to have been of Toltec origin. With the Toltecs is associated the mysterious tradition of Quetzalcoatl, a name which presents itself in Mexican religion as that of a great deity, god of the air, and in legend as that of a saintly ruler and civilizer. His brown and beardless worshippers describe him as of another race, a white man with noble features, long black hair and full beard, dressed in flowing robes. He came from Tullan

[1] It should be noticed that this word is not etymologically connected with the somewhat similar word *Anahuac*, of which the meaning is given at page 206.

or from Yucatan (for the stories differ widely), and dwelt twenty years among them, teaching men to follow his austere and virtuous life, to hate all violence and war, to sacrifice no men or beasts on the altars, but to give mild offerings of bread and flowers and perfumes, and to do penance by the votaries drawing blood with thorns from their own bodies. Legend tells stories of his teaching men picture-writing and the calendar, and also the artistic work of the silversmith, for which Cholula was long famed; but at last he departed, some say towards the unknown land of Tlapallan, but others to Coatzacualco on the Atlantic coast on the confines of Central America, where native tradition still keeps up the divine names of Gucumatz among the Quichés (see p. 208) and Cukulcan among the Mayas, these names having the same meaning as Quetzalcoatl in Aztec, viz., "Feathered Serpent." Native tradition held that when Quetzalcoatl reached the Atlantic he sent back his companions to tell the Cholulans that in a future age his brethren, white men and bearded like himself, should land there from the sea where the sun rises, and come to rule the country. That there is a basis of reality in the Toltec traditions is shown by the word *toltecatl* having become among the later Aztecs a substantive signifying an artist or skilled craftsman. It is further related by the Mexican historians that the Toltec nation all but perished in the 11th century by years of drought, famine, and pestilence, a few only of the survivors remaining in the land, while the rest migrated into Yucatan and Guatemala, where, as has been already pointed out, their name is commemorated in local records. After the Toltecs came the Chichimecs, whose name, derived from *chichi*, "dog," is applied to many rude tribes; the Chichimecs here in question are said to have come from Amaquemecan under a king named Xolotl, names which being Aztec imply that the nation was Nahua; at any rate they appear afterwards as fusing with more cultured Nahua nations in the neighbourhood of Tezcuco. Lastly is recorded the Mexican immigration of the seven nations, Xochimilca, Chalca, Tepaneca, Acolhua, Tlahuica, Tlascalteca, Azteca. This classification of the Nahuatlac tribes has a meaning and value. It is true that Aztlan, the land whence the Aztecs traced their name and source, cannot be identified by geographers, while the story of the separation of the seven nations at the place called Chicomoztoc or Seven Caves looks like national legend rather than real history. But the later stages of the long Aztec migration seem historical, and the map of Mexico still shows the names of several settlements recorded in the curious migration-map published by Gemelli Careri (*Giro del Mondo*, Venice, 1728) and commented on by Humboldt; among these local names are Tzompanco, "place of skulls," now Zumpango in the north of the Mexican valley, and Chapultepec, "grasshopper hill," now a suburb of the city of Mexico itself, where the Aztecs are recorded to have celebrated in 1195 the festival of tying up the "bundle of years" and beginning a new cycle. The Aztecs moving from place to place in Anahuac found little welcome from the Nahua peoples already settled there, whose own history was indeed one of incessant jealousy and quarrel. One of the first clear events of the Aztec arrival is their being made tributary by the Tepanecs, in whose service or alliance they began to manifest their warlike prowess in the fight near Tepeyacac, where now stands the famous shrine of Our Lady of Guadalupe. Thus they overcame in arms the Acolhuas, their superiors in civilization, who had made Tezcuco a centre of prosperity and improvement. By the 13th century the Aztecs by their ferocity had banded their neighbours together against them; some were driven to take refuge on the reedy lake shore at Acoculco, while others were taken as captives into Culhuacan. The king of this district was Coxcoxtli, whose name has gained an undeserved reputation even in Europe as "Coxcox, the Mexican Noah," from a scene in the native picture-writing where his name appears together with the figure of a man floating in a dug-out tree, which has been mistaken even by Humboldt for a representation of the Mexican deluge-myth. Coxcoxtli used the help of the Aztecs against the Xochimilco people, but his own nation, horrified at their bloodthirsty sacrifice of prisoners, drove them out to live for years in want and misery on the islands and swamps of the great salt lagoon, where they are said to have taken to making their *chinampas* or floating gardens of mud heaped on rafts of reeds and brush, which in later times were so remarkable a feature of Mexico. As one of the Aztec chiefs at the time of the founding of their city was called Tenoch, *i.e.*, "Stone-cactus," it is likely that from him was derived the name Tenochtitlan or "Stone-cactus place." Written as this name is in pictures or rebus, it probably suggested the invention of the well-known legend of a prophecy that the war-god's temple should be built where a prickly pear was found growing on a rock, and perched on it an eagle holding a serpent; this legend is still commemorated on the coins of Mexico. Mexico-Tenochtitlan, founded about 1325, for many years afterwards probably remained a cluster of huts, and the higher civilization of the country was still to be found among the other nations, especially among the Acolhuas in Tezcuco. The wars of this nation with the Tepanecs, which went on into the 15th century, were merely destructive, but larger effects arose from the expeditions under the Culhua king Acamapichtli, where the Aztec warriors were prominent, and which extended far outside the valley of Anahuac. Especially a foray southward to Quauhnahuac, now Cuernavaca, on the watershed between the Atlantic and Pacific, caused the bringing of goldsmiths and other craftsmen home to Tenochtitlan, which now began to rise in arts, the Aztecs laying aside their rude garments of aloe-fibre for more costly clothing, and going out as traders for foreign merchandise. In the 14th century the last great national struggle took place. The Acolhuas had at first the advantage, but Ixtlilxochitl did not follow up the beaten Aztecs but allowed them to make peace, whereupon, under professions of submission, they fell upon and sacked the city of Tezcuco. The next king of Tezcuco, Nezahualcoyotl, turned the course of war, when Azcapuzalco, the Tepanec stronghold, was taken and the inhabitants sold as slaves by the conquering Acolhuas and Aztecs; the place thus degraded became afterwards the great slave-market of Mexico. In this war we first meet with the Aztec name Moteuczoma, afterwards so famous in its Spanish form Montezuma. About 1430 took place the triple alliance of the Acolhua, Aztec, and Tepanec kings, whose capitals were Tezcuco, Mexico, and Tlacopan, the latter standing much below the other two. In fact the Aztecs now became so predominant that the rest of native history may be fairly called the Aztec period, notwithstanding the picturesque magnificence and intellectual culture which made Tezcuco celebrated under Nezahualcoyotl and his son Nezahualpilli. When the first Moteuczoma was crowned king of the Aztecs, the Mexican sway extended far beyond the valley plateau of its origin, and the gods of conquered nations around had their shrines set up in Tenochtitlan in manifest inferiority to the temple of Huitzilopochtli, the war-god of the Aztec conquerors. The rich region of Quauhnahuac became tributary; the Miztec country was invaded southward to the Pacific, and the Xicalanca region to what is now Vera Cruz. It was not merely for conquest and tribute that the fierce Mexicans ravaged the neighbour-lands, but they had a stronger motive than either in the desire to obtain multitudes of prisoners whose hearts were to be torn out

by the sacrificing priests to propitiate a pantheon of gods who well personified their bloodthirsty worshippers. The desire for war-captives as acceptable victims is related to have brought about an almost incredible agreement among nations of the Mexican alliance, that they should from time to time fight battles among themselves in order to provide prisoners for the altars. Thus there was something of the character of a religious war in the expedition made in 1469 under Axayacatl as far down the isthmus as Tehuantepec, whence the Mexican army came back with loads of rich plunder and thousands of captives, and the later ravaging of the Totonac region as far as the Atlantic, when the inhabitants were taken for sacrifice and their land recolonized by Aztecs. Ahuitzotl left the Aztec empire (as it is often somewhat ambitiously called) at the height of apparent power, but the cruel oppression of the subject regions had made their life almost unbearable, and the second Moteuczoma, coming to a rule already liable to break up from within, weakened it still more by upholding the class of chiefs or nobles against the common people who as warriors and traders had in great measure made the prosperity of the allied nations. The Mexicans had long tried to subjugate the stubborn little nation of Tlaxcallan (Tlascala), which had obstinately held out, though so hemmed in that for years the people lived without salt, this being no longer to be had from the sea-coast. Moteuczoma made a last effort to crush them, but in vain, and when the Spaniards came they were there as ready-made allies planted on the high road to Mexico. From the date when the festival of the new cycle was first celebrated in Chapultepec six 52-year periods had passed when in 1507 the new fire symbolizing the beginning of a new cycle was kindled for the last time on the breast of a human victim. Rumours of the coming of the Europeans may have before this date spread from Cuba, but in 1517 Cordova touched in Yucatan, and in 1518 Grijalva was on the east coast of Mexico, and the Aztecs first met the white men, in whom they saw, partly with hope and partly with fear, the fulfilment of the prophecy that Quetzalcoatl should one day return. With the Spanish conquest under Hernando Cortes (see CORTES) the native history of Mexico comes to an end.

CIVILIZATION.

Government. While the prairie tribes of America lived under the loose sway of chiefs and councils of old men, the settled nations of Mexico had attained to a somewhat highly organized government. This may be seen by the elaborate balance of power maintained in the federation of Mexico, Tezcuco, and Tlacopan, where each king was absolute in his own country, but in war or other public interests they acted jointly, with powers in something like the proportion in which they divided conquered lands and spoil, which was two-fifths each to Mexico and Tezcuco and one-fifth to Tlacopan. The successor of the Aztec king was customarily a chosen brother or nephew, the eldest having the first claim unless set aside as incompetent, and having to be a tried warrior; this mode of succession, which has been looked on as an elaborate practical device for securing practical advantages, seems rather to have arisen out of the law of choice among the descendants of the female line, found in American tribes of much lower culture. Something like this appears in the succession of kings of Tezcuco and Tlacopan, which went to sons by the principal wife, who was usually of the Aztec royal family. The Mexican chronicles, however, show instances of the king's son succeeding, or of powerful chiefs being elected to the kingship. The term republic is sometimes used to describe the little state of Tlascala, but this was in fact a federation of four chiefs, with an assembly of nobles. In the Zapotec district the Wiyatao or high-priest of Zopaa was a divine ruler before whom all prostrated themselves with faces to the ground; he was even too sacred to allow his foot to touch the earth, and was only seen carried in a litter.

Palaces, &c. The accounts given by the Spanish and native Mexican writers of the courts and palaces of the native kings must be taken with some reserve, from the tendency to use descriptive terms not actually untrue, but which convey erroneous ideas taken from European architecture; thus what are called columns of porphyry and jasper supporting marble balconies might perhaps be better described as piers carrying slabs, while the apartments and terraces must have been more remarkable for number and extent than architectural grandeur, being but low one-storied buildings. The principal palace of Mexico consisted of hundreds of rooms and halls ranged round three open squares, with women's apartments, granaries, storehouses, menageries, aviaries, of such extent that one of the companions of Cortes records having four times wandered about till he was tired, without seeing the whole. Not less remarkable was the palace of Tezcuco, surrounded with its groves and pleasure-gardens; and, though now hardly anything remains of the buildings above ground, the neighbouring hill of Tezcotzinco still has its stone steps and terraces; and the immense embankment carrying the aqueduct-channel of hewn stone which supplied water to basins cut in the solid rock still remains to prove that the chroniclers' descriptions, if highly-coloured, were at any rate genuine. Till the last century the gigantic figures of Axayacatl and his son Montezuma were to be seen carved in the porphyry hill of Chapultepec, but these as well as the hanging gardens have been destroyed, and only the groves of *ahuehuete* (cypress) remain of the ancient beauties of the place. That in the palace gardens flowers from the tierra caliente were transplanted, and water-fowl bred near fresh and salt pools fit for each kind, that all kinds of birds and beasts were kept in well-appointed zoological gardens where there were homes even for alligators and snakes,—all this testifies, not merely to barbaric ostentation, but to a cultivation of natural history which was really beyond the European level of the time. From the palaces and retinues of thousands of servants attached to the royal service may be inferred at once the despotic power of the Mexican rulers and the heavy taxation of the people; in fact some of the most remarkable of the picture-writings are tribute-rolls enumerating by hundreds and thousands the mantles, ocelot-skins, bags of gold-dust, bronze hatchets, loads of chocolate, &c., furnished periodically by the towns. Below the king was a numerous and powerful class of nobles, the highest of whom (*tlatoani*) were great vassals owing little more than homage and tribute to their feudal lord, while the natural result of the unruliness of the noble class was that the king to keep them in check increased their numbers, brought them to the capital as councillors, and balanced their influence by military and household officers, and by a rich and powerful merchant class. The nobles not only had privileges of rank and dignity, but substantial power over the plebeian or peasant class (*macehualli*), who submitted to much the same oppression and extortion at their hands as was customary in the Old World. The tenures of land in Mexico were those generally appearing in barbaric countries where invasion and military despotism have encroached on but not totally superseded the earlier tribal laws. The greatest estates belonged to the king, or had been granted to military chiefs whose sons succeeded them, or were the endowments of temples, but the *calpulli* or village community still survived, and each freeman of the tribe held and tilled his portion of the common lands. Below the freemen were the slaves, who were war-captives, persons enslaved for punishment, or children sold by their parents. Prisoners of war were mostly doomed to sacrifice, but other classes of slaves were mildly treated, retaining civil rights, and their children were born free.

The superior courts of law formed part of the palace, and there were tribunals in the principal cities, over each of which presided a supreme judge or *cihuacoatl*, who was irremovable, and whose criminal decisions not even the king might reverse; he appointed the lower judges and heard appeals from them; it is doubtful whether he judged in civil cases, but both kinds of suits were heard in the court below, by the *tlacatecatl* and his two associates, below whom were the ward-magistrates. Lands were set apart for the maintenance of the judges, and indeed nothing gives a higher idea of the elaborate civilization of Mexico than this judicial system, which culminated in a general court and council of state presided over by the king. The laws and records of suits were set down in picture-writings, of which some are still to be seen; sentence of death was recorded by drawing a line with an arrow across the portrait of the condemned, and the chroniclers describe the barbaric solemnity with which the king passed sentence sitting on a golden and jewelled throne in the divine tribunal, with one hand on an ornamented skull and the golden arrow in the other. Among the resemblances to Old-World law was the use of a judicial oath, the witness touching the ground with his finger and putting it to his lips, thus swearing by Mother Earth. The criminal laws were of extreme severity, even petty theft being punished by the thief being enslaved to the person he had robbed, while to steal a tobacco pouch or twenty ears of corn was death; he who pilfered in the market was then and there beaten to death, and he who insulted Xipe, the god of the gold- and silver-smiths, by stealing his precious metal, was skinned alive and sacrificed to the offended deity. Though aloe-beer or "pulque" was allowed for feasts and to invalids in moderation, and old people over seventy seem to be represented in one of the picture-writings as having liberty of drunkenness, young men found drunk were clubbed to death and young women stoned. Such a Draconian standard prevailing, it is hardly needful to enumerate the special penalties of such offences as witchcraft, fraud, removing landmarks, adultery, &c., which differed as to Justice.

whether the criminal had his heart cut out on the altar, his head crushed between two stones, &c.; while even lesser punishments were harsh, such as that of slanderers, whose hair was singed with a pine-torch to the scalp.

War. Based on conquest as the Aztec kingdom was, and with the craving for warlike glory fostered by the most bloodthirsty religion the world ever saw, it follows that the nation was above all other pursuits organized as a fighting community. To be a tried soldier was the road to honour and office, and the king could not be enthroned till he had with his own hand taken captives to be butchered on the war-god's altar at his coronation. The common soldiers were promoted for acts of daring, and the children of chiefs were regularly trained to war, and initiated by being sent into battle with veterans, with whose aid the youth took his first prisoner, but his future rise depended on how many captives he took unaided in fight with warlike enemies; by such feats he gained the dignity of wearing coloured blankets, tassels, and lip-jewels, and reached such military titles as that of "guiding eagle." The Mexican military costumes are to be seen in the picture-writings, where the military orders of princes, eagles, and tigers are known by their braided hair, eagles' beaks, and spotted armour. The common soldiers went into battle brilliant in savage war-paint, but those of higher rank had helmets like birds and beasts of prey, armour of gold and silver, wooden greaves, and especially the *ichcapilli*, the quilted cotton tunic two fingers thick, so serviceable as a protection from arrows that the Spanish invaders were glad to adopt it. The archers shot well and with strong bows, though their arrows were generally tipped only with stone or bone; their shields or targets, mostly round, were of ordinary barbaric forms; the spears or javelins had heads of obsidian or bronze, and were sometimes hurled with a spear-thrower or *atlatl*, of which pictures and specimens still exist, showing it to be similar in principle to those used by the Australians and Eskimo. The most characteristic weapon of the Mexicans was the *maquahuitl* or "hand-wood," a club set with two rows of large sharp obsidian flakes, a well-directed blow with which would cut down man or horse. These two last-mentioned weapons have the look of highly-developed savage forms, while on the other hand the military organization was in some respects equal to that of an Asiatic nation, with its regular companies commanded each by its captain and provided with its standard. The armies were very large, an expedition often consisting of several divisions each numbering eight thousand men, but the tactics of the commanders were quite rudimentary, consisting merely of attack by arrows and javelins at a distance, gradually closing into a hand-to-hand fight with clubs and spears, with an occasional feigned retreat to draw the enemy into an ambuscade. Fortification was well understood, as may still be seen in the remains of walled and escarped strongholds on hills and in steep ravines, while lagoon-cities like Mexico had the water approaches defended by fleets of boats, and the causeways protected by towers and ditches; even after the town was entered, the pyramid-temples with their surrounding walls were forts capable of stubborn resistance. It was held unrighteous to invade another nation without a solemn embassy to warn their chiefs of the miseries to which they exposed themselves by refusing the submission demanded, and this again was followed by a declaration of war, but in Mexico as in other more cultured countries this act of national morality degenerated into a ceremonial farce, where tribute was claimed from some neighbouring nation, or an Aztec god was offered to be worshipped in their temples, in order to pick a quarrel as a pretext for an invasion already planned to satisfy the soldiers with lands and plunder, and to meet the priests' incessant demands for more human sacrifices.

Among the accounts of the Mexican religion are some passages referring to the belief in a supreme deity. The word *teotl*, god, has been thought in some cases to bear this signification, but its meaning is that of deity in general, and it is applied not only to the sun-god but to very inferior gods. It is related that Nezahualcoyotl, the poet-king of Tezcuco, built a nine-storied temple with a starry roof above, in honour of the invisible deity called Tloquenahuaque, "he who is all in himself," or Ipalnemoan, "he by whom we live," who had no image, and was propitiated, not by bloody sacrifices, but by incense and flowers. Those who adopt the opinion of Asiatic admixture in Mexican culture will use it to account for this remarkable religious phenomenon, less easily accounted for by native development, while also the appearance of a rival deity of evil, bearing the name of Tlacatecolotl, or "man-owl," is mysterious. These divinities, however, seem to have had little or no place in the popular faith, which was occupied by polytheistic gods of more ordinary barbaric type. Tezcatlipoca was held to be the highest of these, and at the festival of all the gods his footsteps were expected to appear in the flour strewn to receive this sign of their coming. He was plainly an ancient deity of the race, for attributes of many kinds are crowded together in him, and he was prayed to in interminable formulas for help in war and for health and fortune, to deliver the nation from a wicked king, or to give pardon and strength to the penitent who had confessed his sins and been purified by washing. Between him and Quetzalcoatl, the ancient deity of Cholula, there had been old rivalry, as is related in legends of Quetzalcoatl coming into the land to teach men to till the soil, to work metals, and to rule a well-ordered state; the two gods played their famous match at the ball-game, and Tezcatlipoca, in the guise of a hoary-headed sorcerer, persuaded the sick and weary Quetzalcoatl to drink the magic pulque that sent him roaming to the distant ocean, where he embarked in his boat and disappeared from among men. These deities are not easily analysed, but on the other hand Tonatiuh and Metztli, the sun and moon, stand out in the distinctest personality as nature gods, and the traveller still sees in the huge adobe pyramids of Teotihuacan, with their sides oriented to the four quarters, an evidence of the importance of their worship. The war-god Huitzilopochtli, of whom one legend relates a supernatural conception in the ancient Tullan, while another story declares him to have been (like the Chinese war-god) a deified warrior-chief, was the real head of the Aztec pantheon; his idol remains in Mexico, a huge block of basalt on which is sculptured on the one side his hideous personage, adorned with the humming-bird feathers on the left hand which signify his name, while the not less frightful war-goddess Teoyaomiqui, or "divine-war-death," occupies the other side. Centeotl, the goddess of the all-nourishing maize, was patroness of the earth and mother of the gods, while Mictlanteuctli, lord of dead-land, ruled over the departed in the dim under-world. Numbers of lesser deities presided over classes of society, events, and occupations of life, such as Tlazolteotl, goddess of pleasure, worshipped by courtesans, Tezcatzoncatl, god of strong drink, whose garment in grim irony clothed the drunkard's corpse, and Xipe, patron of the goldsmiths. Below these were the usual crowd of nature-spirits of hills and groves, whose shrines were built by the roadside to receive offerings from passers-by. The temples were called *teocalli* or "god's house," and the teocallis of the greater deities rivalled in size as they resembled in form the temples of ancient Babylon. They were pyramids on a square or oblong base, rising in successive terraces to a small summit-platform. The great teocalli of Huitzilopochtli in the city of Mexico stood in an immense square, whence radiated the four principal thoroughfares, its courtyard being enclosed by a square, of which the stone wall, called the *coatepantli* or serpent-wall from its sculptured serpents, measured nearly a quarter of a mile on each side. In the centre, the oblong pyramid of rubble cased with hewn stone and cemented, 375 × 300 feet at the base, and rising steeply in five terraces to the height of 86 feet, showed conspicuously to the city the long processions of priests and victims winding along the terraces and up the corner flights of steps. On the paved platform were three-story tower temples in whose ground-floor stood the stone images and altars, and before that of the war-god the green stone of sacrifice, humped so as to bend upward the body of the victim that the priest might more easily slash open the breast with his obsidian knife, tear out the heart and hold it up before the god, while the captor and his friends were waiting below for the carcase to be tumbled down the steps for them to carry home to be cooked for the feast of victory. Before the shrines reeking with the stench of slaughter, the eternal fires were kept burning, and on the platform stood the huge drum covered with snakes' skin, whose fearful sound was heard for miles. From the terrace could be seen seventy or more other temples within the enclosure, with their images and blazing fires, and the *tzompantli* or "skull-place," where the skulls of victims by tens of thousands were skewered on cross-sticks or built into towers. There also might be seen the flat circular *temalacatl* or "spindle-stone," where captives armed with wooden weapons were allowed the mockery of a gladiatorial fight against well-armed champions. The great pyramid of Cholula with its hemispherical temple of Quetzalcoatl at the top, now an almost shapeless hill surmounted by a church, was about thrice as long and twice as high as the teocalli of Mexico. A large fraction of the Mexican population were set apart as priests or attendants to the services of the gods. The rites performed were such as are found elsewhere, prayer, sacrifice, processions, dances, chants, fasting and other austerities, but there are some peculiarities of detail. Prayers and other formulas have been copied down by Sahagun and other chroniclers, of endless prolixity, but not without occasional touches of pathos. The following are a few sentences from a prayer to Tezcatlipoca, interceding for the poor: "O our lord, protector most strong and compassionate, invisible and impalpable, thou art the giver of life; lord of all, and lord of battles, I present myself here before thee to say some few words concerning the need of the poor people, the people of none estate or intelligence. . . . Know, O Lord, that thy subjects and servants suffer a sore poverty, that cannot be told of more than that it is a sore poverty and desolateness. The men have no garments nor the women to cover themselves with, but only rags rent in every part that let the wind and cold in. . . . If they be merchants, they now sell only cakes of salt and broken pepper; the people that have something despise their wares, so that they go out to sell from door to door and from house to house; and when they sell nothing they sit down sadly by some fence or wall, or in some corner,

licking their lips and gnawing their nails for the hunger that is in them, they look on one side and the other at the mouths of those who pass by, hoping peradventure that one may speak some word to them. O compassionate God, the bed on which they lie is not a thing to rest upon, but to endure torment in; they draw a rag over them at night and so sleep. . . . O our Lord, in whose power it is to give all content, consolation, sweetness, softness, prosperity, and riches, for thou alone art lord of all good, have mercy upon them, for they are thy servants. . . . I supplicate thee that thou wilt lift up their heads with thy favour and aid, that thou wilt see good that they enjoy some days of prosperity and tranquillity, so that they may sleep and know repose, having prosperous and peaceable days of life. . . . Should this nation, for whom I pray and entreat thee to do them good, not understand what thou hast given, thou canst take away the good and pour out cursing, so that all evil may come upon them, and they become poor, in need, maimed, lame, blind, and deaf; then indeed they shall waken and know the good that they had and have not, and they shall call upon thee and lean toward thee; but thou will not listen, for in the day of abundance they would not understand thy goodness towards them." These prayers seem essentially genuine; indeed there was no European model from which they could have been imitated; but at the same time it must be remembered that they come down in Spanish writing, and not untouched by Spanish influence, as in one passage where there is a mention of sheep, an animal of course unknown to the native Mexicans. As to sacrifice, maize and other vegetables were offered, and occasionally rabbits, quails, &c.; but, in the absence of cattle, human sacrifice was the chief rite, and cannibalism prevailed at the feasts. Incense was constantly used, especially the *copalli* (copal) well known to us for varnish; little terra-cotta censers are among the commonest of Mexican antiquities. Long and severe religious fasts were customary at special seasons, and drawing blood from the arms, legs, and body, by thrusting in aloe thorns, and passing sharp sticks through the tongue, was an habitual act of devotion recalling the similar practices of devotees in India. The calendar of religious festivals for the whole course of the Mexican year has been preserved. Each 20-day period had one or more such celebrations. In the month of the "diminishing of waters" the rain-gods or Tlalocs were propitiated by a procession of priests with music of flutes and trumpets carrying on plumed litters infants with painted faces, in gay clothing with coloured paper wings, to be sacrificed on the mountains or in a whirlpool in the lake. It is said that the people wept as they passed by; but if so this may have been a customary formality, for the religion of these nations must have quenched all human sympathy. In the next month the god Xipe-totec, already mentioned, had his festival called the "flaying of men" from the human victims being flayed, after their hearts were torn out, for young men to dress in their skins and perform dances and sham fights. The succeeding festival of Camaxtli was marked by a severe fast of the priests, after which stone knives were prepared with which a hole was cut through the tongue of each, and numbers of sticks passed through. For the great festival of Tezcatlipoca, the handsomest and noblest of the captives of the year had been chosen as the incarnate representative of the god, and paraded the streets for public adoration dressed in an embroidered mantle with feathers and garlands on his head and a retinue like a king; for the last month they married him to four girls representing four goddesses; on the last day wives and pages escorted him to the little temple of Tlacochcalco, where he mounted the stairs, breaking an earthenware flute against each step; this was a symbolic farewell to the joys of the world, for as he reached the top he was seized by the priests, his heart torn out and held up to the sun, his head spitted on the tzompantli, and his body eaten as sacred food, the people drawing from his fate the moral lesson that riches and pleasure may turn into poverty and sorrow. The manner of the victim's death in these festivals afforded scope for variety; they dressed them and made them dance in character, threw them into the fire for the fire-god, or crushed them between two balanced stones at the harvest-festival. The ordinary pleasures of festivals were mingled with all this, such as dances in beast-masks, sham fights, and children's games, but the type of a religious function was a sickening butchery followed by a cannibal feast.

Picture-writing. The Mexican priesthood, being the educated class, were much concerned with the art of picture-writing, which they had developed to a stage quite above the rude figures of the American hunting-tribes, and used systematically as a means of recording religious festivals and legends, as well as keeping calendars of years and recording the historical events which occurred in them. Facsimiles of several of these interesting documents, with their translations, may be seen in Kingsborough. On inspecting these it will be seen that their main principle is pictorial. Gods are represented with their appropriate attributes,—the fire-god hurling his spear, the moon-goddess with a shell, &c.; the scenes of human life are pictures of warriors fighting with club and spear, men paddling in canoes, women spinning and weaving, &c. An important step towards phonetic writing appears, however, in the picture-names of places and persons. The simplest forms of these depict the objects signified by the name, as where *Chapultepec* or "grasshopper-hill" is represented by a grasshopper on a hill, or a stone with a cactus on it stands for *Tenoch* or "stone-cactus," the founder of *Tenochtitlan*. The system had, however, risen a stage beyond this when objects were drawn to represent, not themselves, but the syllables forming their names, as where a trap, an eagle, a pricker, and a hand are put together not to represent these objects, but in order that the syllables of their names *mo-quauh-zo-ma* should spell the word Moquauhzoma (see Aubin's introduction to Brasseur, *Hist. du Mexique*, vol. i. p. lxviii.). The analogy of this to the manner in which the Egyptian hieroglyphs passed into phonetic signs is remarkable, and writing might have been invented anew in Mexico had it not been for the Spanish conquest. The Aztec numerals, which were vigesimal or reckoned by scores, were depicted by dots or circles up to 20, which was represented by a flag, 400 (a score of scores) by a feather, and 8000 (a score of scores of scores) by a purse; but for convenience these symbols might be halved and quartered, so that 534 might be shown by one feather, one quarter of a feather, one flag, one-half of a flag, and four dots. The Mexican calendar depended on the combination of numbers with picture-signs, of which the four principal were the rabbit, reed, flint, house—*tochtli, acatl, tecpatl, calli.* The cycle of 52 years was reckoned by combining these signs in rotation with numbers up to 13, thus:—1 rabbit, 2 reed, 3 flint, 4 house, 5 rabbit, 6 reed, &c. By accident this calendar may be exactly illustrated with a modern pack of cards laid out in rotation of the four suits, as, ace of hearts, 2 of spades, 3 of diamonds, 4 of clubs, 5 of hearts, 6 of spades, &c. In the Mexican ritual calendar of the days of the year, the same method is carried further, the series of twenty day-signs being combined in rotation with numbers up to 13; as this cycle of days only reaches 260, a series of nine other signs are affixed in addition, to make up the 365-day year. It is plain that this rotation of signs served no useful purpose whatever, being less convenient than ordinary counting such as the Mexicans employed in their other calendar already mentioned, where the 20-day periods had each a name like our months, and their days had signs in regular order. Its historical interest depends on its resemblance to the calendar-system of central and eastern Asia, where among Mongols, Tibetans, Chinese, &c., series of signs are thus combined to reckon years, months, and days; for instance, the Mongol cycle of 60 years is recorded by the zodiac or series of 12 signs—mouse, bull, tiger, &c., combined in rotation with the five male and female elements—fire, earth, iron, water, wood; as "male-fire-bull" year, &c. This comparison is worked out in Humboldt's *Vues des Cordillères*, as evidence of Mexican civilization being borrowed from Asia. Naturally the Mexican calendar-system lent itself to magic in the same way as the similar zodiac-signs of the Old World, each person's fate being affected by the qualities of the signs he was born under, and the astrologer-priests being called in to advise on every event of life. Of all Mexican festivals the most solemn was that of the *xiuhmolpilli*, or "year-binding," when the 52-year cycle or bundle of years came to an end. It was believed that the destruction of the world, which after the Hindu manner the Mexicans held to have already taken place three or four times, would happen again at the end of a cycle. As the time drew near, the anxious population cleansed their houses and put out all fire, and on the last day after sunset the priests, dressed in the garb of gods, set out in procession for the hill of Huixachtla, there to watch for the approach of the Pleiades to the zenith, which gave the auspicious signal for the lighting of the new fire. The finest of the captives was thrown down and fire kindled on his breast by the wooden drill of the priest; then the victim's heart was torn out, and his body flung on the pile kindled with the new flame. The people watching from their flat housetops all the country round saw with joy the flame on the sacred hill, and hailed it with a thank-offering of drops of blood drawn from their ears with sharp stone-flakes. Swift runners carried burning brands to rekindle the fires of the land, the sacred fire on the teocalli of the war-god blazed up again, and the people began with feasting and rejoicing the new cycle.

Education. Mexican education, at any rate that of the upper class, was a systematic discipline much under the control of religion, which here presents itself under a more favourable light. After the birth of a child, the *tonalpouhqui* or "sun-calculator" drew its horoscope from the signs it was born under, and fixed the time for its solemn lustration or baptism, performed by the nurse with appropriate prayers to the gods, when a toy shield and bow were provided if it was a boy, or a toy spindle and distaff if it was a girl, and the child received its name. An interesting picture-writing, to be seen in Kingsborough, shows the details of the boy's and girl's education, from the early time when three small circles over the child show it to be three years old, and a drawing of half a tortilla or corn-cake shows its allowance for each meal; as they grow older the lads are seen beginning to carry burdens, paddle the canoe, and fish, while the girls learn to spin and weave, grind maize, and cook,—good conduct being enforced by punishments of increasing severity, up to pricking their bodies with aloe-thorns and holding

their faces over burning chillis. The schools were extensive buildings attached to the temples, where from an early age boys and girls were taught by the priests to sweep the sanctuaries and keep up the sacred fires, to fast at proper seasons and draw blood for penance, and where they received moral teaching in long and verbose formulas. Those fit for a soldier's life were trained to the use of weapons and sent early to learn the hardships of war; children of craftsmen were usually taught by their fathers to follow their trade; and for the children of nobles there was elaborate instruction in history, picture-writing, astrology, religious doctrines, and laws. Marriages depended much, as they do still in the East, on comparison of the horoscopes of the pair to ascertain if their birth-signs were compatible. Old women were employed as go-betweens, and the marriage ceremony was conducted by a priest who after moral exhortations united the young couple by tying their garments together in a knot, after which they walked seven times round the fire, casting incense into it; after the performance of the marriage ceremony the pair entered together on a four days' fast and penance before the marriage was completed. The funeral rites of the Mexicans are best seen in the ceremonies at the death of a king. The corpse laid out in state was provided by the priest with a jug of water for his journey, and with bunches of cut papers to pass him safely through each danger of the road—the place where the two mountains strike together, the road guarded by the great snake and the great alligator, the eight deserts and the eight hills; they gave him garments to protect him from the cutting wind, and buried a little dog by his side to carry him across the nine waters. Then the royal body was invested in the mantles of his patron-gods, especially that of the war-god, for Mexican kings were warriors; on his face was placed a mask of turquoise mosaic, and a green chalchihuite-stone as a heart between his lips. In older times the dead king was buried on a throne with his property and dead attendants round him. But after cremation came in a mourning procession of servants and chiefs carried the body to the funeral pyre to be burnt by the demon-dressed priests, after which the crowd of wives and slaves were exhorted to serve their lord faithfully in the next world, were sacrificed and their bodies burnt. Common people would not thus be provided with a ghostly retinue, but their simpler funeral ceremonies were as far as they went similar to those of their monarch.

The staple food of the Mexicans before the conquest has continued with comparatively little change among the native race, and has even been adopted by those of European blood. Maize or Indian corn was cultivated on patches of ground where, as in the Hindu *jûm*, the trees and bushes were burnt and the seed planted in the soil manured by the ashes. A sharp-pointed planting stick, a wooden shovel, and a bronze-bladed hoe called a *coatl* were the simple implements. The Mexicans understood digging channels for irrigation, especially for the cultivation of the *cacahuatl*, from which they taught the Europeans to prepare the beverage *chocollatl*; these native names passed into English as the words cacao, or cocoa, and chocolate. Other vegetables adopted from Mexico are the tomata (*tomatl*) and the *chilli*, used as flavouring to native dishes. The maize was ground with a stone roller on the grinding stone or *metlatl*, still known over Spanish America as the *metate*, and the meal baked into thin oval cakes called by Aztecs *tlaxcalli*, and by Spaniards *tortilla*, which resemble the *chapati* of India and the oat-cake of Scotland. The Mexicans were also skilful makers of earthen pots, in which were cooked the native beans called by the Spanish *frijoles*, and the various savoury stews still in vogue. The juice extracted by tapping the great aloe before flowering was fermented into an intoxicating drink about the strength of beer, *octli*, by the Spaniards called *pulque*. Tobacco, smoked in leaves or cane-pipes or taken as snuff, was in use, especially at feasts. It is related that in old times Mexican clothing was of skins or woven aloe and palm fibre, but at the time of the conquest cotton was largely cultivated in the hot lands, spun with a spindle, and woven in a rudimentary loom without a shuttle into the mantles and breech-cloths of the men and the chemises and skirts of the women, garments often of fine texture and embroidered in colours. Ornaments of gold and silver, and jewels of polished quartz and green chalchihuite were worn,—not only the ears and nose but the lips being pierced for ornaments. The artificers in gold and silver melted the metals by means of a reed-blowpipe and cast them solid or hollow, and were also skilled in hammered work and chasing, as some fine specimens remain to show, though the famous animals modelled with gold and silver fur, feathers, and scales have disappeared. Iron was not known, but copper and tin ores were mined, and the metals combined into bronze of much the same alloy as in the Old World, of which hatchet blades and other instruments were made, though their use had not superseded that of obsidian and other sharp stone flakes for cutting, shaving, &c. Metals had passed into a currency for trading purposes, especially quills of gold-dust and T-shaped pieces of copper, while cocoa-beans furnished small change. The vast size of the market-squares with their surrounding porticos, and the importance of the caravans of merchants who traded with other nations, show that mercantile had risen into some proportion to military interests. Nor was the wealth and luxury of Mexico and surrounding regions without a corresponding development of art. The stone sculptures such as that remaining of Xochicalco, which is figured by Humboldt, as well as the ornamented woodwork, feather-mats, and vases, are not without artistic merit. The often-cited poems attributed to Nezahualcoyotl may not be quite genuine, but at any rate poetry had risen above the barbaric level, while the mention of ballads among the people, court odes, and the chants of temple choirs would indicate a vocal cultivation above that of the instrumental music of drums and horns, pipes and whistles, the latter often of pottery. Solemn and gay dances were frequent, and a sport called the bird-dance excited the admiration of foreigners for the skill and daring with which groups of performers dressed as birds let themselves down by ropes wound round the top of a high mast, so as to fly whirled in circles far above the ground. The ball-game of the Mexicans, called *tlachtli*, was, like tennis, the pastime of princes and nobles; special courts were built for it, and the ball of india-rubber (perhaps the first object in which Europeans became acquainted with this valuable material) might not be touched by the hands, but was driven against the walls by blows of the knee or elbow, shoulder or buttock. The favourite game of *patolli* has been already mentioned for its similarity to the *pachisi* of modern India.

Art and pastime.

Central-American culture.

The accounts given by Spanish writers of the Central Americans in their state after the Spanish conquest are very scanty in comparison with the voluminous descriptions of Aztec life. They bring out perfectly, however, the fact of close connexion between the two civilizations. Some Central-American peoples were actually Mexican in their language and culture, especially the Pipils of Guatemala and a large part of the population of Nicaragua, but these were descendants of Aztecs or allied peoples who in the comparatively modern times of Aztec power invaded and colonized these distant countries (see Buschmann, *Aztek. Ortsnamen*, viii., ix.). With regard to the Central-American nations proper, especially the Mayas of Yucatan and the Quichés of Guatemala, who dwelt in the cities and worshipped in the temples of Chichen-Itza and Uxmal, Palenque and Copan, the problem of Aztec connexion is deeper and obscurer. How closely related these nations were in institutions to the Mexicans appears, not only in their using the same peculiar weapons, such as the spear-thrower and the toothed club or maquahuitl, but in the similarity of their religious rites, such as drawing blood from their bodies as an act of penance, and sacrificing human victims by cutting open the breast and tearing out the heart; the connexion is evident in such special points as the ceremony of marriage by tying together the garments of the couple, or in holding an offender's face over burning chillis as a punishment; the native legends of Central America make mention of the royal ball-play, which was the same as the Mexican game of tlachtli already mentioned. At the same time many of the Central-American customs differed from the Mexican; thus in Yucatan we find the custom of the youths sleeping in a great bachelor's house, an arrangement common in various parts of the world, but not in Mexico; the same remark applies to the Maya exogamous law of a man not taking a wife of his own family name (see Diego de Landa, *Relacion de Yucatan*, ed. Brasseur de Bourbourg, p. 140), which does not correspond with Mexican custom. We have the means of comparing the personal appearance of the Mexicans and Central Americans by their portraits on early sculptures, vases, &c.; and, though there does not appear any clear distinction of race-type, the extraordinary back-sloping foreheads of such figures as those of the bas-reliefs of Palenque prove that the custom of flattening the skull in infancy prevailed in Central America to an extent quite beyond any such habit in Mexico. It is from the ruined cities now buried in the Central-American forests that we gain the best information as to the nations who built them. The notion sometimes propounded that these famous cities were of great antiquity and the work of extinct nations has no solid evidence; some of them may have been already abandoned before the conquest, but others were inhabited, and by the ancestors of the Indians who now build their mean huts and till their patches of maize round the relics of the grander life of their ancestors. In comparing these ruins through the districts of Yucatan, Chiapas, Guatemala, and Honduras, it is evident that, though they are not the work of a single nation, but of two or more highly distinct in language, yet these nations had the great bond of a common system of pictorial or written characters. One specimen of a Central-American inscription may give a general idea of them all, whether it be from the sculptured façade of a temple sketched by Catherwood, or from the painted deerskin called the Dresden Codex (reproduced in Kingsborough), or from the chapter of Diego de Landa where he professes to explain and translate the characters themselves. These consist of combinations of faces, circles, lines, &c., arranged in compartments in so complex a manner that hardly two are found alike. How they conveyed their meaning, how far they pictorially represented ideas or spelt words in the different languages of the country, is a question not yet answered in a complete way; Landa's description (p. 320) gives a table of a number of their elements as phonetically representing letters or syllables, but, though there may be a partial truth in his rules, they

are too insufficient or too erroneous to serve for any general decipherment. Most of what has been written on this enticing subject is worthless, but a promising attempt has been made by E. S. Holden, who has analysed the combined figures into their elementary lines (*First Annual Report of Bureau of Ethnology*, Smithsonian Institution, Washington, 1881; see also Charencey, *Mélanges de Philologie et de Paléographie Américaines*, Paris, 1883). One point as to the Central-American characters is clear, that part of them are calendar-signs recording dates. From the accounts given by Landa and other writers it is plain that the Central-American calendar, reckoning the year in twenty-eight periods of thirteen days, was the same in its principle of combining signs as that of Mexico here mentioned at page 212. The four leading Maya signs called *kan*, *muluc*, *ix*, *cauac* corresponded in their position to the four Aztec signs rabbit, reed, flint, house, but the meanings of the Maya signs are, unlike the Aztec, very obscure. A remarkable feature of the Central-American ruins is the frequency of truncated pyramids built of hewn stone, with flights of steps up to the temple built on the platform at top. The resemblance of these structures to the old descriptions and pictures of the Mexican teocallis is so striking that this name is habitually given to them. The teocallis built by the Nahua or Mexican nations have been mostly destroyed, but two remain at Huatusco and Tusapan (figured in Bancroft, vol. iv. pp. 443, 456), which bear a strong resemblance to those of Palenque. On the whole it is not too much to say that, in spite of differences in style, the best means of judging what the temples and palaces of Mexico were like is to be gained from the actual ruins in Central America. On the other hand, there are features in Central-American architecture which scarcely appear in Mexican. Thus at Uxmal there stands on a terraced mound the long narrow building known as the governor's house (Casa del Gobernador), 322 feet long, 39 feet wide, 26 feet high, built of rubble stone and mortar faced with square blocks of stone, the interior of the chambers rising into a sloping roof formed by courses of stonework gradually overlapping in a "false arch." The same construction is seen in the buildings forming the sides of a quadrangle and bearing the equally imaginary name of the nunnery (Casa de Monjas); the resemblance of the interior of one of its apartments to an Etruscan tomb has often been noticed (see Fergusson, *History of Architecture*, vol. i.; Viollet-le-Duc, in Charnay). Attempts to trace the architecture of Central America to direct derivation from Old-World types have not been successful, while on the other hand its decoration shows proof of original invention, especially in the imitations of woodwork which, as the above-mentioned architects have pointed out, passed into sculptured ornament when the material of construction became stone, instead of wood. Thus the architectural remains, though they fail actually to solve the historical problem of the high culture of the nations round the Gulf of Mexico, throw much light on it when their evidence is added to that of religion and customs. Whether Mexican civilization was a barbaric copy of that which flourished in the now deserted Central-American cities, or whether the nations who built these cities themselves raised to a higher level a civilization derived from Mexico, two things seem probable,—first, that the civilizations of Mexico and Central America were pervaded by a common influence in religion, art, and custom; second, that this common element shows traces of the importation of Asiatic ideas into America.

Among works of reference on the ancient history and civilization of Mexico and Central America may be mentioned H. H. Bancroft, *The Native Races of the Pacific States of North America*, London, 1875-6 (contains the most complete summary, with references to original authorities); Brasseur de Bourbourg, *Histoire des Nations Civilisées du Mexique et de l'Amérique-Centrale*, Paris, 1857-59 (a valuable collection of materials, but the author's own views are mostly fanciful); Prescott, *History of the Conquest of Mexico*; Clavigero, *Storia Antica del Messico*, Cesena, 1780 (contains the substance of earlier writers, such as Gomara, Torquemada, Acosta, Boturini, &c.). For special topics:—Lord Kingsborough, *Antiquities of Mexico*, London, 1831-48 (contains facsimiles and interpretations of picture-writings, the native chronicles of Ixtlilxochitl and Tezozomoc, a reprint of Sahagun, &c.); A. von Humboldt, *Vues des Cordillères, et Monumens des Peuples Indigènes de l'Amérique*, Paris, 1816 (Mexican civilization, picture-writing, calendar, &c.). Travels and descriptions of antiquities, &c.:—Dupaix (in Kingsborough); C. Nebel, *Viaje Pintoresco y Arqueológico sobre la República Mejicana*. Paris, 1839; F. de Waldeck, *Voyage Pittoresque et Archéologique dans la Province d Yucatan*, Paris, 1838, and *Palenqué et Autres Ruines*. Paris, 1866; D. Charnay, *Cités et Ruines Américaines*, avec texte par Viollet-le-Duc, Paris, 1863; J. L. Stephens, *Incidents of Travel in Central America*, &c., New York, 1841; *Incidents of Travel in Yucatan*, New York, 1858; Brantz Mayer, *Mexico*, New York, 1854; Tylor, *Anahuac, or Mexico and the Mexicans*, London, 1861, &c.

Plate I.

II. THE REPUBLIC OF MEXICO.

Mexico, Aztec *Mexitli*.[1] (Estados Unidos de Mexico), is a federal republic in North America, bounded N. by the United States (California, Arizona, and New Mexico), E. by Texas and the Gulf of Mexico, S. by Guatemala and British Honduras, where the boundary lines are still partly undetermined, W. by the Pacific Ocean. Lying between 33° and 15° N. lat. and 87° and 117° W. long., Mexico stretches about 1950 miles north-north-west and south-south-east, with a mean breadth of 400 miles, varying from about 1000 in 26° N. to 130 at the narrowest part of the Tehuantepec isthmus. It has a coast-line of nearly 6000 miles,—about 4200 on the Pacific and 1600 on the Atlantic. The seaboard is little varied either by deep inlets, bold headlands, broad estuaries, or large islands. On the west side are the vast Gulf of California, in outline somewhat resembling the Red Sea, and so named by some of the early navigators, and the open Bay of Tehuantepec, besides the smaller inlets of Acapulco and San Blas, forming two of the finest harbours in the world, and almost the only safe ones in the republic. On the east side the coast is mostly beset by lagoons and sand-banks, with no good havens, Campéche, Vera Cruz, Tampico, and Matamoras being all little better than open roadsteads exposed to the fierce "nortes," or north-easterly gales, that sweep the Gulf of Mexico for a great part of the year. Of headlands the most prominent are Capes S. Lucas and Palmas at the south extremity of Lower California, Corrientes south from San Blas, and Catoche in the north-east of Yucatan. Besides this peninsula, which projects north-north-east, the only other is that of Lower California, which projects south-south-east parallel to the mainland. The islands are few in number, and all of insignificant size, the most noteworthy being Tiburon and Angel de la Guarda in the Gulf of California, the uninhabited Revillagigedo group in the Pacific, and Cozumel off the Yucatan coast. Mexico comprises altogether twenty-seven confederate states, one territory, and the Federal District, with areas, populations, and chief towns as under:[2]—

	States.	Area in Square Miles.	Population (1880).	Capital.	Population (1877-80).
Northern.	Sonora	81,022	139,140	Ures	9,700
	Chihuahua	105,295	180,758	Chihuahua	12,116

		763,804	9,577,279		

Since the appearance of A. von Humboldt's classic work on *New Spain*, as Mexico was called in the colonial times, this region has continued to be regarded as forming a main link in the vast chain supposed to stretch across the entire length of the American continent from Cape Physical features. Plateaus and mountains.

[1] In this, as in all other Aztec names, the *x* (or *j*) represents the English sound *sh*; hence *Mexitli* and *Mexico* should be properly pronounced *Meshitli*, *Meshico*. But they do not appear to have ever been so pronounced by the Spaniards, who naturally gave to the *x* its ordinary Spanish sound of the German *ch*.

[2] These figures, in the absence of scientific surveys and a trustworthy census, are necessarily more or less approximate. The areas are those of Ripley and Dana, based on A. Garcia Cuba's *Carta geografica* (Mexico, 1874); the populations of the states and capitals are the estimates of Emiliano Busto in his *Estadistica de la Republica Mexicana* (Mexico, 1880). A writer in the *Times* of December 7, 1882, estimates the whole population at 12,000,000, much too high a figure.

flow through the profound rocky gorges or *barrancas*, as they are here called, which form a characteristic feature of the Mexican table-lands.[1] On the east side some of these barrancas, here running mostly west and east, attain depths of 800 to 1000 feet in the unfossiliferous limestones of that region; and even on the west coast the De Beltran cañon is flanked by sheer rocky walls over 500 feet high. Hence the rivers are almost useless for irrigation purposes, and available as means of communication only for short distances in their lower reaches, where they flow through the narrow alluvial strips of level coast-lands to the sea. Even the Rio Grande del Norte, which is by far the largest, and which forms the frontier line between Mexico and Texas, is navigable by large vessels only for a few miles above its port of Matamoras. The Rio Grande de Santiago, the largest on the Pacific side, is almost everywhere obstructed by falls and rapids. On this coast the next in importance is the Mercala, or Rio de las Balsas, which, like the Panuco, Alvaredo, Coatzacoalas, Grijalva, and Usumacinta flowing to the Gulf of Mexico, is subject to sudden freshets during the rains.

At this season the waters which find no seaward outlet are collected in the depressions of the plateaus, where extensive tracts remain flooded for several months at a time. But these lacustrine basins of the Anahuac and Chihuahua table-lands, standing at elevations of from 4000 to 7000 feet, are, by evaporation under semi-tropical suns, rapidly reduced to their normal level. The diminished size of the Anahuac lakes shows that since the conquest a steady process of desiccation has been going on, due probably to the reckless destruction of the upland forests by the European settlers. None of these lakes are of great size except Lake Chapala, which is traversed by the Rio Grande de Santiago, and has a reputed area of about 1300 square miles. Amongst those of the plateau especially noteworthy for their magnificent scenery are Tezcuco and Chalco, in whose sparkling waters are reflected the surrounding volcanic peaks and extinct craters of the Anahuac table-land, with a background formed by the Cordilleras, whose snowy summits rise here and there high above the dark pine forests of the lower slopes.

Geology and minerals.

In the higher ranges the prevailing formations are granites, which seem also to form the foundation of the plateaus, above which rise the traps, basalts, mineral-bearing porphyries, and more recent lavas. Hence Lyell's theory that Mexico consisted originally of granitic ranges with intervening valleys subsequently filled up to the level of the plateaus by subterranean eruptions. Igneous rocks of every geologic epoch certainly to a large extent form the superstructure of the central plateau. But the Mexican table-land seems to consist mainly of metamorphic formations, which have been partly upheaved, partly interpenetrated and overlaid by igneous masses of all epochs, and which are chiefly represented by shales, greywacke, greenstones, silicious schists, and especially unfossiliferous limestone. All these formations are alike remarkable for the abundance and variety of their metalliferous ores, such as silver, silver-glance, copper, and gold. Gneiss and micaceous schists prevail in Oajaca and on all the southern slopes facing both oceans. But the highest ranges are formed mainly of plutonic and volcanic rocks, such as granites, syenites, diorites, mineral-bearing trachytes, basalts, porphyries, obsidian, pearlstone, sulphur, pumice, lavas, tufa, and other recent volcanic discharges. Obsidian (*itztli*) was the chief material formerly used by the natives in the manufacture of their cutting implements, as shown by the quarries of the Cerro de las Navajas ("Knife Cliff") near Zimapan. Vast deposits of pumice and the purest sulphur are found at Huichapa and in many of the craters. But immeasurably the most valuable rocks are the argentiferous porphyries and schists of the central plateau and in Sinaloa, unless they are destined to be rivalled by the auriferous deposits of Sonora.[2] Horizontal and stratified rocks, of extremely limited extent in the south, are largely developed in the northern states, and chalk becomes very prevalent towards the Rio Grande and Rio Gila valleys. To this chalk and to the sandstones are probably to be referred the sandy plains which cover vast tracts in North Mexico, stretching thence far into New Mexico and Texas. Here the Bolson de Mapimi, a vast rocky wilderness inhabited only by wild tribes, occupies a space of perhaps 50,000 square miles in Coahuila and parts of the surrounding states.

None of the horizontal layers seem to be very rich in ores, which are found mainly in the metamorphic, palæozoic, and hypogene rocks of Durango, Chihuahua, and the south. Apart from Sinaloa and Sonora, which are now known to contain vast stores of the precious metals, nearly all the historical mines lie on the south central plateau at elevations of from 5500 to 9500 feet. A line drawn from the capital to Guanajuato, and thence northwards to the mining town of Guadalupe y Calvo in Chihuahua, and southwards to Oajaca, thus cutting the main axis of upheaval at an angle of 45°, will intersect probably the richest known argentiferous region in the whole world. The central group of mines in the three mineral districts of Guanajuato, Zacatecas, and Catorze (San Luis Potosi), which have yielded more than half of all the silver hitherto found in Mexico, lie between 21° and 24° 30′ N., within an area of about 13,000 square miles. Here the Veta Madre lode of Guanajuato alone produced £504,000 between 1556 and 1803, besides £10,000 of gold. This metal, however, occurs chiefly, not on the plateau in association with silver, but on the slopes facing the Pacific, and apparently in greatest abundance in Sonora, near the auriferous region of New California. In recent times over half of the silver produced in the whole world has been supplied by Mexico, and the total yield of the precious metals between 1537 and 1880 was as under:[3]—

	Gold.	Silver.	Total.
1537 to 1821......	£14,000,000	£418,000,000	£432,000,000
1821 to 1880......	10,000,000	180,000,000	190,000,000
Total...........	£24,000,000	£598,000,000	£622,000,000

Of other minerals the most important are copper, found in a pure state near the city of Guanajuato, and associated with gold in Chihuahua, Sonora, Guerrero, Jalisco,

[1] "Near the mountain ranges, from which the water after heavy rains rushes down in innumerable forest streams, these ravines are filled with incredible rapidity as high as 30 feet,—the torrent importing (*sic*) trees and bearing away rocks with a thundering noise and irresistible power" (Egloffstein, p. 22).

[2] On the general character and distribution of the igneous formations Von Egloffstein remarks: "Intimate relations exist between the metalliferous and non-metalliferous porphyries. The metalliferous porphyry is less frequent, but constitutes the most important formation, bearing the precious metals, . . . embracing the rich lodes of Real-del-Monte, Pachuca, Chico, Capula, and Santa Rosa, all of great richness and magnitude. They further form the mineral districts of Angangueo, Oro, Huautla, &c., and part of the mountains of Zimapan and Istapa-del-Oro. The lodes found in this porphyry are characterized by their magnitude and the consistency of the ores they contain. . . . The richest ores of native silver and sulphuret, chloride, and oxide of silver are found in the lodes of Real-del-Monte, Pachuca, and Santa Rosa. . . . The gold seems to exist in small particles in the metamorphic porphyry mountains, whence it is carried by the rains to the valleys as the rocks become disintegrated" (pp. 6–8).

[3] *Times* correspondent, December 7, 1882. Guanajuato seems to be still the greatest producer, yielding from £1,500,000 to £1,750,000 yearly, although the great Valenciana mine is flooded, and of the hundred opened only fifty-two are now worked (Geiger).

Michoacan, and elsewhere; iron in immense masses in Michoacan and Jalisco, and in Durango, where the Cerro del Mercado is a solid mountain of magnetic iron ore; lead associated with silver, especially in Oajaca; tin in Michoacan and Jalisco; sulphur in many craters; platinum recently found in Tlaxcala and Hidalgo; cinnabar also recently in Morelos and Guerrero; "steppe salt" in the sandy districts of the north; "bitter salt" at Tepeyac; coal in limited quantities at various points; bismuth in many parts; marble, alabaster, gypsum, and rock-salt in great abundance throughout the plateau and the sierras. In 1882 there were open altogether 569 mines:—541 silver, 14 gold, 4 copper, 4 lead, 3 salt, 2 coal, and 1 mercury.[1]

Climate and vegetation. Intersected about midway by the Tropic of Cancer, and stretching across seventeen parallels of latitude, Mexico, from its position alone, necessarily enjoys a great diversity of climate. But from its peculiar configuration this feature is affected far more by the relief of the land than by its distance from pole or equator. This is especially true of the more fertile and populous section lying within the torrid zone, where three distinct climatic regions are distinguished, not according to their horizontal, but according to their vertical position. The temperature falling steadily with the elevation of the land, which here rises rapidly from sea-level to nearly 18,000 feet above the surrounding waters, the low-lying coast-lands, up to about 3000 feet on the scarps and terraces of the central plateau, are comprised within the first zone of *tierras calientes*, or "hot lands." Within this zone are included all the sandy and marshy tracts fringing the Gulf of Mexico, the lower slopes facing eastwards and exposed to the hot and moist winds from the Caribbean Sea, and most of Yucatan and the Tehuantepec isthmus, besides the narrow strip between the uplands and the Pacific which broadens northwards along the east side of the Gulf of California. Here the mean temperature varies from 77° to 82° Fahr., seldom falling below 60°, but often rising to 105°, and in the sultry districts of Vera Cruz and Acapulco to 110°. The extreme north-western parts of this region come almost within the rainless zone, and the Californian peninsula itself is subject to excessive droughts, rendering it almost uninhabitable. But farther south the climate on both seaboards may be described as humid, hot, and extremely unhealthy, especially for Europeans. Yellow fever and black vomit are here endemic. But these scourges are at least compensated by a magnificent tropical vegetation and extensive virgin forests abounding in valuable timbers, dyewoods, and medicinal and other useful plants. Of the 114 species of trees and cabinet woods, 17 of oil-bearing plants, and over 60 of medicinal plants and dyewoods indigenous to Mexico, and often differing specifically from kindred varieties in Central and South America, by far the larger part are represented in the tierras calientes. Amongst the most important of these forest plants are mahogany, rosewood, copal, caucho (india-rubber), jalap, sarsaparilla, and vanilla. Here also maize, supplying the staple food of the people, yields prodigious returns, multiplying from two hundred to four hundred fold, and affording two, three, and even four successive crops within the year. Rice, indigo, cotton, tobacco, and coffee all thrive well, while sugar, cocoa, the banana, and several varieties of beans are largely cultivated. The tobacco of Vera Cruz and Tabasco, the coffee of Colima, and the cocoa of Oajaca and Chiapas are of unrivalled excellence.

To the "hot lands" succeed in vertical position the *tierras templadas*, or "temperate lands," which comprise all the higher terraces and the central plateaus themselves between about 3000 and 8000 feet. With a mean temperature of from 62° to 70° Fahr., and oscillating between such moderate extremes as 50° and 86°, this region enjoys one of the very finest climates on the globe. The Puebla and Anahuac table-lands are described by enthusiastic travellers as "terrestrial Edens," with a perennial spring symbolized by the evergreen oak, cedars, and many analogous plants, which here attain their greatest perfection. The transition from the lower zone is often very gradual; and, while endemic fevers cease altogether at altitudes of 2700 and 2800 feet, the tropical flora invades many parts of the terrace lands, and even of the plateaus to heights of 4000 and 5000 feet.[2] A certain uniformity is thus imparted to the Mexican landscape by the wide range of the maize, wheat, tobacco, vine, coffee, and other plantations, as well as by the palms, evergreens, mango, olive, orange, lemon, yucca, and an endless variety of the cactus family, one species of which forms hedges 20 feet high on the Anahuac uplands. The central zone is on the whole drier than the southern lowlands, although the scarps facing seawards are often wrapped in the fogs and mists of the intercepted moisture-charged atmospheric currents. The heaviest recorded rainfall (90 to 100 inches) occurs in the healthy Huatusco district of Vera Cruz, at an altitude of 4380 feet.

In the highest zone of *tierras frias*, or "cold lands," embracing all the highlands from about 8000 feet upwards, the rainfall is five times less than on the tierras templadas. Hence snow rests throughout the year only on the four most elevated peaks of Popocatepetl, Orizaba, Nevada de Toluca (15,000 feet), and Ixtaccihuatl. Characteristic both of the tierras frias and templadas is the maguey (*Agave mexicana*), whose fruit is edible, and whose fermented juice has from time immemorial supplied the famous *pulque*, or national beverage of the Mexicans. From the fibre of the heniquen, an allied species, is produced the "Sisal hemp" of commerce, which has in recent years become the staple export of Yucatan.

Speaking generally, the four seasons are clearly marked north of 28° N. lat. only. South of that parallel they merge in the *estacion de las aguas*, or rainy season, from May to October, and the *estacion seca*, or dry season, which prevails for the rest of the year. The rains generally begin on the east coast, gradually moving westwards. In the Pacific the moist atmospheric currents are deflected northwards, whence the striking contrast between the

[1] Lorenzo Castro, *Mexico in* 1882. According to this authority the total yield of the Mexican mines between 1537 and 1880 was £776,276,000, while another estimate based on a report of the Mexican mint gives it at £930,786,000. Of this a large amount has been coined in Mexico, where there were eleven mints at work in 1876, with a total annual yield of about £5,000,000. The total coinage since the conquest has been estimated as high as £600,000,000, not more than 5 per cent. of this being gold. With regard to coal, the existence of which in Mexico has been recently denied by Mr Bigelow in *Harper's Magazine*, official returns for 1882 give a list of over twenty places where it has been found, though nowhere as yet in large quantities. Petroleum also appears to be very abundant in several localities. Amongst other natural products mention should be made of amber, found on the Yucatan coast. Mineral springs are very numerous everywhere on the plateaus and terrace-lands. The most famous are El Peñon and N. Señora de Guadelupe near the capital, and Aguas Calientes farther north.

[2] On the Amilpas plateau, which stretches south of Popocatepetl at a mean height of 5000 to 5400 feet, "coffee, sugar, and indigo are cultivated, and most of the tropical fruits grow luxuriantly" (Egloffstein, p. 17). The same authority gives the limits of vegetation in this region at 12,614 feet, and the snow-line at 14,960 feet. He observes that "nothing is more surprising to the traveller than the varieties of climate under this zone, which vary according to the different elevations above the sea. In a few hours we descended from the cold regions of the fir and the oak, on the heights of Ozumba, to a hot climate, *tierra caliente*, where we found the most luxuriant vegetation, passing in that short time through successive changes of the most diversified species of trees, plants, birds, insects" (p. 22).

the regular clergy suppressed, and their monasteries, together with all other superfluous ecclesiastical structures, appropriated by the state. During the last few years American Protestant missions have claimed some partial success, and the so-called "Church of Jesus," an undenominational body of a somewhat original type, has found a number of adherents, especially on the Anahuac tableland. But the *Indios bravos*, or uncivilized aborigines, everywhere follow the old spirit worship, while the Christianity of the Fideles is little more than a cloak for the continuous practice of the former Aztec heathenism. The pomp of the Roman ritual is supplemented by the feasts of the national worship, and the Pagan deities of the old cult are still represented by the saints of the Roman calendar.[1]

Administration.

Mexico constitutes at present a confederation of states modelled on that of the North-American Union, and administered according to the constitution of 1857 as amended in 1873–74. By popular suffrage are chosen the president, the upper house (fifty-two members), and the supreme judiciary for four years, and the lower house (two hundred and twenty-seven members) for two years. The senate, abolished in 1853, was restored in 1874, and the chief justice is *ex officio* vice-president. The federal states, which are divided into a number of administrative districts, enjoy full autonomy in all local matters. The several constitutions are modelled on that of the central government, and like it comprise three departments—legislative, executive, and judicial. Each state is represented in the federal congress in the proportion of one member for every 80,000 inhabitants, and in the federal senate by two members elected by suffrage in the local congress. All external affairs and questions of general interest are reserved for the central government. The constitution as now established thus represents in theory the complete overthrow of mediævalism, and the absolute triumph of the new ideas which in the Old World are still in so many places struggling for the ascendency.

History. Colonial period.

It is this struggle between privilege and popular rights that lends its human interest to the otherwise monotonous record of unresisted oppression and apparently aimless revolutions which characterize the early and the later periods of Mexican history, from the overthrow of the native rule down to the present day. The early or colonial period covers exactly three hundred years,—from the death in 1521 of Guatemozin, last of the Aztec emperors, to the withdrawal of the last Spanish viceroy, Don Juan O'Donoju, in 1821. During these three centuries the attitude of the masses was one rather of sullen submission than of active resistance to grinding oppression. By the Spanish Government Mexico was looked on merely as a vast metalliferous region, to be jealously guarded against foreign intrusion and worked exclusively for the benefit of the crown. The natives were evangelized chiefly for the purpose of being employed as slaves above and below ground, and thus was introduced from the West Indies the system of *repartimientos*, or distribution of the aborigines on the plantations and in the mines. But, while this system proved fatal to the natives of Cuba and Hayti, where it had to be replaced by negro labour, the hardier populations of the Anahuac plateau successfully resisted its blighting influences. It proved in fact more disastrous to the oppressor than to the oppressed. In those days Spain was commonly compared to a sieve, never the richer for all the boundless wealth drawn from the New World. But the aborigines derived at least some advantage from contact and partial fusion with a people of superior culture. This fusion, which may be regarded as the chief outcome of the colonial administration, has contributed to the formation of the present exceedingly complex Mexican nationality, in which the Indian continues to be the predominating element. Taking the whole population at less than ten millions, its ethnical distribution appears to be at present as under:—

1. Full-blood Indians	5,000,000
2. Mestizoes (half-caste Indians and whites)	3,000,000
3. Creoles (whites of Spanish descent)	1,500,000
4. Gachupines[2] (Spaniards by birth)	50,000
5. Other Europeans and Americans	100,000
6. Full-blood negroes	10,000
7. Zambos or "Chinos" (Indo-Africans)	45,000
8. Mulattoes (Eurafricans)	5,000

Under the Spanish administration, which was marked on the surface by few stirring events, such as warlike expeditions, civil strife, or serious internal troubles, Mexico, or New Spain, formed a viceroyalty at one time stretching from the isthmus of Panama to Vancouver's Island. Antonio de Mendoza, appointed in 1535 after government by *audiencias* had proved a signal failure, was the first of sixty-four viceroys who ruled with almost autocratic power, but scarcely any of whom has left a name in history. Don Juan de Acuña (1722–34) is mentioned as having been the only native American among them, and Don Juan V. G. Pacheco (1789–94) had at least the merit of betraying some regard for the social welfare of his subjects. Under him a regular police, the lighting and draining of towns, and other municipal improvements were introduced.

But down to the early years of the present century all emoluments in church and state, most of the large plantations, of the mines, and of the commerce of the country, continued to be monopolized by the privileged gachupines, whom the creoles and mestizoes had already begun to regard as aliens. Hence the first reactionary movements, stimulated by Napoleon's deposition of King Ferdinand and arrest of the viceroy Hurrigaray in 1808, were aimed rather against odious class distinctions and the intolerable oppression of these aliens than against the abstract rights of the Spanish crown. The long smouldering spirit of discontent at last broke into open revolt in 1810 at Guanajuato, under the leadership of Don Miguel Hidalgo. After his defeat and execution in 1811, the struggle was continued by Morelos, who, like Hidalgo, was a priest, and shared his fate in 1815. But he had already called a national assembly at Chilpanzinco, and by this body Mexican independence was for the first time proclaimed in 1813. A guerilla warfare kept the national spirit alive till a fresh stimulus was given to it by the Spanish revolution of 1820. Under the leadership of the "Liberator" Iturbide, Mexican independence was again proclaimed on February 24, 1821, and the same year the capital was surrendered by O'Donoju, the last of the viceroys. But even after the revolt had thus been crowned with success a change of *personnel* rather than of system was contemplated; nor was Iturbide proclaimed emperor until the Mexican crown had been declined by a royal prince of Spain.

Period of independence.

Almost simultaneously with this event the republican standard had been raised by Santa Anna at Vera Cruz (December 1822). Thus the nation had no sooner got rid of foreign rule than it became torn by internal dissension. But henceforth the struggle is not so much against the privileged classes as between Conservative and Liberal principles,—the former represented chiefly by the church and the superstitious populace, the latter by the more enlightened but not less unscrupulous sections of the community. From both the Indios Bravos, that is, about a third of the whole population, hold entirely aloof, and take advantage of the public disorders to continue their aggres-

[1] On the general state of religion in Mexico Bates well remarks:—"The educated classes conform to the outward ceremonies and ordinances of the church, while inwardly believing little or nothing of its dogmas. The lower grades of society are, on the other hand, steeped in the most grovelling superstition, intensified by many traditional Indian reminiscences. This section of the community yields a blind obedience to the clergy, notwithstanding the severe laws with which the Government has endeavoured to counteract the influence of the priests. Even so recently as 1874 a genuine case of witch-burning occurred in Mexico."—*Central America*, p. 34.

[2] From the Aztec *Catzopin*, centaur; also known as *Chapetones*.

sive warfare against all alike.[1] Events now follow in quick succession, and as many as three hundred successful or abortive revolutions are recorded during the brief but stormy life of Mexican national independence.[2] But amid the confusion of empires, republics, dictatorships, and military usurpations, succeeding each other with bewildering rapidity, the thoughtful student will still detect a steady progress towards the ultimate triumph of those Liberal ideas which lie at the base of true national freedom. A brief tabulated summary of the more salient incidents in this eventful struggle must here suffice:—

1821–23. Mexican independence acknowledged by Spain; regency under Iturbide, who (1822) is elected hereditary constitutional emperor; in December Santa Anna proclaims the republic in Vera Cruz.

1823–24. Provisional Government; Iturbide abdicates; exiled, withdraws to London, but returning is shot (1824).

1824. First Liberal constitution,—"Acta Constitutiva de la Federacion Mexicana," then comprising nineteen states and five territories; first president D. Felix Victoria, known as "Guadalupe Victoria."

1828–30. Contested presidencies of Pedraza, Guerrero, and Bustamente.

1835. Reaction of the church party; constitution of 1824 abolished; the confederate states fused in a consolidated republic under Santa Anna as president, but practically dictator.

1836. Texas refusing to submit secedes, defeats and captures Santa Anna.

1837. Santa Anna returning resumes office.

1839. Bravo's brief presidency followed by much anarchy.

1841–44. Santa Anna's first dictatorship with two others.

1844. Constitution restored with Santa Anna president; banished same year, he is succeeded by Canalizo.

1845. Herrera president; disastrous war with United States to recover Texas.

1846. Santa Anna again president.

1848. Treaty of Guadalupe; California and New Mexico ceded to United States.

1853. Santa Anna's second dictatorship; treaty of Mesilla (negotiated by Gadsden) ceding extensive territory to United States and reducing Mexico to its present limits; great financial embarrassment; "Plan of Ayutla"; flight of Santa Anna followed by universal chaos.

1855. Provisional Government under President Comonfort.

1856. Constitutional convention; radical reforms; rupture with Spain.

1857. Liberal constitution of March 11; suspended December 1; Comonfort dictator; the reaction supported by the church, large part of the army, and all Conservatives; opposed at Vera Cruz by Vice-president Benito Juarez at the head of the "Puros," or advanced Liberals; the "War of Reform" begins, and lasts till 1860.

1858–59. In the capital Comonfort is deposed by Zuloaga, who abdicates in favour of Miramon, general of the Conservative forces; but, declining the presidency, Miramon restores Zuloaga; British legation violated; in Vera Cruz the United States envoy MacLean acknowledges Juarez, who introduces further Liberal measures.

1860. Capitulation of Guadalajara; flight of Miramon from the capital; triumph of the Liberals.

1861. Triumphal entry of Juarez into the capital; further radical reforms; marriage declared a civil contract; celibacy and ecclesiastical tribunals suppressed; confiscation of church property valued at £75,000,000 and over a third of the soil; final separation of church and state; Spain, France, and England urge claims for losses of their subjects resident in Mexico; convention of London; intervention of the allies, who occupy Vera Cruz in December.

1862. England and Spain withdraw, their claims having been settled by negotiation; war continued by France.

1863–64. The capital occupied by the French; Louis Napoleon dreams of a universal fusion of the Latin races; offers the Mexican imperial crown to the Austrian archduke Ferdinand Maximilian, who accepts, and arrives in June 1864.

1867. After diverse issues the French withdraw; Maximilian, abandoned to his fate, is captured and shot at Querétaro (June 19).

1867–69. Various pronunciamientos by Santa Anna and others.

1871–72. Juarez president; he dies in office July 1872; succeeded by his secretary Lerdo de Tejada.

1873–74. The Liberal constitution of 1857, which had been twice suspended (1858–60 and 1863–67), is now largely amended, and continues to be henceforth the organic law of Mexico.

1876. Tejada succeeded by Porfirio Diaz.

1880. Manuel Gonzalez, reigning president

Since 1869 the Liberal party has succeeded in preserving peace at home and abroad, while establishing democratic institutions on a firm basis. A. v. Humboldt's gloomy anticipations[3] have not been realized, and for the first time in its chequered history Mexico may look forward with some confidence to a bright future. The plague spot is the uncivilized Indian element. But with boundless natural resources at its disposal, a wise administration may hope to overcome that difficulty, and gradually effect a complete fusion of the antagonistic racial elements.

Ratzel's *Aus Mexico*, Breslau, 1878. (A. H. K.)

III. THE CITY OF MEXICO.

Mexico, the capital formerly of the Aztec empire and of the Spanish colony of New Spain, and now of the republic, state, and federal district of Mexico, stands on the Anahuac plateau, 7524 feet above sea-level, 2½ miles from the south-west side of Lake Tezcuco (Texcoco), the lowest and largest of six basins filling the deepest depression in the hill-encircled Mexican valley. Situated in 19° 25′ 45″ N. lat. and 99° 7′ W. long., it is 173 miles by rail from Vera Cruz on the Atlantic, 290 from Acapulco on the Pacific, 285 from Oajaca, 863 from Matamoros on the United States frontier. Mexico is the largest and finest city in Spanish America, forming a square nearly 3 miles both ways, and laid out with perfect regularity, all its six hundred streets and lanes running at right angles north to south and east to west, and covering within the walls an area of about 10 square miles, with a population (in 1880) of 230,000. Most of the inhabitants are pure-blood Indians or mestizoes; but the foreigners, chiefly French, English, Germans, Americans, and Spaniards, monopolize nearly all the trade, and as capitalists, bankers, merchants, and dealers enjoy an influence out of all proportion to their numbers. A large portion of the natives are mendicants or vagrants, and the distinctly criminal element (26,470 in 1878) is kept in order by a police force of 1320 men; yet in that year there were as many as 5370 knife-attacks and 3250 robberies. The

[1] In December 1882 a party of seventy-five Mexicans and Americans were massacred in the state of Chihuahua by a band of Bravos.

[2] Between 1821 and 1868 the form of government was changed ten times; over fifty persons succeeded each other as presidents, dictators, or emperors; both emperors were shot, Iturbide in 1824, Maximilian in 1867, and according to some calculations there occurred at least three hundred *pronunciamientos*.

[3] Consulted shortly before his death as to the future prospects of Mexico, with which his name was so intimately associated, Humboldt ventured to prophesy that "die Vereinigten Staaten werden es an sich reissen und dann selbst zerfallen."

broad, well-paved, and gas-lit streets present a picturesque appearance with their quaint two- and three-storied stone houses gaily painted in white, red, yellow, or green, and terminating everywhere with a background of rugged sierras or snowy peaks which, owing to the bright atmosphere at this elevation, seem quite close, although really 30 or 40 miles distant. All the main thoroughfares converge on the central Plaza de Armas (Plaza Mayor, or Main Square), which covers 14 acres, and is tastefully laid out with shady trees, garden plots, marble fountains, and seats. Here also are grouped most of the public buildings, towering above which is the cathedral, the largest and most sumptuous church in America, which faces the north side of the plaza on the site of the great pyramidal teocalli or temple of Huitzilopochtli, titular god of the Aztecs. This edifice, which was founded in 1573 and finished in 1657, at a cost of £400,000 for the walls alone, forms a Greek cross 426 feet long and 203 wide, with two great naves and three aisles, twenty side chapels, and a magnificent high altar supported by marble columns, and surrounded by a tumbago balustrade with sixty-two statues of the same rich gold, silver, and copper alloy serving as candelabra. The elaborately carved choir is also enclosed by tumbago railings made in Macao, weighing 26 tons, and valued at about £300,000. In the interior the Doric style prevails, Renaissance in the exterior, which is adorned by a fine dome and two open towers 218 feet high. At the foot of the left tower is placed the famous calendar stone, the most interesting relic of Aztec culture. The east side of the plaza is occupied by the old viceregal residence, now the National Palace, with 675 feet frontage, containing most of the Government offices (ministerial, cabinet, treasury), military headquarters, archives, meteorological department with observatory, and the spacious hall of ambassadors with some remarkable paintings by Miranda and native artists. North of the National Palace, and apparently forming portions of it, are the post-office and the national museum of natural history and antiquities, with a priceless collection of Mexican remains. Close to the cathedral stands the Monte de Piedad, or national pawnshop, a useful institution, endowed in 1744 by Terreros with £75,000, and now possessing nearly £2,000,000 of accumulated funds. Facing the cathedral is the Palacio Municipal (city hall), 252 feet by 122, rebuilt in 1792 at a cost of £30,000, and containing the city and district offices, the corporation jail, and the lonja, or merchants' exchange. Around the Plaza San Domingo are grouped the convent of that name, said to contain vast treasures buried within its walls, the old inquisition, now the school of medicine, and the custom-house. In the same neighbourhood are the church of the Jesuits and the school of arts, "an immense workshop, including iron and brass foundries, carriage and cart mending, building and masonry, various branches of joinery and upholstery work, and silk and cotton hand-weaving" (Brocklehurst). Other noteworthy buildings are the national picture gallery of San Carlos, the finest in America, in which the Florentine and Flemish schools are well represented, and which contains the famous Las Casas by Felix Parra; the national library of St Augustine, with over 100,000 volumes, numerous MSS., and many rare old Spanish books; the mint, which since 1690 has issued coinage, chiefly silver, to the amount of nearly £400,000,000; the Iturbide hotel, formerly the residence of the emperor Iturbide; the Mineria, or school of mines, with lecture-rooms, laboratories, rich mineralogical and geological specimens, and a fossil horse 3 feet high of the Pleistocene period. Owing to the spongy nature of the soil, the Mineria and many other structures have settled out of the perpendicular, thus often presenting irregular lines and a rickety appearance. Among the twenty scientific institutes mention should be made of the Geographical and Statistical Society, whose meteorological department issues charts and maps of unsurpassed excellence.

Besides the chief market south of the National Palace there are three others, all well stocked with meat, fish, and especially vegetables, fruits, and flowers grown mainly on the *chinampas*, or floating gardens of Lakes Chalco and Xochimilco. These gardens, which were far more numerous in the Aztec times, are formed by placing layers of turf on the matted aquatic vegetable growths to a height of 2 or 3 feet above the water, and securing them by long willow poles driven through them to the bottom, where they take root. They form plots 100 to 200 feet long by 20 to 100 broad, and are firm enough to support the huts of the cultivators. From the still extant illuminated tribute-rolls it appears that the Aztec rulers derived a large share of the taxes from these gardens, which at that time also covered the brackish waters of Lake Tezcuco.

Before 1860 half of the city consisted of churches, convents, and other ecclesiastical structures, most of which have been sequestrated and converted into libraries, stores, warehouses, and even stables, or pulled down for civic improvements. Nevertheless there still remain fourteen parish and thirty other churches, some of large size with towers and domes, and their number has now been increased by six Protestant churches including the Anglican cathedral in San Francisco Street. This is the leading thoroughfare, and is rivalled in splendour only by the new Cinco de Mayo Street running from the National Theatre to the cathedral.

The city is supplied by two monumental aqueducts, from Chapultepec and the south-west, with good water at the rate of 44 gallons per day per inhabitant.

Its industries are varied but unimportant, consisting chiefly of gold and silver work, coarse glazed and unglazed pottery of peculiar form and ornamentation, paper, feather-work remarkable for its taste and beautiful designs, toys, rosaries, crucifixes, religious pictures, lace, and some weaving.

Mexico enjoys an equable climate, with a temperature varying from 70° to 50° F., but rendered unhealthy by the exhalations from the lakes and the bad drainage. The death-rate in 1876 was 59 per 1000, and 45 in 1878, pneumonia being most fatal (12 per cent. of the total). Standing at the lowest level of a lacustrine valley, 1400 square miles in extent, and completely encircled by hills with no natural outlet, the city has always been subject to floodings from the overflow of the neighbouring freshwater Lakes Zumpango and Xaltocan on the north and Xochimilco and Chalco on the south, which, in the 17th century, laid the whole district under water in 1607, and again for five years from 1629 to 1634. To remedy the evil the engineer Martinez began in 1607 the great cutting 13 miles long through the Nochistongo hill in order to draw off the discharge of Lake Zumpango, the highest in the valley, to the river Tula, a tributary of the Panuco, flowing to the Atlantic. This work, which cost the lives of 70,000 natives, was completed in 1789; but the result was not satisfactory, and the city is still often flooded.

The chief public promenades are the Alameda, planted with stately beeches; the Vega, skirted by the Vega Canal, and adorned with the colossal bust of Guatemozin, the last of the Aztec emperors; the Paseo de la Riforma, a fine avenue 3 miles long running south to the famous castle of Chapultepec, a place intimately associated with the names both of Montezuma and Maximilian. The present castle, erected in 1785 by the viceroy Galvez on the site of Montezuma's palace, commands a superb view of the city and surrounding district, and is approached by avenues of gigantic cypresses (*Cupressus disticha*) dating from Aztec times, growing to a height of 120 feet, and measuring from 30 to 40 feet round the stem. Other good roads with horse or steam trams lead to Tacubaya and the "Noche Triste" tree, where Cortes is traditionally supposed to have rested after the disastrous retreat from Mexico on the night of June 30, 1520, to the pleasant summer suburb of Tacubaya, and to the renowned shrine of Our Lady of Guadalupe, 3 miles to the east on the border of Lake Tezcuco. Here stands the most famous church in Mexico, erected to commemorate the legendary apparitions of the Madonna to the Indian Juan Diego in December 1531, and still visited by thousands of pilgrims or sightseers.

Mexico dates either from the year 1325 or 1327, when the Aztecs after long wanderings over the plateau were directed by the oracle to settle at this spot. For here had been witnessed the auspicious omen of an eagle perched on a nopal (cactus) and devouring a snake. Hence the original name of the city, Tenochtitlan (nopal on a stone), changed afterwards to Mexico in honour of the war god Mexitli. With the progress of Aztec culture the place rapidly improved, and about 1450 the old mud and rush houses were replaced by solid stone structures erected partly on piles amid the islets of Lake Tezcuco, and grouped round the central enclosure of the great teocalli. The city had reached its highest splendour on the arrival of the Spaniards in 1519, when it comprised from 50,000 to 60,000 houses, with perhaps 500,000 inhabitants, and seemed to Cortes "like a thing of fairy creation rather than the work of mortal hands" (Prescott). It was at that time about 12 miles in circum-

ference, every where intersected by canals, and connected with the mainland by six long and solidly constructed causeways, as is clearly shown by the plan given in the edition of Cortes's letters published at Nuremberg in 1524 (reproduced in vol. iv. of H. H. Bancroft's *History of the Pacific States*, San Francisco, 1833, p. 280). After its almost total destruction in November 1521, Cortes employed some 400,000 natives in rebuilding it on the same site; but since then the lake seems to have considerably subsided, for although still 50 square miles in extent it is very shallow, and has retired 2½ miles from the city. During the Spanish rule the chief event was the revolt of 1692, when the municipal buildings were destroyed. Since then Mexico has been the scene of many revolutions, and after the battle of Chapultepec (September 13, 1847) the city was held by the United States troops till the treaty of Guadalupe, May 1848. But since the disorders ending with the death of Maximilian it has turned to peaceful ways, and has become a great centre of civilizing influences for the surrounding semi-barbarous peoples. (A. H. K.)

MEYERBEER, Giacomo (1791–1863), first known in Germany as Jakob Meyer Beer, was born at Berlin on September 5, 1791,[1] of a wealthy and talented Jewish family. His father, Herz Beer, was a banker; his mother, Amalie (*née* Wulf), was a woman of high intellectual culture; and two of his brothers distinguished themselves in astronomy and literature. He studied the pianoforte, first under Lauska, and afterwards under Lauska's master, Clementi. When seven years old he played Mozart's Concerto in D Minor in public, and at nine he was pronounced the best pianist in Berlin. For composition he was placed under Zelter, whose lessons were soon exchanged for those of Bernard Weber, then director of the Berlin opera, by whom he was introduced to the Abbé Vogler. Struck by his brilliant talent, Vogler invited him to Darmstadt, and in 1810 received him into his house, where he formed an intimate friendship with Karl Maria von Weber, who, though his senior by eight years, shared the daily lessons he received from the abbé in counterpoint, fugue, and extempore organ-playing. At the end of two years the grand-duke appointed Meyerbeer composer to the court. His early works, however, were far from successful,—his first opera, *Jephtha's Gelübde*, failing lamentably at Darmstadt in 1811, and his second, *Wirth und Gast* (*Alimelek*), at Vienna in 1814. These checks discouraged him so cruelly that he feared he had mistaken his vocation. Nevertheless, by advice of Salieri, he determined to study vocalization in Italy, and then to form a new style. But at Venice he was so captivated by the style of Rossini that, renouncing all thought of originality, he produced a succession of seven Italian operas—*Romilda e Costanza*, *Semiramide riconosciuta*, *Edouardo e Cristina*, *Emma di Rosburgo*, *Margherita d'Anjou*, *L'Esule di Granata*, and *Il Crociato in Egitto*—which all achieved a success as brilliant as it was unexpected. Against this act of treason to German art Weber protested most earnestly; and before long Meyerbeer himself grew tired of his defection, though the success of *Il Crociato* was so great that he was crowned upon the stage. An invitation to Paris in 1826 led him to review his position fairly and dispassionately, and he could not conceal from himself the fact that he was wasting in imitation powers which, rightly used, might make his name immortal. For several years after this he produced nothing in public; but, in concert with Scribe, he planned the work which first made known the reality of his transcendent genius—his first French opera, *Robert le Diable*. This gorgeous drama was produced at the Grand Opéra in 1831, and received with acclamation. It was the first of its race; a grand romantic opera, abounding with scenes of startling interest, with situations more powerfully dramatic than any that had been attempted either by Cherubini or Rossini, with mysterious horrors and chivalric pomp, and with ballet music such as had never yet been heard, even in Paris. Its popularity exceeded all previous expectation; yet for five years after this signal triumph Meyerbeer appeared before the public no more. We cannot doubt that his motive for this retirement was the determination to produce something greater still; and in some respects his next opera, *Les Huguenots*, really was greater, though it fell short of the deep romance which rendered *Robert le Diable* so incomparably captivating.

The first performance of *Les Huguenots* took place in 1836. In gorgeous colouring, in depth of passion, in consistency of dramatic treatment, and in careful delineation of individual character, it is at least the equal of *Robert le Diable*. In two points only did its interest fall short of that inspired by the earlier work. Meyerbeer had shown himself so great a master in his treatment of the supernatural that one regretted the unavoidable omission of that powerful element in his second grand opera; and, more important still, the fifth act of *Les Huguenots* was so arranged by the librettist as to render effective musical treatment impossible. The substitution of a noisy fusillade for a legitimate dramatic situation was fatal to the anticipated climax. The music which accompanies this division of the work is necessarily inferior to all that precedes it. The true interest of the drama culminates at the close of the fourth act, when Raoul, leaping from the window, leaves Valentine fainting upon the ground. The spectator needs not to be told that the former will be shot down the moment he arrives in the street, or that the latter will mourn for him to the end of her days. Neither musically nor dramatically does anything more remain to be said; and therefore it is that those who quit the theatre when the curtain falls for the fourth time carry away with them a far more perfect ideal than those who remain to the end.

After the production of *Les Huguenots* Meyerbeer again retired from public view, and spent many years in the preparation of two of his greatest works—the greatest of all except the two we have already mentioned—*L'Africaine* and *Le Prophète*. The libretti of both these operas were furnished by Scribe; and both were subjected to countless changes of detail before they satisfied the composer's fastidious taste; in fact, the story of *L'Africaine* was more than once entirely rewritten.

Meanwhile Meyerbeer accepted the appointment of kapellmeister to the king of Prussia, and spent some years at Berlin, where he produced *Ein Feldlager in Schlesien*, a German opera, in which the matchless cantatrice Jenny Lind made her first appearance in Prussia, with unprecedented success. Here also he composed, in 1846, the overture to his brother Michael's drama, *Struensee*. But his chief care at this period was bestowed upon the worthy presentation of the works of others. He began by producing his dead friend Weber's *Euryanthe*, with scrupulous attention to the composer's original idea. With equal unselfishness he procured the acceptance of *Rienzi* and *Der Fliegende Holländer*, the first two operas of Richard Wagner, who, then languishing in poverty and exile, would, but for him, have found it impossible to obtain a hearing in Berlin. With Jenny Lind as prima donna and Meyerbeer as conductor, the opera flourished brilliantly in the Prussian capital; but the anxieties of this thankless period materially shortened the composer's life.

Meyerbeer produced *Le Prophète* at Paris in 1849; and, if it did not at first create so great a sensation as *Les Huguenots*, this was simply because it needed to be better

[1] Or, according to some accounts, 1794.

both men and women, are shorter and darker-complexioned than the Chinese, their faces also are rounder and their features sharper. In disposition, too, they are very unlike their civilized neighbours. They are brave, passionate, suspicious, revengeful, and indifferent to cold and hunger; they are free and easy in their manners, and are as noisily joyous as the Chinese are grave and sedate.

They are divided into between forty and fifty clans, each of which is distinguished by a name which is generally derived either from some physical characteristic, or from some custom, or from the habitat of the clan, as, for example, "The Black Miau," "the narrow-headed Miau," so named from their manner of dressing their hair, "the six-valley Miau," &c. Among these clans there exist wide differences of culture, some being in no way removed from savages, while others who have been brought under the influence of Chinese civilization show themselves apt and ready learners. Very few of them, so far as is known, possess any written records. The Yaou-jin, or Goblin clan, are said to have books, which, though they are now unable to read, they still regard with reverent awe. "The barbarous characters" used in these books are, according to a Chinese writer, "like knotted worms, and are utterly unintelligible." The Ko-los also are said to be a lettered clan, but for the most part the Miautse content themselves with conveying information and preserving records by means of notched sticks. Their language as well as their ethnic characteristics prove them to be closely related to the Siamese, Anamese, Cambodians, and the inhabitants of Hainan; in fact they form part of the race which is spread over the whole of south-eastern Indo-China. Their social customs are as widely different as their appearance is from those of the Chinese. The widest latitude is given to the youth of both sexes in the choice of their husbands and wives. As among the hill tribes of Chittagong, the selection is commonly made on the mountain side, where on moonlight nights in the "leaping month" the young men and maidens meet to sing or to play at ball, or to dance round the "devil's staff" (*Anglice*, Maypole), and to choose their partners for life. Among some clans the "couvade" is an established custom. Their funeral rites vary according to the districts, those living within reach of the influence of the Chinese having adopted their customs, while those more remote still hang their dead in baskets from trees, or lay them in the ground and disinter them yearly to wash their bones. In dress they are fond of bright colours, and commonly wear loose but short jackets, sometimes with and sometimes without trousers. The men wear turbans wound round their hair, which is raised above the head in the shape of a spiral shell, and the women either don a kind of cap, or dress their hair in the shape of a ram's horn. For many years the relations of the Miautse with the Chinese Government have been generally of a peaceable nature, and in the *Peking Gazette* of April 1881 there was published a new system of government by which it is hoped that the incorporation of the mountaineers into the empire may become more real and complete.

See *Sketches of the Miau-tsze*, translated by E.C. Bridgman; J. Edkins, *The Miau-tsi Tribes, their History*; and "Quaint customs in Kwei-chow," *Cornhill Magazine*, January 1872.

MICAH (מִיכָה) is the short form of a name which in various modifications—*Mīcāiāhū*, *Mīcāiĕhū*, *Mīcāiāh*—is common in the Old Testament, expressing as it does a fundamental point of Hebrew faith: Who is like Jehovah? The name was borne among others by the Danite whose history is given in Judg. xvii. *sq.*, by the prophet who opposed Ahab's expedition to Ramoth-Gilead (1 Kings xxii.), and by the subject of the present article, the contemporary and fellow-worker of Isaiah, whose name is prefixed to the sixth in order of the books of the minor prophets.[1]

It is at once apparent that the book of Micah divides itself into at least two distinct discourses, chap. vi. 1 forming a new commencement; and from what we know in general of the compilation of the prophetic collection we cannot at once determine whether the second discourse, which has no title, is to be ascribed to the author of the immediately preceding prophecy, or is to be regarded as an independent and anonymous piece. To decide this question, if it can be decided, we must begin by a separate study of the earlier chapters to which the title in Micah i. 1 directly belongs. These again fall into two parts. Chaps. i.–iii. (with the exception of two verses, ii. 12, 13) are a prediction of judgment on the sins of Judah and Ephraim. In a majestic exordium Jehovah Himself is represented as coming forth in the thunderstorm (comp. Amos i. 2) from His heavenly palace, and descending on the mountains of Palestine, at once as witness against His people, and the executer of judgment on their sins. Samaria is sentenced to destruction for idolatry; and the blow extends to Judah also, which participates in the same guilt (chap. i.). But, while Samaria is summarily dismissed, the sin of Judah is analysed at length in chaps. ii. and iii., in which the prophet no longer deals with idolatry, but with the corruption of society, and particularly of its leaders—the grasping aristocracy whose whole energies are concentrated on devouring the poor and depriving them of their little holdings, the unjust judges and priests who for gain wrest the law in favour of the rich, the hireling and gluttonous prophets who make war against every one "that putteth not into their mouth," but are ever ready with assurances of Jehovah's favour to their patrons, the wealthy and noble sinners that fatten on the flesh of the poor. The prophet speaks with the strongest personal sympathy of the sufferings of the peasantry at the hands of their lords, and contemplates with stern satisfaction the approach of the destroyer who shall carry into exile "the luxurious sons" of this race of petty tyrants (i. 16), and leave them none to stretch the measuring line on a field in the congregation of Jehovah (ii. 5). The centre of corruption is the capital, the city of Zion, grown great on the blood and wrongs of the provincials, the seat of the cruel princes, the corrupt judges and diviners. For their sake, he concludes, Zion shall be plowed as a field, Jerusalem shall lie in ruins, and the temple hill return to jungle (iii. 12).

The situation thus sketched receives its elucidation from the data supplied by the title (i. 1) and confirmed and rendered more precise by a remarkable passage in Jeremiah. According to the title Micah flourished in the reigns of Jotham, Ahaz, and Hezekiah; according to Jeremiah (xxvi. 18 *sq.*) the prophecy of the destruction of Jerusalem just cited was spoken under Hezekiah, and bore fruit in the repentance of king and people, by which the judgment was averted. The allusion beyond doubt is to Hezekiah's work of religious reformation (2 Kings xviii. 4 *sq.*). It is hardly possible to separate this reformation from the influence of Isaiah, which did not become practical in the conduct of the state till the crisis of Sennacherib's invasion; and the conclusion that Hezekiah was not from the first a reforming king, which is forced on us by many passages of Isaiah, is confirmed by the prophecy of Micah, which, after Hezekiah's accession, still represents wickedness as seated in the high places of the kingdom. The internal disorders of the realm depicted by Micah are also prominent in Isaiah's prophecies; they were closely connected, not only with the foreign complications due to the approach of the Assyrians, but with the break-up of the old agrarian system within Israel, and with the rapid and uncompensated aggrandisement of the nobles during those prosperous years when the conquest of Edom by Amaziah and the occupation of the port of Elath by his son (2 Kings xiv. 7, 22) placed the lucrative trade between the Mediterranean and the Red Sea in the hands of the rulers of Judah. On the other hand the democratic tone which distinguishes Micah from Isaiah, and his announcement of the impending fall of the capital (the deliverance of which from the Assyrian appears to Isaiah as the necessary condition for the preservation of the seed of a new and better kingdom), are explained by the fact that, while Isaiah lived in the centre of affairs, Micah was a Morasthite or inhabitant of Moresheth Gath, a place near the Philistine frontier so unimportant as to be mentioned

[1] A confusion between the two prophets of the name has led to the insertion in the Massoretic text of 1 Kings xxii. 28 of a citation from Micah i. 2, rightly absent from the LXX.

only in Micah i. 14.[1] The provincial prophet sees the capital and the aristocracy entirely from the side of a man of the oppressed people, and foretells the utter ruin of both. But this ruin does not present itself to him as involving the captivity or ruin of the nation as a whole; the congregation of Jehovah remains in Judæa when the oppressors are cast out (ii. 5); Jehovah's words are still good to them that walk uprightly; the glory of Israel is driven to take refuge in Adullam, as in the days when David's band of broken men was the true hope of the nation, but there is no hint that it is banished from the land. Thus upon the prophecy of judgment we naturally expect to follow a prophecy of the redintegration of Jehovah's kingship in a better Israel, and this we find in ii. 12, 13 and in chaps. iv., v. Both passages, however, present difficulties. The former seems to break the pointed contrast between ii. 11 and iii. 1, and is therefore regarded by Ewald as an example of the false prophecies on which the wicked rulers trusted. The thought, however, is one proper to all true prophecy (comp. Hos. i. 11 [ii. 2], Isa. xi. 11 *sq.*, Zeph. iii. 14, Jer. xxxi. 8), and precisely in accordance with chaps. iv., v., even in the details of expression and imagery.[2] It is indeed possible that these verses are a separate oracle of Micah, which did not originally stand in its present connexion. The sequence of thought in chaps iv., v., on the other hand, is really difficult, and has given rise to much complicated discussion.[3] There is a growing feeling among scholars that iv. 11–13 stands in direct contradiction to iv. 9, 10, and indeed to iii. 12. The last two passages agree in speaking of the capture of Jerusalem, the first declares Zion inviolable, and its capture an impossible profanation. Such a thought can hardly be Micah's; even if we resort to the violent harmonistic process of imagining that two quite distinct sieges, separated by a renewal of the theocracy, are spoken of in consecutive verses. An interpolation, however, in the spirit of such passages as Ezek. xxxviii., xxxix., Joel iii. [iv.], Zech. xiv., is very conceivable in post-exilic times, and in connexion with the growing impulse to seek a literal harmony of all prophecy on lines very different from the pre-exilic view in Jer. xxvi., that predictions of evil may be averted by repentance. Another difficulty lies in the words "and thou shalt come even to Babylon" in iv. 10. Micah unquestionably looked for the destruction of Jerusalem as well as of Samaria in the near future and by the Assyrians (i. 9), and this was the judgment which Hezekiah's repentance averted. If these words, therefore, belong to the original context, they mark it as not from Micah's hand; but it is easy to see that they are really a later gloss. The prophetic thought is that the daughter (population) of Zion shall not be saved by her present rulers or defensive strength; she must come down from her bulwarks and dwell in the open field; there, and not within her proud ramparts, Jehovah will grant deliverance from her enemies. This thought is in precise harmony with chaps. i.–iii., and equally characteristic is what follows in chap. v. Micah's opposition to present tyranny expresses itself in recurrence to the old popular ideal of the first simple Davidic kingdom (iv. 8) to which he had already alluded in i. 15. These old days shall return once more. Again guerilla bands (בת־גדוד) gather to meet the foe as they did in the time of Philistine oppression. A new David, like him whose exploits in the district of Micah's home were still in the mouths of the common people, goes forth from Bethlehem to feed the flock in the strength of Jehovah. The kindred Hebrew nations are once more united to their brethren of Israel (comp. Amos ix. 12, Isa. xvi. 1 *sq.*). The remnant of Jacob springs up in fresh vigour, inspiring terror among the surrounding peoples, and there is no lack of chosen captains to lead them to victory against the Assyrian foe. In the rejuvenescence of the nation the old stays of that oppressive kingship which began with Solomon, the strongholds, the fortified cities, the chariots and horses so foreign to the life of ancient Israel, are no more known; they disappear together with the divinations, the soothsayers, the idols, the *maççebas* and *asheras* of the high places Jehovah is king on Mount Zion, and no inventions of man come between Him and His people.

The elements of this picture, drawn so largely from the most cherished memories of the Judæans, could not fail to produce a wide impression, especially when the invasion of Sennacherib, although it spared Jerusalem, fulfilled in the most striking way a great part of Micah's predictions of judgment. Of this we have evidence, not only in Jer. xxvi., but in the political and religious ideas of the book of Deuteronomy. The picture of the right king (Deut. xvii. 14 *sq.*) and the condemnation of the high-places alike follow the doctrine of Micah.

A difficulty still remains in the opening verses of chap. iv. Micah iv. 1–3 and Isa. ii. 2–4 are but slightly modified recensions of the same text, and as Isa. ii. is older than the prophecy of Micah, while on the other hand Micah iv. 4 seems the natural completion of the passage, it is common to suppose that both copy an older prophet. But the words have little connexion with the context in Isaiah, and may be the quotation of a copyist suggested by ver. 5. On the other hand it has been urged that the passage belongs to a later stage of prophetic thought than the 8th century B.C. There is, however, no real difficulty in the idea that foreign nations shall seek law and arbitrament at the throne of the king of Zion (comp. the old prophecy Isa. xvi.); and the mention of the temple as the seat of Jehovah's sovereignty may be illustrated by Isa. vi., where the heavenly palace (Micah i. 3) is at least pictured in the likeness of the temple on Zion. At the same time the Jerusalem of Micah iv. 8 is the Jerusalem of David not of Solomon, the ideas of iv. 1–4 do not reappear in chap. v., and the whole prophecy would perhaps be more consecutive and homogeneous if iv. 6 (where the dispersed and the suffering are, according to chap. ii., the victims of domestic not of foreign oppression) followed directly on iii. 12.

The sixth chapter of Micah presents a very different situation from chaps. i.–v. Jehovah appears to plead with his people for their sins, but the sinners are no longer a careless and oppressive aristocracy buoyed up by deceptive assurances of Jehovah's help, by prophecies of wine and strong drink; they are bowed down by a religion of terror, wearied with attempts to propitiate an angry God by countless offerings, and even by the sacrifice of the first-born. Meantime the substance of true religion—justice, charity, and a humble walk with God—is forgotten, fraud and deceit reign in all classes, the works of the house of Ahab are observed (worship of foreign gods). Jehovah's judgments are multiplied against the land, and the issue can be nothing else than its total desolation. All

[1] That Micah lived in the Shephela or Judæan lowland near the Philistine country is clear from the local colouring of i. 10 *sq.*, where a number of places in this quarter are mentioned together, and their names played upon in a way that could hardly have suggested itself to any but a man of the district. The paronomasia makes the verses difficult, and in i. 14 none of the ancient versions recognizes Moresheth Gath as a proper name. The word Morasthite (*Mōrashti*) was therefore obscure to them; but this only gives greater weight to the traditional pronunciation with ō in the first syllable, which is as old as the LXX., and goes against the view, taken by the Targum both on Micah and on Jeremiah, and followed by some moderns (including Roorda), that Micah came from Mareshah. When Eusebius places Μωρασθεί near Eleutheropolis it is not likely that he is thinking of Mareshah (Maresa), for he speaks of the former as a village and of the latter as a ruin 2 miles from Eleutheropolis. Jerome too in the *Epit. Paulæ* (*Ep.* cviii.), speaking as an eye-witness, distinguishes Morasthim, with the church of Micah's sepulchre, from Maresa. This indeed was after the pretended miraculous discovery of the relics of Micah in 385 A.D.; but the name of the village which then existed (*Præf. in Mich.*) can hardly have been part of a pious fraud.

[2] The figure of the shepherd gathering a scattered flock certainly does not presuppose a total captivity, as Stade (*Z. f. A.T. W.*, i. 161 *sq.*) argues.

[3] See, besides the commentaries, Nöldeke in the *Bibel-lex.*, iv. 214; a paper by Oort and two by Kuenen in *Theol. Tijdsch.*, 1872; Wellhausen-Bleek, *Einleitung*, p. 426; Stade, *l.c.*, and *ibid.*, iii. 1 *sq.* Stade goes so far as to make the whole of Micah iv., v. presuppose the exile, and to find still later additions in iv. 5–10., v. 5, 6 [v. 4, 5]. Giesebrecht, *Theol. LZ.*, 1881, col. 443 *sq.*, rejects chap. iv. only. The arguments cannot be here cited at length, but they are tacitly kept in view in what follows.

these marks fit exactly the evil times of Manasseh as described in 2 Kings xxi. Chap. vii. 1–6, in which the public and private corruption of a hopeless age is bitterly bewailed, obviously belongs to the same context (comp. vol. xiii. p. 415). Micah may very well have lived into Manasseh's reign, but the title in i. 1 does not cover a prophecy which certainly falls after Hezekiah's death, and the style has nothing in common with the earlier part of the book. It is therefore prudent to regard the prophecy, with Ewald, as anonymous. Ewald ascribes the whole of chaps. vi., vii. to one author. Wellhausen, however, remarks with justice that the thread is abruptly broken at vii. 6, and that verses 7–20 represent Zion as already fallen before the heathen and her inhabitants as pining in the darkness of captivity. The hope of Zion is in future restoration after she has patiently borne the chastisement of her sins. Then Jehovah shall arise mindful of His oath to the fathers, Israel shall be forgiven and restored, and the heathen humbled. The faith and hope which breathe in this passage have the closest affinities with the book of Lamentations and Isa. xl.–lxvi.

We have seen that the text of Micah has suffered from redactors; it is also not free from verbal corruptions which make some places very obscure. The LXX. had many readings different from the present Hebrew, but their text too was far from sound. Of commentaries on Micah, that which deals most fully with the question of the text is Roorda's Latin work, Leyden, 1869. The most elaborate book on Micah is Caspari's (*Ueber Micha den Morasthiten und seine prophetische Schrift*, Christiania, 1851–52). In English Pocock's *Commentary* (2d ed., 1692) and Cheyne's *Micah* (1882) are to be noted. See also the literature on the minor prophets in general cited under HOSEA, and W. R. Smith's *Prophets of Israel* (1882). (W. R. S.)

MICHAEL (מִיכָאֵל, "who is like God?") appears in the Old Testament as a man's name, synonymous with Micaiah or Micah. In the book of Daniel the same name is given to one of the chief "princes" of the heavenly host, the guardian angel or "prince" of Israel (Dan. x. 13, 21; xii. 1), and as such he naturally appears in Jewish theosophy as the greatest of all angels, the first of the four who surround the throne of God (see GABRIEL). It is as guardian angel of Israel, or of the church, the true Israel, that Michael appears in Jude 9 and Rev. xii. 7. In the Western Church the festival of St Michael and All Angels (Michaelmas) is celebrated on September 29th; it appears to have grown out of a local celebration of the dedication of a church of St Michael either at Mount Garganus in Apulia or at Rome, and was a great day by the beginning of the 9th century. The Greek Church dedicates November 8 to St Michael, St Gabriel, and All Angels.

MICHAEL, the name of several Byzantine emperors.

MICHAEL I. (Rhangabé) was an obscure nobleman who had married Procopia, the daughter of Nicephorus I., and been made master of the palace; his elevation to the throne was due to a revolutionary movement against his brother-in-law Stauracius, who reigned only two months after the death of Nicephorus on the battlefield (812). Elected as the tool of the bigoted orthodox party in the church, Michael diligently persecuted the Iconoclasts on the northern and eastern frontiers of the empire, but meanwhile allowed the Bulgarians to ravage a great part of Macedonia and Thrace; having at last taken the field in the spring of 813, he was defeated near Bersinikia, and Leo the Armenian was saluted emperor in his stead in the following summer. Michael, after having been compelled to become a monk, was permitted thenceforward to live unmolested in the island of Prote, where he died in 845.

MICHAEL II. (The Stammerer), a native of Amorium in Phrygia, was of humble origin, and began life as a private soldier, but rose by his talents and assiduity to the rank of general. He was one of those who had favoured the election to the throne of his old companion in arms Leo the Armenian in 813, but, detected in a conspiracy against the government of that emperor, had been sentenced to death in December 820; his partisans, however, succeeded in assassinating Leo on the morning of Christmas Day, and called Michael from the prison to the throne. The principal features of his reign (820–829) were a protracted struggle (of nearly three years) against his brother general, Thomas, who aimed at the throne, the conquest of Crete by the Saracens in 823, and the beginning of their attacks upon Sicily (827). Conciliatory on the whole in his policy towards the image worshippers (his own sympathies were iconoclastic), he incurred the wrath of the monks by entering into a second marriage with Euphrosyne, daughter of Constantine VI., who had previously taken the veil. He died in October 829, and was succeeded by Theophilus his son.

MICHAEL III. (The Drunkard) was the grandson of Michael the Stammerer, and succeeded his father Theophilus when only three years of age (842). Until his majority at the age of eighteen the affairs of the empire were managed by the empress-regent his mother Theodora; his education was shamefully neglected, and it was during this period that Michael formed the disgraceful personal habits which are indicated by his surname. In 861 Michael, together with his uncle Bardas, undertook an expedition against the Bulgarians, which resulted in the conversion of the Bulgarian king, who thenceforth bore the Christian name of Michael. The emperor had been less successful in the campaign which he led in person against Omar of Melitene in 860, but in 863 his uncle Petronas gained an important victory over the Saracens in Asia Minor. The year 865 was marked by the first appearance of the Russians in the Bosphorus. Michael was assassinated in his palace in 867 by Basilius the Macedonian, whom he had associated with himself in the empire in the previous year.

MICHAEL IV. (The Paphlagonian) owed his elevation to Zoe, daughter of Constantine IX., the last of the Macedonian dynasty; this princess was married to Romanus III., but becoming enamoured of Michael, her chamberlain, she poisoned her husband and married her attendant (1034). Michael, however, being of a weak character and subject to epileptic fits, possessed the supreme power only in name, and was a mere instrument in the hands of his brother, John the Eunuch, who had been first minister both of Constantine and Romanus. John's diplomacy was successful in keeping the Arabs in the archipelago and Egypt quiet for some time, and he was at last able to secure a victory for the imperial arms at Edessa in 1037. The attempt to recover Sicily in the following year with the help of the Normans was less prosperous, and in 1040 the island wholly ceased to be a Byzantine province. About the same time, the Bulgarians having overrun Macedonia and Thrace, and threatening Constantinople, the indolent and infirm emperor, to the surprise alike of friends and foes, put himself at the head of the army, and not only drove the enemy beyond the frontier, but followed them into their own territory. He died, shortly after his triumph, on December 10, 1041.

MICHAEL V. (Calaphates or The Caulker), nephew and successor of the preceding, derived his surname from his father Stephen, who had originally followed the occupation of a caulker of ships. He owed his elevation (December 1041) to his uncle John, whom along with Zoe he almost immediately banished; this led to a popular tumult and his dethronement after a brief reign of four months (April 1042). He lived for many years afterwards in the quiet obscurity of a monastery.

MICHAEL VI. (The Warlike) was already an old man when chosen by the empress Theodora as her successor shortly before her death in 1056. His government was feeble in the extreme, and he was at last compelled to abdicate by Isaac Comnenus, who had defeated his army in Phrygia (August 1057). He also spent the rest of his life in a monastery.

MICHAEL VII. (Ducas or Parapinaces) was the eldest son of Constantine XI. Ducas, by whom along with his brothers Andronicus I. and Constantine XII. he was invested with the title of Augustus; this joint succession took place in 1067, but in 1071 it suited the policy of the uncle Joannes Cæsar to make Michael sole emperor. For

this position Michael, whose "character was degraded, rather than ennobled, by the virtues of a monk and the learning of a sophist," was by no means fitted, and at length two generals of the name of Nicephorus, surnamed Bryennius and Botaniates, simultaneously rebelled against him in 1078; with hardly a struggle he resigned the purple and retired into a monastery, where he afterwards received the title of archbishop of Ephesus.

MICHAEL VIII. (Palæologus), born in 1234, was the son of Andronicus Palæologus Comnenus and Irene Angela the granddaughter of Alexius Angelus, emperor of Constantinople. At an early age he rose to distinction, and ultimately became commander of the French mercenaries in the employment of the emperors of Nicæa. A few days after the death of Theodore Lascaris II. in 1259, Michael, by the assassination of Muzalon (which he is believed but not proved to have encouraged), succeeded to the guardianship, shared with the patriarch Arsenius, of the young emperor John Lascaris, then a lad of only eight years. Afterwards invested with the title of "despot," he was finally proclaimed joint-emperor, and crowned alone at Nicæa on January 1, 1260. In the following year (July 1261) Constantinople fell into the hands of the Cæsar Alexius Strategopulus, and Michael, having got himself crowned anew in the church of St Sophia, caused his boy colleague to be blinded and sent into banishment. For this last act he was excommunicated by Arsenius, and the ban was not removed until six years afterwards (1268), on the accession of a new patriarch. In 1263 and 1264 respectively Michael, with the help of Urban IV., concluded peace with Villehardouin, prince of Achaia, and Michael, despot of Epirus, who had previously been incited by the pope to attack him; the friendly intervention had been secured by a promise on the emperor's part to help forward the reunion of the Eastern and Western churches. In 1269 Charles of Sicily, aided by John of Thessaly, again made war with the alleged purpose of restoring Baldwin to the throne of Constantinople, and pressed Michael so hard that ultimately, yielding to the importunities of Gregory X., he caused the deputies of the Eastern church to attend the council of Lyons (1274) and there accept the "filioque" and papal supremacy. The union thus brought about between the two churches was, however, extremely distasteful to the Greeks, and the persecution of his "schismatic" subjects to which the emperor was compelled to resort weakened his power so much that Martin IV. was tempted to enter into alliance with Charles of Anjou and the Venetians for the purpose of reconquering Constantinople. The invasion, however, failed, and Michael so far had his revenge in the "Sicilian Vespers," which he helped to bring about. He died in Thrace in December 1282, and was succeeded by his son Andronicus II.

MICHAEL IX. (Palæologus) was the son of Andronicus II., and was associated with him on the throne from 1295, but predeceased him (1320).

MICHAELIS, JOHANN DAVID (1717–1791), one of the most influential scholars and teachers of last century, belonged to a family which had the chief part in maintaining that solid discipline in Hebrew and the cognate languages which distinguished the university of Halle in the period of Pietism. Johann Heinrich Michaelis (1668–1738) was the chief director of Francke's *Collegium Orientale Theologicum*, a practical school of Biblical and Oriental philology then quite unique, and the author of an annotated Hebrew Bible and various exegetical works of reputation, especially the *Adnotationes uberiores in Hagiographos*, 1720. In his chief publications J. H. Michaelis had as fellow-worker his sister's son Christian Benedict Michaelis (1680–1764), the father of Johann David, who was likewise influential as professor at Halle, and a very sound scholar, especially in Syriac. J. D. Michaelis was trained for academical life under his father's eye. Halle was not then the best of universities; a narrow theological spirit cramped all intellectual activity, and the eager vivacious youth, already distinguished by a love for realities and a distaste for small pedantries, found much of the teaching wearisome enough. He acquired, however, a good knowledge of the Latin classics,—Greek, he tells us, was hardly taught at all, and his knowledge of Greek literature was gained by his own reading in later years,—learned all that his father could teach, and was influenced, especially in philosophy, by Baumgarten, the link between the old Pietism and Semler, while he cultivated his strong taste for history under Ludwig. In the winter-semester 1739–40 he qualified as university lecturer. One of his dissertations was a defence of the antiquity and divine authority of the vowel points in Hebrew. His scholarship still moved in the old traditional lines in which no further progress was possible, and he was also much exercised by religious scruples, the conflict of an independent mind with that submission to authority at the expense of reason encouraged by the type of Lutheranism in which he had been trained. A long visit to England in 1741–42 lifted him out of the narrow groove of his earlier education. In passing through Holland he made the acquaintance of the great Schultens, whose influence on his philological views was not immediate, but became all-powerful a few years later. England offered to him no such commanding personal influence, and he was not yet able to turn to profit the stores of the great libraries, but his personality was strengthened by contact with a larger life, and his theological views were turned aside from the pietistic channel. Michaelis never ceased to regard himself as essentially orthodox, though he did not feel able fully to subscribe the Lutheran articles, and more than once declined on this account to be professor of theology. But his views acquired a distinctly rationalistic complexion, and the orthodoxy of his Göttingen lectures and publications on dogmatic (delivered from a philosophical chair) is of a very washed-out kind. His really useful work, however, lay in other directions; the change of his theological views was important because it relieved him from trammels that hampered the free course of his development as a scholar. From England Michaelis went back to Halle; but he felt himself out of place, and in 1745 gladly accepted an invitation to Göttingen as privat-docent. In 1746 he became extraordinary, in 1750 ordinary, professor, and in Göttingen he remained till his death in 1791. In the first years of his new position Michaelis passed through a second education. In the young and intellectually vigorous Georgia Augusta he came under the powerful personal influence of such men as Gesner and Haller. His intellect was active in many directions; universal learning indeed was perhaps one of his foibles. Literature—modern as well as ancient—occupied his attention; one of his works was a translation of four parts of *Clarissa*; and translations of some of the then current English paraphrases on Biblical books manifested his sympathy with a school which, if not very learned, attracted him by its freer air. His Oriental studies were reshaped by diligent perusal of the works of Schultens; for the Halle school, with all its learning, had no conception of the principles on which a fruitful connexion between Biblical and Oriental learning can be established. His linguistic work indeed was always hampered by the lack of MS. material which is felt in his philological writings, *e.g.*, in his valuable *Supplementa* to the Hebrew lexicons (1784–92).[1] He could not become

[1] By a strange fortune of war it was the occupation of Gottingen by the French in the Seven Years' War, and the friendly relations he

such an Arabist as Reiske; and, though for many years the most famous teacher of Semitic languages in Europe, he had little of the higher philological faculty, and neither his grammatical nor his critical work, highly praised as it then was, has left a permanent mark, with the exception perhaps of his text-critical studies on the Peshito.[1] His tastes were all for *realia*—history, antiquities, especially geography and natural science; in his autobiography he half regrets that he did not choose the medical profession. Here he found a field hardly touched since Bochart, in whose footsteps he followed in the *Spicilegium geographiæ Hebræorum exteræ post Bochartum* (1769–80). To his impulse we owe the famous Eastern expedition of Von Haven, Forskål, and Niebuhr. He prepared the instructions for their journey, and drew up a series of questions and elucidations to guide their researches, which place in strong relief his comprehensive grasp of all that was then known of the East, and the keen delight in the knowledge of tangible and natural things, paired with a sober and patient judgment, which was his chief intellectual characteristic. The best part of this knowledge was turned to the profit of Biblical study; in his exegetical writings, for example, one of the main features is what was then the novelty of illustrations from Eastern travel. In spite of his doctrinal writings—which at the time made no little noise, so that his *Compendium of Dogmatic* (1760) was confiscated in Sweden, and the knighthood of the North Star was afterwards given him in reparation—it was the natural side of the Bible that really attracted him, and no man did more to introduce the modern method of studying Hebrew antiquity as an integral part of ancient Eastern life. The permanent influence of his works indeed has not been great, and many of them are now hardly readable; for, with all his historic tastes and learning, he had no large historic conceptions, and, what is closely akin to this defect, was singularly deficient in imagination and poetic sympathy. But the vivacity of his mind, his manysidedness, his singularly attractive though discursive method of lecturing, and above all his power of feeling and inspiring interest in every kind of fact, was a potent stimulus much needed in the Germany of that age, and did not soon die. Different as the three men are, there is a true historic nexus between the three great Göttingen Orientalists, Michaelis, Eichhorn, and Ewald.

The personal character of Michaelis can be read between the lines of his autobiography with the aid of the other materials collected by the editor Hassencamp (*J. D. Michaelis Lebensbeschreibung*, &c., 1793). To understand the secret of his enormous influence, it is not enough to read his books, now for the most part dull enough to us; we must see the upright vivacious laborious man, with a good deal of worldly prudence and a good deal of temper, much absorbed in his manifold academic activities in the university and Royal Society of Göttingen, yet ever full of interest in the larger world, and of shrewd judgments and lively talk, with a strong sense of his rights and dignity, yet with a good and warm heart; shining especially in the lecture-room, where he dealt forth knowledge with discursive hand from a full store, displaying the methods as well as the results of his all-sided research, not without a touch of the vanity of the polyhistor, and loving to leave the chair under a storm of applause at a parting bon-mot which he acknowledged at the door in a backward glance of triumph. The same volume contains a full list of his works. Besides those already mentioned it is sufficient to refer to his New Testament *Introduction* (the first edition, 1750, preceded the full development of his powers, and is a very different book from the later editions), his reprint of Lowth's *Prælectiones* with important additions (1758–62), his German translation of the Bible with notes (1773–92), his *Orientalische und Exegetische Bibliothek* (1775–85), and *Neue O. and E. Bib.* (1786–91), his *Mosaisches Recht* (1770–71), and his edition of Castle's *Lexicon Syriacum* (1787–88). His *Litterarischer Briefwechsel* (1794–96) contains much that is interesting for the history of learning in his time. (W. R. S.)

formed with the officers, that procured him the Paris MS. from which he edited Abulfeda's description of Egypt.

[1] *Curæ in Actus Apostolorum Syriacos*, 1755.

MICHAUD, Joseph (1767–1839), French historian and publicist, was born of an old family on June 19, 1767, at Albens, Savoy, was educated at Bourg-en-Bresse, and afterwards engaged in literary work at Lyons, where the events of 1789 first called into activity the dislike to revolutionary principles which manifested itself throughout the rest of his life. In 1791 he went to Paris, where, not without danger, he took part in editing several royalist journals. In 1794 he started *La Quotidienne*, for his connexion with which he was arrested after the 13th of Vendémiaire; he succeeded in escaping his captors, but was sentenced to death *par contumace* by the military council. Having resumed the editorship of his newspaper on the establishment of the Directory, he was again proscribed on the 18th of Fructidor, but at the close of two years returned to Paris when the consulate had superseded the Directory. His Bourbon sympathies led to a brief imprisonment in 1800, and on his release he for the time abandoned journalism, and began to write or edit books. Along with his brother and two colleagues he published in 1806 a *Biographie moderne, ou dictionnaire des hommes qui se sont fait un nom en Europe depuis* 1789, the earliest work of its kind; in 1808 the first volume of his *Histoire des Croisades* appeared, and in 1811 he originated the *Biographie Universelle*. In 1814 he resumed the editorship of the *Quotidienne*, and in the same year was elected Academician. In 1815 his brochure entitled *Histoire des quinze Semaines ou le dernier règne de Bonaparte* met with extraordinary success, passing through twenty-seven editions within a very short time. His political services were now rewarded with the cross of an officer in the Legion of Honour and the modest post of king's reader, of which last he was deprived in 1827 for having opposed Peyronnet's "Loi d'Amour" against the freedom of the press. In 1830–31 he travelled in Syria and Egypt for the purpose of collecting additional materials for the *Histoire des Croisades*; his correspondence with a fellow explorer, Poujoulat, consisting practically of discussions and elucidations of various important points in that work, was afterwards published (*Correspondance d'Orient*, 7 vols., 1832–35). The *Bibliothèque des Croisades*, in four volumes more, contained the "pièces justificatives" of the *Histoire*. Michaud died on September 30, 1839, at Passy, where his home had been since 1832. His *Histoire des Croisades* was published in its final form in six volumes in 1841 under the editorship of his friend Poujoulat (9th ed., with appendix, by Huillard-Bréholles, 1856). Michaud along with Poujoulat also edited and in part wrote *Nouvelle Collection des Mémoires pour servir à l'Histoire de France*, 32 vols., 1836–44. See Sainte-Beuve, *Causeries du Lundi*, vol. vii.

MICHAUX, André (1746–1802), a French botanist, best known for his works on the flora of North America and as a botanical traveller. In 1779 he spent some time botanizing in England, and in 1780 he explored Auvergne, the Pyrenees, and the north of Spain. In 1782 he was sent by the French Government on a botanical mission to Persia. His journey began unfavourably, as he was robbed by Arabs of all his equipments except his books; but he gained influential support in Persia, having cured the shah of a dangerous illness. After two years he returned to France with a fine herbarium, and also introduced numerous Eastern plants into the botanic gardens of France. In 1785 he was sent by the French Government to North America, and travelled through Canada, Nova Scotia, and the United States as far west as the Mississippi. The outbreak of the French Revolution deprived him of means to continue his work in America, and in 1796 he returned to France. He was shipwrecked, and lost most of his collections on the voyage. In 1800

he went to Madagascar to investigate the flora of that island, and died there in 1802. His work as a botanist was chiefly done in the field, and he added largely to what was previously known of the botany of the East and of America. He also introduced many plants into European botanic gardens. He wrote two valuable works on North-American plants,—the *Histoire des chênes de l'Amérique Septentrionale* (1801), with 36 plates, and the *Flora Boreali-Americana* (1803), 2 vols., with 51 plates.

MICHAUX, François André (1770–1855), son of the preceding, was, like his father, employed by the French Government to explore the forests of North America with a view to the introduction into France of trees valuable for their wood or other products. He was very successful in carrying out this object. He published in 1810–13 a *Histoire des Arbres forestières de l'Amérique Septentrionale*, in 3 vols., with 156 plates, a work full of information on the characters, uses, distribution, and other points of interest in the various species. In 1817–19 a translation of it appeared under the title *North American Sylva.* He also wrote a *Voyage a l'ouest des Monts Alléghanys*, 1804, besides articles in scientific magazines.

MICHELANGELO (1475–1564). Michelangelo Buonarroti, best known simply as Michelangelo, the last and most famous of the great artists of Florence, was the son of Ludovico Buonarroti, a poor gentleman of that city, and of his wife Francesca di Neri. Ludovico was barely able to live on the income of his estate, but made it his boast that he had never stooped to add to it by mercantile or mechanical pursuits. The favour of the Medici procured him employment in some minor offices of state, and in the autumn of 1474 he was appointed resident magistrate of Caprese, in the Casentino, for a period of six months. Thither he accordingly repaired with his family, and there, on March 6, 1475, his second son Michelagniolo or Michelangelo was born. Immediately afterwards the family returned to Florence, and the child was put to nurse with a marble-worker's wife of Settignano. His mother's health had already, it would seem, begun to fail; at all events in about two years from this time, after she had borne her husband two more sons, she died. While still a young boy, Michelangelo determined in spite of his father's opposition to be an artist. He had sucked in the passion, as he himself used to say, with his foster-mother's milk. After a sharp struggle, his stubborn will overcame his father's pride of gentility, and at thirteen he got himself articled as a paid assistant in the workshop of the brothers Ghirlandaio. Domenico Ghirlandaio, bred a jeweller, had become by this time the foremost painter of Florence. In his service the young Michelangelo laid the foundations of that skill in fresco with which twenty years afterwards he confounded his detractors at Rome. He studied also, like all the Florentine artists of that age, in the Brancacci chapel, where the frescos of Masaccio, painted some sixty years before, still victoriously held their own; and here, in a quarrel with an ill-conditioned fellow-student, Torrigiani, he received the blow of which his face bore the marks to his dying day.

Though Michelangelo's earliest studies were directed towards painting, he was by nature and predilection much more inclined to sculpture. In that art he presently received encouragement and training under the eye of an illustrious patron, Lorenzo dei Medici. On the recommendation, it is said, of Ghirlandaio, he was transferred, before the term of his apprenticeship as a painter had expired, to the school of sculpture established by Lorenzo in the Medici gardens. Here he could learn to match himself against his great predecessor, Donatello, one of whose pupils was the director of the school, and to compare the works of that master and his Tuscan contemporaries with the antiques collected for the instruction of the scholars. Here, too, he could listen to discourses on Platonism, and steep himself in the doctrines of an enthusiastic philosophy which sought to reconcile with Christian faith the lore and the doctrines of the Academy. Michelangelo remained a Christian Platonist to the end of his days; he was also from his youth up a devoted student of Dante. His powers of mind and hand soon attracted attention, and secured him the regard and favour of his patrons in spite of his rugged, unsociable exterior, and of a temper which at best was but a half-smothered volcano.

Michelangelo had been attached to the school and household of the Medici for barely three years when, in 1492, his great patron Lorenzo died. Lorenzo's son Piero dei Medici inherited the position, but not the qualities, of his father; Florence soon chafed under his authority; and towards the autumn of 1494 it became apparent that disaster was impending over him and his adherents. Michelangelo was constitutionally subject to dark and sudden presentiments: one such seized him now, and, without awaiting the popular outbreak which soon followed, he took horse with two companions and fled to Bologna. There, being now in his twentieth year, he was received with kindness by a member of the Aldovrandi family, and on his commission executed two figures of saints, and one of an angel, for the shrine of St Dominic in the church of St Petronius. After about a year, work at Bologna failing, and his name having been included in his absence on the list of artists appointed to provide a new hall of assembly for the Great Council of Florence, Michelangelo returned home. The strange theocracy established by Savonarola was now in force, and the whole character of civic life at Florence was for the time being changed. But Michelangelo was not left without employment. He found a friend in another Lorenzo, the son of Pierfrancesco dei Medici, for whom he at this time executed a statue of the boy St John. Having also carved a recumbent Cupid in imitation of the antique, it was suggested to him by the same patron that it should be so tinted and treated as to look like a real antique, and sold accordingly. Without increasing the price he put upon the work, Michelangelo for amusement lent himself to the counterfeit, and the piece was then actually sold for a large sum to a Roman collector, the cardinal San Giorgio, as a genuine work of antiquity,—the dealer appropriating the profits. When presently the cardinal discovered the fraud, he caused the dealer to refund; but as to Michelangelo himself, it was represented to the young sculptor that if he went to Rome, the amateur who had just involuntarily paid so high a tribute to his skill would certainly befriend him. He set forth accordingly, and arrived at Rome for the first time at the end of June 1496. Such hopes as he may have entertained of countenance from the cardinal San Giorgio were quickly dispelled. Neither did the banished Piero dei Medici, who also was now living at Rome, do anything to help him. On the other hand Michelangelo won the favour of a Roman nobleman, Jacopo Galli, and through him of the French cardinal Jean de Villiers de la Grolaie, abbot of St Denis. From the former he received a commission for a Cupid and a Bacchus, from the latter for a *Pietà*, or Mary lamenting over the body of Christ,—works of which probably all three, the last two certainly, are preserved.

Michelangelo's stay in Rome at this time lasted five years, from the summer of 1496 till that of 1501. The interval had been one of extreme political distraction at Florence. The excitement of the French invasion, the mystic and ascetic regimen of Savonarola, the reaction which led to his overthrow, and finally the external wars and internal dissidences which preceded a new settlement, had all created an atmosphere most unfavourable to art.

Nevertheless Ludovico Buonarroti, who in the troubles of 1494 had lost a small permanent appointment he held in the customs, and had come to regard his son Michelangelo as the mainstay of his house, had been repeatedly urging him to come home.

A spirit of family duty and family pride was the ruling principle in all Michelangelo's conduct. During the best years of his life he submitted himself sternly and without a murmur to pinching hardship and almost superhuman labour for the sake of his father and brothers, who were ever selfishly ready to be fed and helped by him. Having now, after an illness, come home in 1501, Michelangelo received the request from the cardinal Francesco Piccolomini to adorn with a number of sculptured figures a shrine already begun in the cathedral of Siena in honour of the most distinguished member of his house, Pope Pius II. Four only of these figures were ever executed, and those not apparently, or only in small part, by the master's hand. A work of greater interest in Florence itself had diverted him from his engagement to his Sienese patron. This was the execution of the famous colossal statue of David, popularly known as the Giant. It was carved out of a huge block of marble on which another sculptor, Agostino d'Antonio, had begun unsuccessfully to work forty years before, and which had been lying idle ever since. Michelangelo had here a difficult problem before him. Without much regard to tradition or the historical character of his hero, he carved out of the vast but cramped mass of material a youthful, frowning colossus, which amazed every beholder by its freedom and science of execution, and its victorious energy of expression. All the best artists of Florence were called in council to determine on what site it should be set up, and after much debate the terrace of the Palace of the Signory was chosen, in preference to the neighbouring Loggia dei Lanzi. Here accordingly the colossal David of Michelangelo took, in the month of May 1504, the place which it continued to hold ever afterwards, until ten years ago, in 1873, it was removed for the sake of protection to a hall in the Academy of Fine Arts. Other works of sculpture by the same indomitable hand also belong to this period: among these another David, in bronze, and on a smaller scale; a great rough-hewn St Matthew begun but never completed for the cathedral of Florence; a Madonna and Child executed on the commission of a merchant of Bruges; and two unfinished bas-reliefs of the same subject.

Neither was Michelangelo idle at the same time as a painter. Leaving disputed works for the moment out of sight, he in these days at any rate painted for his and Raphael's common patron, Angelo Doni, the Holy Family now in the Uffizi at Florence. And in the autumn of 1504, the year of the completion of the David, he received from the Florentine state a commission for a work of monumental painting on an heroic scale. Leonardo da Vinci had been for some months engaged on his great cartoon of the Battle of Anghiari, to be painted on the wall of the great hall of the municipal council. The gonfaloniere Soderini now procured for Michelangelo the commission to design a companion work. Michelangelo chose an incident of the Pisan war, when the Florentine soldiery had been surprised by the enemy in the act of bathing: he dashed at the task with his accustomed fiery energy, and had carried a great part of the cartoon to completion when, in the early spring of 1505, he broke off the work in order to obey a call to Rome which reached him from Pope Julius II. His unfinished cartoon showed how greatly Michelangelo had profited by the example of his elder rival, Leonardo, little as, personally, he yielded to his charm or could bring himself to respond to his courtesy. The work of Michelangelo's youth is for the most part comparatively tranquil in character. His early sculpture, showing a degree of science and perfection unequalled since the antique, has also something of the antique serenity. It bears strongly the stamp of intellectual research, but not by any means that of storm or strain. In the cartoon of the Bathers, he on the other hand appropriated and carried further the mastery, which Leonardo had first asserted, over every variety of violent action and every extreme of energetic movement. In it the qualities afterwards proverbially associated with Michelangelo—his *furia*, his *terribilità*, the tempest and hurricane of the spirit which accompanied his unequalled technical mastery and knowledge—first found expression.

With Michelangelo's departure to Rome early in 1505 the first part of his artistic career may be said to end. It will be convenient here to recapitulate its principal results in sculpture and painting, both those preserved, and those recorded but lost.

SCULPTURE.—Florence, 1489–94. *Head of a Faun*, National Museum, Florence (?). Condivi describes Michelangelo's first essay in sculpture as a head of an aged faun with a front tooth knocked out, this latter point having been an afterthought suggested by Lorenzo dei Medici. The head is commonly identified with one in the National Museum at Florence, which, however, bears no marks of Michelangelo's style, and is in all probability spurious. *Madonna Seated on a Step*, Casa Buonarroti, Florence. This bas-relief is a genuine example of Michelangelo's early work in the Medicean school under Bertoldo. It is executed in low relief in imitation of the technical style of Donatello; but the attitudes and characters of the figures, and the long-drawn, somewhat tormented folds of drapery, recall rather the manner of Jacopo della Quercia. *Centauromachia*, Casa Buonarroti. A fine and unquestionably genuine work in full relief, of probably somewhat later date than the last-mentioned; Michelangelo has followed the antique in his conception and treatment of the nude, but not at all in the arrangement of the subject, which occurs frequently in works of ancient art.

Bologna, 1494–95. *Kneeling Angel*, supporting the shrine of St Dominic. This is the figure, with crisp hair, short resolute features, and drapery clinging to show the limbs, on the right-hand side of the spectator as he fronts the altar. The prettier and more engaging figure at the opposite end was long taken to be Michelangelo's work, but is really that of Niccolò dell' Arca. Michelangelo also finished the figure of St Petronius on the cornice of the same altar, begun by the same Niccolò, and executed one of St Proculus which has perished.

Florence, 1495–96. *St John in the Wilderness*, Berlin Museum. During the year between Michelangelo's return from Bologna and his first departure to Rome he executed, as has been narrated above, a statue of S. Giovannino for Lorenzo di Pierfrancesco dei Medici. This had for centuries been supposed lost, when in 1874 it was declared to have been found in the possession of Count Gualandi-Rossalmini at Pisa. Vehement and prolonged discussions arose as to the authenticity of the work, and at last it was bought for the Berlin Museum, where its genuineness is with apparently good reason maintained. The stripling saint stands naked but for a skin about his loins, holding a honeycomb in his left hand and lifting to his mouth a goat's horn full of honey with his right. *Restoration of an antique group of Bacchus and Ampelus*, Uffizi Gallery, Florence. This interesting restoration of an antique torso, by the addition of a head, the lower part of the legs, and the accessory figure of an attendant genius, a plinth, and mask, is not one of the works traditionally ascribed to Michelangelo; but has lately, and as it seems rightly, been claimed for him on internal evidence. *Recumbent Cupid*, bought by the cardinal San Giorgio as an antique. This work, which played an important part in Michelangelo's history, is unfortunately lost.

Rome, 1495–1501. *Kneeling Cupid*, South Kensington Museum, London. This beautiful statue of an athletic youth kneeling on the right knee, looking over his right shoulder, with the right hand lowered and the left raised, and having a quiver on the ground beside him, is acknowledged on internal grounds as an early work of Michelangelo. There is some ambiguity about the character and action of the personage; but the work is usually identified with the Cupid which Michelangelo is recorded to have executed at this time for Jacopo Galli. *Bacchus and Young Faun*, National Museum, Florence. This is unquestionably the "Bacchus" commissioned by the same patron. The finely-framed but soft-limbed youthful god, his weight supported somewhat staggeringly on the left leg, holds up a wine cup in his right hand, and with his loosely-hanging left hand holds a cluster of grapes, at which a child-faun standing a little behind him grasps and nibbles. The surface highly finished and polished, as in the Berlin St John. *Virgin Lamenting the Dead Christ*, St Peter's, Rome. This group, executed for the French abbot of St Denis, is the finest of all

Michelangelo's early sculptures, and one of the finest of his life. It still recalls the ideals of some of the earlier Tuscan masters, especially Jacopo da Quercia; but the execution is of a mastery and nobility unprecedented in Italian art. The Virgin, in drapery of magnificent design, with her left knee somewhat raised and her right hand slightly extended, sits holding on her lap the dead Christ,—a figure of splendid frame and modelling as well as of admirable pathos and dignity in expression.

Florence, 1501–6. *Four Saints decorating the Shrine of Pius II.*, in the cathedral of Siena. These figures represent the only part which Michelangelo ever completed of his contract with the cardinal Piccolomini and his heirs. They are evidently carried out by the hand of pupils only. *Virgin and Child*, Liebfrauenkirche, Bruges. This pleasing group has been since the days of Albert Dürer attributed to Michelangelo, and bears the manifest stamp of his design, though its execution may be partly by inferior hands. It is placed close to the tombstone of a member of the Moscheroni (or Moskeron) family. We know that Michelangelo executed at this time, for one of this very family, a work which the ancient biographers describe as having been in bronze,—a medallion in that metal, says explicitly Vasari; but it is probably really the marble group in question. *Virgin and Child*, Royal Academy, London. This beautiful unfinished circular relief is identified with one recorded to have been executed by the master for Taddeo Gaddi. *Virgin and Child*, National Museum, Florence,—a similar relief, also unfinished, originally ordered by Bartolommeo Pitti. *Youthful David*, Academy of Arts, Florence. Of this colossal work, which in spite of its scale and subject has still, in grace of pose and style, a considerable artistic affinity with the earlier Bacchus and St John, enough has been said. *Figure of David*, a small statue in bronze. Several extant works have been pointed out as probably identical with this lost statue; but the claims of none have been generally acknowledged.

PAINTING.—*Holy Family*, Uffizi, Florence. This circular picture, painted for Angelo Doni, and mentioned by the earliest biographers, is the only perfectly well-attested panel-painting of Michelangelo which exists. His love of restless and somewhat strained actions is illustrated by the action of the Madonna, who kneels on the ground holding up the child on her right shoulder; his love of the nude by the introduction (wherein he follows Luca Signorelli) of some otherwise purposeless undraped figures in the background. *Virgin and Child with Four Angels*, National Gallery, London. This unfinished painting, marked by great grace as well as severity of feeling and design, was formerly attributed to Domenico Ghirlandaio, but is now commonly held to be the earliest extant picture by Michelangelo. Of his manner, especially in the design and treatment of the drapery, it bears evident marks; but the execution seems like that of some weaker pupil or companion, perhaps Ridolfo Ghirlandaio or Granacci. *Entombment of Christ*, National Gallery, London. This picture, also unfinished, has in like manner been much contested. Its composition is unfortunate; weaker hands have disfigured some portions of the work; but the extraordinary excellence of other portions, and the grandeur of some of the actions, render it probable that the work is one begun and afterwards abandoned by Michelangelo himself. *Cartoon of the Battle of Anghiari*. Of this famous lost work (begun, though apparently not completed, in the period now engaging us) the only authentic record is contained in two early engravings, one by Marcantonio and the other by Agostino Veneziano. An elaborate drawing of many figures at Holkham Hall, well known and often engraved, seems to be a later *cento* destitute of real authority.

Michelangelo had not been long in Rome before Pope Julius devised fit employment for him. That capacious and headstrong spirit, on fire with great enterprises, had conceived the idea of a sepulchral monument to commemorate his glory when he should be dead, and to be executed according to his own plans while he was still living. He entrusted this congenial task to Michelangelo. The design being approved, the artist spent the winter of 1505–6 at the quarries of Carrara, superintending the excavation and shipment of the necessary marbles. In the spring he returned to Rome, and when the marbles arrived fell to with all his energy at the preparations for the work. For a while the pope followed their progress eagerly, and was all kindness to the young sculptor. But presently his disposition changed. In Michelangelo's absence an artist who was no friend of his, Bramante of Urbino, had been selected by Julius to carry out a new architectural scheme, commensurate with the usual vastness of his conceptions, namely the rebuilding of St Peter's church. To the influence and the malice of Bramante Michelangelo attributed the unwelcome invitation he now received to interrupt the great work of sculpture which he had just begun, in order to decorate the Sixtine chapel with frescos. Soon, however, schemes of war and conquest interposed to divert the thoughts of Julius, not from the progress of his own monument merely, but from artistic enterprises altogether. One day Michelangelo heard him say at table to his jeweller that he meant to spend no more money on pebbles either small or great. To add to the artist's discomfiture, when he went to apply in person for payments due, he was first put off from day to day, and at last actually with scant courtesy dismissed. At this his dark mood got the mastery of him. Convinced that not his employment only but his life was threatened, he suddenly took horse and left Rome, and before the messengers of the pope could overtake him was safe on Florentine territory. Michelangelo's flight took place in April 1506. Once among his own people, he turned a deaf ear to all overtures made from Rome for his return, and stayed throughout the summer at Florence, how occupied we are not distinctly informed, but apparently, among other things, on the continuation of his great battle cartoon.

During the same summer Julius planned and executed the victorious military campaign which ended in his unopposed entry at the head of his army into Bologna. Thither, under strict safe-conduct and promises of renewed favour, Michelangelo was at last prevailed on to betake himself. Julius received the truant artist kindly, as indeed between these two volcanic natures there existed a natural affinity, and ordered of him his own colossal likeness in bronze, to be set up, as a symbol of his conquering authority, over the principal entrance of the church of St Petronius. For the next fifteen months Michelangelo devoted his whole strength to this new task. The price at which he undertook it left him, as it turned out, hardly any margin to subsist on. Moreover, in the technical art of metal casting he was inexperienced, and an assistant whom he had summoned from Florence proved insubordinate and had to be dismissed. Nevertheless his genius prevailed over every hardship and difficulty, and on the 21st of February 1508 the majestic bronze colossus of the seated pope, robed and mitred, with one hand grasping the keys and the other extended in a gesture of benediction and command, was duly raised to its station over the church porch. Three years later it was destroyed in a revolution. The people of Bologna rose against the authority of Julius; his delegates and partisans were cast out, and his effigy hurled from its place. The work of Michelangelo, after being trailed in derision through the streets, was broken up and its fragments cast into the furnace.

Meanwhile the artist himself, as soon as his work was done, had followed his reconciled master back to Rome. The task that here awaited him, however, was after all not the resumption of the papal monument, but the execution of the series of paintings in the Sixtine chapel which had been mooted before his departure. Painting, he always averred, was not his business; and he entered with misgiving and reluctance upon his new undertaking. Destiny, however, so ruled that the work thus thrust upon him remains his chief title to glory. His history is one of indomitable will and almost superhuman energy, yet of will that hardly ever had its way, and of energy continually at war with circumstance. The only work which in all his life he was able to complete as he had conceived it was this of the decoration of the Sixtine ceiling. The pope had at first proposed a scheme including figures of the twelve apostles only. Michelangelo would be content with nought so meagre, and furnished instead a design of many hundred figures, embodying all the history of creation and

of the first patriarchs, with accessory personages of prophets and sibyls dreaming on the new dispensation to come, and, in addition, those of the forefathers of Christ. The whole was to be enclosed and divided by an elaborate framework of painted architecture, with a multitude of nameless human shapes supporting its several members or reposing among them,—shapes mediating, as it were, between the features of the inanimate framework and those of the great dramatic and prophetic scenes themselves. Michelangelo's plan was accepted by the pope, and by May 1508 his preparations for its execution were made. Later in the same year he summoned a number of assistant painters from Florence. Trained in the traditions of the earlier Florentine school, they were unable, it seems, to interpret Michelangelo's designs in fresco either with sufficient freedom or sufficient uniformity of style to satisfy him. At any rate he soon dismissed them, and carried out the remainder of his colossal task alone, except for the necessary amount of purely mechanical and subordinate help. The physical conditions of prolonged work, face upwards, upon this vast expanse of ceiling were adverse and trying in the extreme. But after four and a half years of toil the task was accomplished. Michelangelo had during its progress been harassed alike by delays of payment and by hostile intrigue. The absolute need of funds for the furtherance of the undertaking had even constrained him at one moment to break off work, and pursue his inconsiderate master as far as Bologna. His ill-wishers at the same time kept casting doubts on his capacity, and vaunting the superior powers of Raphael. That gentle spirit would by nature have been no man's enemy, but unluckily Michelangelo's moody, self-concentrated temper prevented the two artists being on terms of amity such as might have stopped the mouths of mischief-makers. Once during the progress of his task Michelangelo was compelled to remove a portion of the scaffolding and exhibit what had been so far done, when the effect alike upon friends and detractors was overwhelming. Still more complete was his triumph when, late in the autumn of 1512, the whole of his vast achievement was disclosed to view.

The main field of the Sixtine ceiling is divided into four larger alternating with five smaller fields. The following is the order of the subjects depicted in them:—(1) the dividing of the light from the darkness; (2) the creation of sun, moon, and stars, and of the herbage; (3) the creation of the waters; (4) the creation of man; (5) the creation of woman; (6) the temptation and expulsion; (7) an enigmatical scene, said to represent the sacrifice of Cain and Abel, but rather resembling the sacrifice of Noah; (8) the deluge; (9) the drunkenness of Noah. The figures in the last three of these scenes are on a smaller scale than those in the first six. In numbers 1, 3, 5, 7, and 9 the field of the picture is reduced by the encroachments of the architectural framework and supporters. These subjects are flanked at each end by the figure of a seated prophet or sibyl alternately; two other prophets are introduced at each extremity of the series, making seven prophets and five sibyls in all. In the angles to right and left of the prophets at the two extremities are the Death of Goliath, the Death of Judith, the Brazen Serpent, and the Punishment of Haman. In the twelve lunettes above the windows, and the similar number of triangular vaulted spaces over them, are mysterious groups, or pairs of groups, of figures, which from Michelangelo's own time have usually been known as Ancestors of Christ. The army of nameless architectural and subordinate figures is too numerous to be here spoken of. The work represents all the powers of Michelangelo at their best. Disdaining all the accessory allurements of the painter's art, he has concentrated himself upon the exclusive delineation of the human form and face at their highest power. His imagination has conceived, and his knowledge and certainty of hand have enabled him to realize, attitudes and combinations of unmatched variety and grandeur, and countenances of unmatched expressiveness and power. But he has not trusted, as he came later to trust, to science and acquired knowledge merely, neither do his personages, so far as they did afterwards, transcend human possibility or leave the facts of actual life behind them. In a word, his sublimity, often in excess of the occasion, is here no more than equal to it; moreover it is combined with the noblest elements of grace and even of tenderness. As for the intellectual meanings of his vast design, over and above those which reveal themselves at a first glance or by a bare description,—they are from the nature of the case inexhaustible, and can never be perfectly defined. Whatever the soul of this great Florentine, the spiritual heir of Dante, with the Christianity of the Middle Age not shaken in his mind, but expanded and transcendentalized, by the knowledge and love of Plato,—whatever the soul of such a man, full of suppressed tenderness and righteous indignation, and of anxious questionings of coming fate, could conceive, that Michelangelo has expressed or shadowed forth in this great and significant scheme of paintings. The details it must remain for every fresh student to interpret in his own manner.

The Sixtine chapel was no sooner completed than Michelangelo resumed work upon the marbles for the monument of Julius. But four months only had passed when Julius died. His heirs immediately entered (in the summer of 1513) into a new contract with Michelangelo for the execution of the monument on a reduced scale. What the precise nature and extent of the original design had been we do not know, but the new one was extensive and magnificent enough. It was to consist of a great quadrilateral structure, two courses high, projecting from the church wall, and decorated on its three unattached sides with statues. On the upper course was to be placed the colossal recumbent figure of the pope under a canopy, and beside it mourning angels, with prophetic and allegoric personages at the angles,—sixteen figures in all. The lower course was to be enriched with twenty-four figures in niches and on projecting pedestals:—in the niches, Victories trampling on conquered Provinces; in the pedestals, Arts and Sciences in bondage. The entire work was to be completed in nine years' time. During the next three years, it would seem, Michelangelo brought to completion three at least of the promised figures, and they are among the most famous of all existing works of the sculptor's art,—namely, the Moses now in the church of S. Pietro in Vincoli at Rome and the two "Slaves" at the Louvre.

The Moses, originally intended for one of the angles of the upper course, is now placed at the level of the eye, in the centre of the principal face of the monument as it was at last finished, on a deplorably reduced and altered scale, by Michelangelo and his assistants in his old age. The prophet, heavily bearded and draped, with only his right arm bare, sits with his left foot drawn back, his head raised and turned to the left with an expression of indignation and menace, his left hand laid on his lap and his right grasping the tables of the law. The work, except in one or two places, is of the utmost finish, and the statue looks like one of the prophets of the Sixtine ceiling done in marble. The "Slaves" at the Louvre are youthful male figures of equally perfect execution, nude but for the band which passes over the breast of one and the right leg of the other. One, with his left hand raised to his head and his right pressed to his bosom, and his eyes almost closed, seems succumbing to the agonies of death; the other, with his arms bound behind his back, looks upward still hopelessly struggling. There is reason to believe that all three of these figures were finished between 1513 and 1516. The beginnings of other figures or groups intended for the same monument are to be found at Florence, where they were no doubt made and then abandoned some years later,—viz., four rudely blocked figures of slaves or prisoners, in a grotto of the Boboli gardens, and the so-called Victory in the National Museum, an unfinished group of a combatant kneeling on and crushing to death a fallen enemy; with these may be associated a wax model known as Hercules and Cacus in the South Kensington Museum, and the figure of a crouching man at St Petersburg.

By this time (1516) Michelangelo's evil star was again in the ascendant. Julius II. had been succeeded on the papal throne by a Medici under the title of Leo X. The Medici, too, had about the same time by force and fraud re-established their sway in Florence, overthrowing the free institutions that had prevailed there since the days of Savonarola. Now on the one hand this family were the hereditary friends and patrons of Michelangelo; on the other hand he was a patriotic son of republican Florence; so that henceforward his personal allegiance and his political sympathies were destined to be at conflict. Over

much of his art, as has been thought, the pain and perplexity of this conflict have cast their shadow. For the present the consequence to him of the rise to power of the Medici was a fresh interruption of his cherished work on the tomb of Julius. Leo X. and his kinsmen insisted that Michelangelo, regardless of all other engagements, must design and carry out a great new scheme for the enrichment of their own family church of San Lorenzo in Florence. The heirs of Julius on their part showed an accommodating temper, and at the request of Leo allowed their three-years'-old contract to be cancelled in favour of another, whereby the scale and sculptured decorations of the Julian monument were again to be reduced by nearly a half. Unwillingly Michelangelo accepted the new commission thus thrust upon him for the church façade at Florence; but, having once accepted it, he produced a design of combined sculpture and architecture as splendid and ambitious in its way as had been that for the monument of Julius. In the summer of 1516 he left Rome for Carrara to superintend the excavation of the marbles.

Michelangelo was now in his forty-second year. Though more than half his life was yet to come, yet its best days had, as it proved, been spent. All the hindrances which he had encountered hitherto were as nothing to those which began to beset him now. For the supply of materials for the façade of San Lorenzo he had set a firm of masons to work, and had himself, it seems, entered into a kind of partnership with them, at Carrara, where he knew the quarries well, and where the industry was hereditary and well understood. When all was well in progress there under his own eye, reasons of state induced the Medici and the Florentine magistracy to bid him resort instead to certain new quarries at Pietrasanta, near Serravalle in the territory of Florence. Hither, to the disgust of his old clients at Carrara and to his own, Michelangelo accordingly had to transfer the scene of his labours. Presently he found himself so impeded and enraged by the mechanical difficulties of raising and transporting the marbles, and by the disloyalty and incompetence of those with whom he had to deal, that he was fain to throw up the commission altogether. The contracts for the façade of San Lorenzo were rescinded in March 1518, and the whole magnificent scheme came to nothing. Michelangelo then returned to Florence, where proposals of work poured in on him from many quarters. The king of France desired something from his hand to place beside the two pictures he possessed by Raphael. The authorities of Bologna wanted him to design a façade for their church of St Petronius; those of Genoa to cast a statue in bronze of their great commander, Andrea Doria. Cardinal Grimani begged hard for any picture or statue he might have to spare; other amateurs importuned him for so much as a pencil drawing or sketch. Lastly his friend and partisan Sebastian del Piombo at Rome, ever eager to keep up the feud between the followers of Michelangelo and those of Raphael, besought him on Raphael's death to return at once to Rome, and take out of the hands of the dead master's pupils the works of painting still remaining to be done in the Vatican chambers. Michelangelo complied with none of these requests. All that we know of his doing at this time was the finishing a commission received and first put in hand four years previously, for a full-sized statue of a nude Christ grasping the Cross. This statue, completed and sent to Rome in 1521 (with some last touches added by subordinate hands in Rome itself), stands now in the church of Sta Maria sopra Minerva; there is little in it of the Christian spirit as commonly understood, although, in those parts which Michelangelo himself finished, there is extreme accomplishment of design and workmanship.

The next twelve years of Michelangelo's life (1522–34) were spent at Florence, and again employed principally in the service of his capricious and uncongenial patrons, the Medici. The plan of a great group of monuments to deceased members of this family, to be set up in their mortuary chapel in San Lorenzo, seems to have been formed, and preparations to have been made by Michelangelo for its execution, as early as 1519. It was not, however, until 1524, after Leo X. had died, and his successor Adrian VI. had been in his turn succeeded by another Medicean pope, Clement VII., that any practical impulse was given to the work. Even then the impulse was a wavering one. First Clement proposed to associate another artist, Sansavino, with Michelangelo in his task. This proposal being on Michelangelo's peremptory demand abandoned, Clement next distracted the artist with an order for a new architectural design,—that, namely, for the proposed Medicean or "Laurentian" library. When at last the plans for the sepulchral monuments took shape, they did not include, as had been at first intended, memorials to the founders of the house's greatness, Cosimo and Lorenzo the Magnificent, or even to Pope Leo X. himself, but only to two younger members of the house lately deceased, Giuliano, duke of Nemours, and Lorenzo, duke of Urbino. Michelangelo brooded long over his designs for this work, and was still engaged on its execution—his time being partly also taken up by the building plans for the Medicean library—when political revolutions interposed to divert his industry. In 1527 came to pass the sack of Rome by the Austrians, and the apparently irretrievable ruin of Pope Clement. The Florentines seized the occasion to expel the Medici from their city, and set up a free republican government once more. Naturally no more funds for the work in San Lorenzo were forthcoming, and Michelangelo, on the invitation of the new signory, occupied himself for a while with designs for a colossal group of Samson and the Philistines, to be wrought out of a block of marble which had been rough-hewn already for another purpose by Baccio Bandinelli. Soon, however, he was called to help in defending the city itself from danger. Clement and his enemy Charles V. having become reconciled, both alike were now bent on bringing Florence again under the rule of the Medici. In view of the approaching siege, Michelangelo was appointed engineer-in-chief of the fortifications. He spent the early summer of 1529 in strengthening the defences of San Miniato; from July to September he was absent on a diplomatic mission to Ferrara and Venice. Returning in the middle of the latter month, he found the cause of Florence hopeless from internal treachery and from the overwhelming strength of her enemies. One of his dark seizures overcame him, and he departed again suddenly for Venice. Not cowardice, but despair of his city's liberties, and still more of his own professional prospects amid the turmoil of Italian affairs, was the motive of his departure. For a while he remained in Venice, negotiating for a future residence in France. Then, while the siege was still in progress, he returned once more to Florence; but in the final death-struggle of her liberties he bore no part. When in 1530 the city submitted to her conquerors, no mercy was shown to most of those who had taken part in her defence. Michelangelo believed himself in danger with the rest, but on the intervention of Baccio Valori he was presently taken back into favour and employment by Pope Clement. For three years more he still remained at Florence, engaged principally on the completion of the Medici monuments, and on the continuance of the Medicean library, but partly also on a picture of Leda for the duke of Ferrara.

The statues of the Medici monument take rank beside the Moses and the Slaves as the finest work of Michelangelo's central time in sculpture; moreover, though some of the figures are unfinished, they constitute as actually executed a complete scheme. They

consist of a Madonna and Child (left imperfect because the marble was short in bulk), and of the two famous monumental groups, each consisting of an armed and seated portrait-statue in a niche, with two emblematic figures reclining on each side of a sarcophagus below. The portraits are treated not realistically but typically. In that of Lorenzo seems to be typified the mood of brooding and concentrated inward thought preparatory to warlike action; in that of Giuliano, the type of alert and confident practical survey immediately preceding the moment of action. To this contrast of the meditative and active characters corresponds to some extent a contrast in the emblematic groups accompanying the portraits. At the feet of the Duke Giuliano recline the shapes of Night and Day,—the former a female, the latter a male personification,—the former sunk in an attitude of deep but uneasy slumber, the latter (whose head and face are merely blocked out of the marble) lifting himself in one of wrathful and disturbed awakening. But for Michelangelo's unfailing grandeur of style, and for the sense which his works convey of a compulsive heat and tempest of thought and feeling in the soul that thus conceived them, both these attitudes might be charged with extravagance. As grand, but far less violent, are those of the two companion figures that recline between sleep and waking on the sarcophagus of the pensive Lorenzo. Of these, the male figure is known as Evening, and the female as Morning (*Crepuscolo* and *Aurora*). In Michelangelo's original idea, figures of Earth and Heaven were to be associated with those of Night and Day on the monument of Giuliano, and others of a corresponding nature, no doubt, with those of the Morning and Evening Twilight on that of Lorenzo; these figures afterwards fell out of the scheme. Michelangelo's obvious and fundamental idea was, as some words of his own record, to exhibit the elements, and the powers of earth and heaven, lamenting the death of the princes; it is a question of much interest, but not to be discussed here, what other ideas of a more personal and deeper kind may have conflicted or come into association with these, and found expression in these majestic works of art, whereof no one who looks upon them can escape the spell.

Michelangelo had never ceased to be troubled by the heirs and executors of Julius, as well as by his own artistic conscience and ambition, concerning the long-postponed completion of the Julian monument. Agreement after agreement had been made, and then from the force of circumstances broken. In 1532, on the completion of the Medicean monuments at Florence, he entered into a new and what he firmly meant to be a binding contract to complete the work, on a scale once more very greatly reduced, and to set it up in the church of S. Pietro in Vincoli in Rome. But once more the demands of the pope diverted his purpose. Clement insisted that Michelangelo must complete his decorations of the Sixtine chapel by painting anew the great end wall above the altar, adorned until then by frescos of Perugino. The subject chosen was the Last Judgment, and Michelangelo began to prepare sketches. For the next two years he lived between Rome and Florence, and in the autumn of 1534, in his sixtieth year, settled finally and for the remainder of his life at Rome. Immediately afterwards Pope Clement died, and was succeeded by a Farnese under the title of Paul III. Even more than his predecessor, Paul insisted on claiming the main services of Michelangelo for himself, and forced him to let all other engagements drift. For the first seven years after the artist's return to Rome, his time was principally taken up with the painting of the colossal and multitudinous Last Judgment. This being completed in 1541, he was next compelled to undertake two more great frescos, one of the Conversion of Paul and another of the Martyrdom of Peter, in a new chapel which the pope had caused to be built in the Vatican, and named after himself *Capella Paolina*.

The fresco of the Last Judgment in the Sixtine chapel is probably the most famous single picture in the world. In it Michelangelo shows more than ever the omnipotence of his artistic science, and the fiery daring of his conceptions. The work exhibits the athletic unclothed human form in every variety and extremity of hitherto unattempted action and predicament. But of moderation, as well as of beauty and tenderness, it is almost entirely devoid. Whether from the complexion of his own thoughts, and the *sæva indignatio* that was native to his breast, or from the influence of the passionate and embittered theological temper of the time, Michelangelo has here neglected the consolatory aspects of Christianity, and insisted on its terrific aspects almost exclusively. Neither in the qualities of colour and execution is the work, so far as the condition of either admits comparison, comparable for charm to the earlier and far more nobly-inspired frescos of the ceiling. It is to these, and not to the Last Judgment, that the student must turn if he would realize what is best and greatest in the art of Michelangelo.

The frescos of the Pauline Chapel are on their part in part so injured as to be hardly susceptible of useful study or criticism. In their ruined state they bear evidence of the same tendencies that made the art of Michelangelo in its latest phase so dangerous an example to weaker men,—the tendency, that is, to seek for energy and violence of action both in place and out, for "terribleness" *quand même*, and to design actions not by help of direct study from nature, but by scientific deduction from the abstract laws of structure and movement. At best these frescos can never have been happy examples of Michelangelo's art.

During the fifteen years (1534–49) when Michelangelo was mainly engaged on these paintings, he had also at last been enabled to acquit himself, although in a manner that can have been satisfactory to none concerned, of his engagements to the heirs of Julius. Once more the influence of the pope had prevailed on them to accept a compromise altogether to their disadvantage. It was agreed that the Moses executed thirty years before should be the central figure of the new scheme; assistants were employed to carve two smaller flanking figures of female personifications; and the three were in 1545 set up in S. Pietro in Vincoli in combination with an architectural structure of rich but incongruous design. During the same years the long-pent human elements of fervour and tenderness in Michelangelo's nature had found vent and utterance such as they had never found before. He had occasionally practised poetry in youth, and there are signs of some transient love-passage during his life at Bologna. But it was not until towards his sixtieth year that the springs of feeling were fairly opened in the heart of this solitary, this masterful and stern, life-wearied and labour-hardened man. Towards that age we find him beginning to address impassioned sonnets, of which the sentiment is curiously comparable to that expressed in some of Shakespeare's, to a beautiful and gifted youth, Tommaso Cavalieri. Soon afterwards he made the acquaintance of the pious, accomplished, and high-souled lady, Vittoria Colonna, widow of the Marquis Pescara. For twelve years until her death, which happened in 1547, her friendship was the great solace of Michelangelo's life. On her, in all loyalty and reverence, he poured out all the treasures of his mind, and all his imprisoned powers of tenderness and devotion. He painted for her a crucifixion of extraordinary beauty, of which many imitations but not the original have come down to us. She was the chief inspirer of his poetry,—in which, along with her praises, the main themes are the Christian religion, the joys of Platonic love, and the power and mysteries of art. Michelangelo's poetical style is strenuous and concentrated like the man. He wrote with labour and much self-correction; we seem to feel him flinging himself on the material of language with the same overwhelming energy and vehemence,—the same impetuosity of temperament, combined with the same fierce desire of perfection,—with which contemporaries describe him as flinging himself on the material of marble.

And so the mighty sculptor, painter, and poet reached old age. An infirmity which settled on him in 1544, and the death of Vittoria Colonna in 1547, left him broken in health and heart. But his strength held on for many a year longer yet. His father and brothers were dead, and his family sentiment concentrated itself on a nephew, Leonardo, to whom he showed unremitting practical kindness, coupled with his usual suspiciousness and fitfulness of temper. In almost all his relations the old man continued to the end to manifest the same loyal and righteous heart, accompanied by the same masterful, moody, and estranging temper, as in youth. Among the artists of

the younger generation he held a position of absolute ascendency and authority; nor was his example, as we have said, by any means altogether salutary for them. During the last years of his life he made but few more essays in sculpture, and those not successful, but was much employed in the fourth art in which he excelled, that of architecture. A succession of popes demanded his services for the embellishment of Rome. For Paul III. he built the palace called after the name of the pope's family the Farnese. On the death of Antonio da San Gallo he succeeded to the onerous and coveted office of chief architect of St Peter's Church, for which he remodelled all the designs, living to see some of the main features, including the supports and lower portion of the great central dome, carried out in spite of all obstacles according to his plans. Other great architectural tasks on which he was engaged were the conversion of a portion of the Baths of Diocletian into the church of Sta Maria degli Angeli, and the embellishment and rearrangement of the great group of buildings on the Roman Capitol. At length, in the midst of these vast schemes and responsibilities, the heroic old man's last remains of strength gave way. He died on the threshold of his ninetieth year, on the 18th of February 1564.

For the bibliography of Michelangelo, which is extensive, see the useful though very imperfect compilation of Passerini, *Bibliografia di Michelangelo Buonarroti*, &c., Florence, 1875. The most important works, taken in chronological order, are the following:—P. Giovio, supplement to the fragmentary *Dialogus de viris litteris illustribus*, written soon after 1527, first published by Tiraboschi, *Storia della Letteratura italiana*, Modena, 1871; G. Vasari, in *Vite degli più eccellenti architettori, pittori, e scultori*, &c., Florence, 1550; A. Condivi, *Vita di Michelangelo Buonarroti*, 1553; this account, for which the author, a pupil and friend of the master's, had long been collecting materials, was much fuller than that of Vasari, who made use of it in rewriting his own life of Michelangelo for his second edition, which appeared after the master's death (1568). The best edition of Vasari is that by Milanesi, Florence, 1878–83; of Condivi, that by Gori and Mariette, Pisa, 1746. The first additions of importance were published by Bottari, *Raccolta di lettere sulla pittura*, &c., Rome, 1754 (2d ed., by Ticozzi, Milan, 1822); the next by Gaye, *Carteggio inedito*, 1840. Portions of the correspondence preserved in the Buonarroti archives were published by Guasti in his notes to the *Rime di Michelangelo Buonarroti*, 1863, and by Daelli in *Carte Michelangelesche inedite*, Milan, 1865. Complete biographies of Michelangelo had been meanwhile attempted by J. Harford, London, 1857, and with more power by Hermann Grimm, *Leben Michelangelo's*, Hanover (5th ed., 1879). A great increment of biographical material was at length obtained by the publication, in the four hundredth year after Michelangelo's birth, of the whole body of his letters preserved in the Buonarroti archives,—*Lettere di Michelangelo Buonarroti*, ed. G. Milanesi, Florence, 1875. This material was first employed in a connected narrative by A. Gotti, *Vita di Michelangelo*, Florence, 1875. Next followed C. Heath Wilson, *Life and Works of Michelangelo Buonarroti*, Florence, 1876, the technical remarks in which, especially as concerns the fresco-paintings, are valuable. Lastly, the combined lives of Michelangelo and Raphael by Professor A. Springer in Dohme's series of *Kunst u. Künstler*, Leipsic, 1878, contain the best biography of the master which has yet appeared. Of the poems of Michelangelo the best edition is that already referred to,—G. Guasti, *Rime di Michelangelo Buonarroti*, 1863; in earlier additions the text had been recklessly tampered with, and the rugged individuality of the master's style smoothed down. An edition with German translations was published by Hasenclever, Leipsic, 1875; for the English student the translations by Mr J. A. Symonds, in *Sonnets of Michelangelo and Campanella*, London, 1878, are invaluable. (S. C.)

MICHELET, Jules (1798–1874), one of the most voluminous and remarkable writers of France, and one who only lacked a keener power of self-criticism to make him one of the greatest, was born at Paris, August 21, 1798. He belonged to a family which had Huguenot traditions, and which was latterly occupied in the art of printing. His father was a master printer, but seems not to have been very prosperous, and the son at an early age assisted him in the actual work of the press. A place was offered him in the imperial printing office, but his father was able to send him to the famous Collége or Lycée Charlemagne, where he distinguished himself. He passed the university examination in 1821, and was shortly after appointed to a professorship or rather mastership of history in the Collége Rollin. Soon after this, in 1824, he married. The period of the Restoration and the July monarchy was one of the most favourable to rising men of letters of a somewhat scholastic cast that has ever been known in France, and Michelet had powerful patrons in Villemain, Cousin, and others. But, though he was an ardent politician (having from his childhood embraced republicanism and a peculiar variety of romantic free-thought), he was first of all a man of letters and an inquirer into the history of the past. His earliest works were school books, and they were not written at a very early age. Between 1825 and 1827 he produced divers sketches, chronological tables, &c., of modern history. His *Précis* of the subject, published in the last-mentioned year, is a sound and careful book, far better than anything that had appeared before it, and written in a sober yet interesting style. In the same year he was appointed maître de conférences at the École Normale. Four years later, in 1831, the *Introduction à l'Histoire Universelle* showed a very different style, exhibiting no doubt the idiosyncrasy and literary power of the writer to greater advantage, but also displaying the peculiar visionary qualities which make Michelet the most stimulating but the most untrustworthy (not in facts, which he never consciously falsifies, but in suggestion) of all historians. The events of 1830 had unmuzzled him, and had at the same time improved his prospects, and put him in a better position for study by obtaining for him a place in the Record Office, and a deputy-professorship under Guizot in the literary faculty of the university. Very soon afterwards he began his chief and monumental work, the *Histoire de France*, which occupied him for about forty years, and of which we shall speak presently. But he accompanied this with numerous other works, chiefly of erudition, such as the *Œuvres Choisies de Vico*, the *Mémoires de Luther écrits par lui-même*, the *Origines du Droit Français*, and somewhat later the *Procés des Templiers*. 1838 was a year of great importance in Michelet's life. He was in the fulness of his powers, his studies had fed his natural aversion to the principles of authority and ecclesiasticism, and at a moment when the revived activity of the Jesuits caused some real and more pretended alarm he was appointed to the chair of history at the Collége de France. Assisted by his friend Quinet, he began a violent polemic against the unpopular order and the principles which it represented, a polemic which made their lectures, and especially Michelet's, one of the most popular resorts of the day. He published, in 1839, a History of the Roman Republic, but this was in his graver and earlier manner. The results of his lectures appeared in the volumes *Le Prêtre, la Femme, et la Famille* and *Le Peuple*. These books do not display the apocalyptic style which, borrowed to a certain though no very great extent from Lamennais, characterizes Michelet's later works, but they contain in miniature almost the whole of his curious ethico-politico-theological creed—a mixture of sentimentalism, communism, and anti-sacerdotalism, supported by the most eccentric arguments, but urged with a great deal of eloquence. The principles of the outbreak of 1848 were in the air, and Michelet was not the least important of those who condensed and propagated them: indeed his original lectures were of so incendiary a kind that the course had to be interdicted. But when the actual revolution broke out Michelet, unlike many other men of letters, did not attempt to enter on active political life, and merely devoted himself more strenuously to his literary work. Besides continuing the great history, he undertook and

carried out, during the years between the downfall of Louis Philippe and the final establishment of Napoleon III., an enthusiastic *Histoire de la Révolution Française.* Despite or because of its enthusiasm, this is by no means Michelet's best book. The events were too near and too well known, and hardly admitted the picturesque sallies into the blue distance which make the charm and the danger of his larger work. In actual picturesqueness as well as in general veracity of picture, the book cannot approach Carlyle's; while as a mere chronicle of the events it is inferior to half a dozen prosaic histories older and younger than itself. The *coup d'état* lost Michelet his place in the Record Office, as, though not in any way identified with the republic administratively, he refused to take the oaths to the empire. But the new *régime* only kindled afresh his republican zeal, and his second marriage (with Mademoiselle Adèle Malairet, a lady of some literary capacity, and of republican belongings) seems to have further stimulated his powers. While the history steadily held its way, a crowd of extraordinary little books accompanied and diversified it. Sometimes they were expanded versions of its episodes, sometimes what may be called commentaries or companion volumes. In some of the best of them natural science, a new subject with Michelet, to which his wife is believed to have introduced him, supplies the text. The first of these (by no means the best) was *Les Femmes de la Révolution* (1854), in which Michelet's natural and inimitable faculty of dithyrambic too often gives way to tedious and not very conclusive argument and preaching. In the next, *L'Oiseau* (1856), a new and most successful vein was struck. The subject of natural history was treated, not from the point of view of mere science, nor from that of sentiment, nor of anecdote, nor of gossip, but from that of the author's fervent democratic pantheism, and the result, though, as was to be expected, unequal, was often excellent. *L'Insecte*, in the same key, but duller, followed. It was succeeded by *L'Amour* (1859), one of the author's most popular books, and not unworthy of its popularity, but perhaps hardly his best. These remarkable works, half pamphlets half moral treatises, succeeded each other as a rule at the twelve months' interval, and the succession was almost unbroken for five or six years. *L'Amour* was followed by *La Femme* (1860), a book on which a whole critique of French literature and French character might be founded. Then came *La Mer* (1861), a return to the natural history class, which, considering the powers of the writer and the attraction of the subject, is perhaps a little disappointing. The next year (1862) the most striking of all Michelet's minor works, *La Sorcière*, made its appearance. Developed out of an episode of the history, it has all its author's peculiarities in the strongest degree. It is a nightmare and nothing more, but a nightmare of the most extraordinary verisimilitude and poetical power.

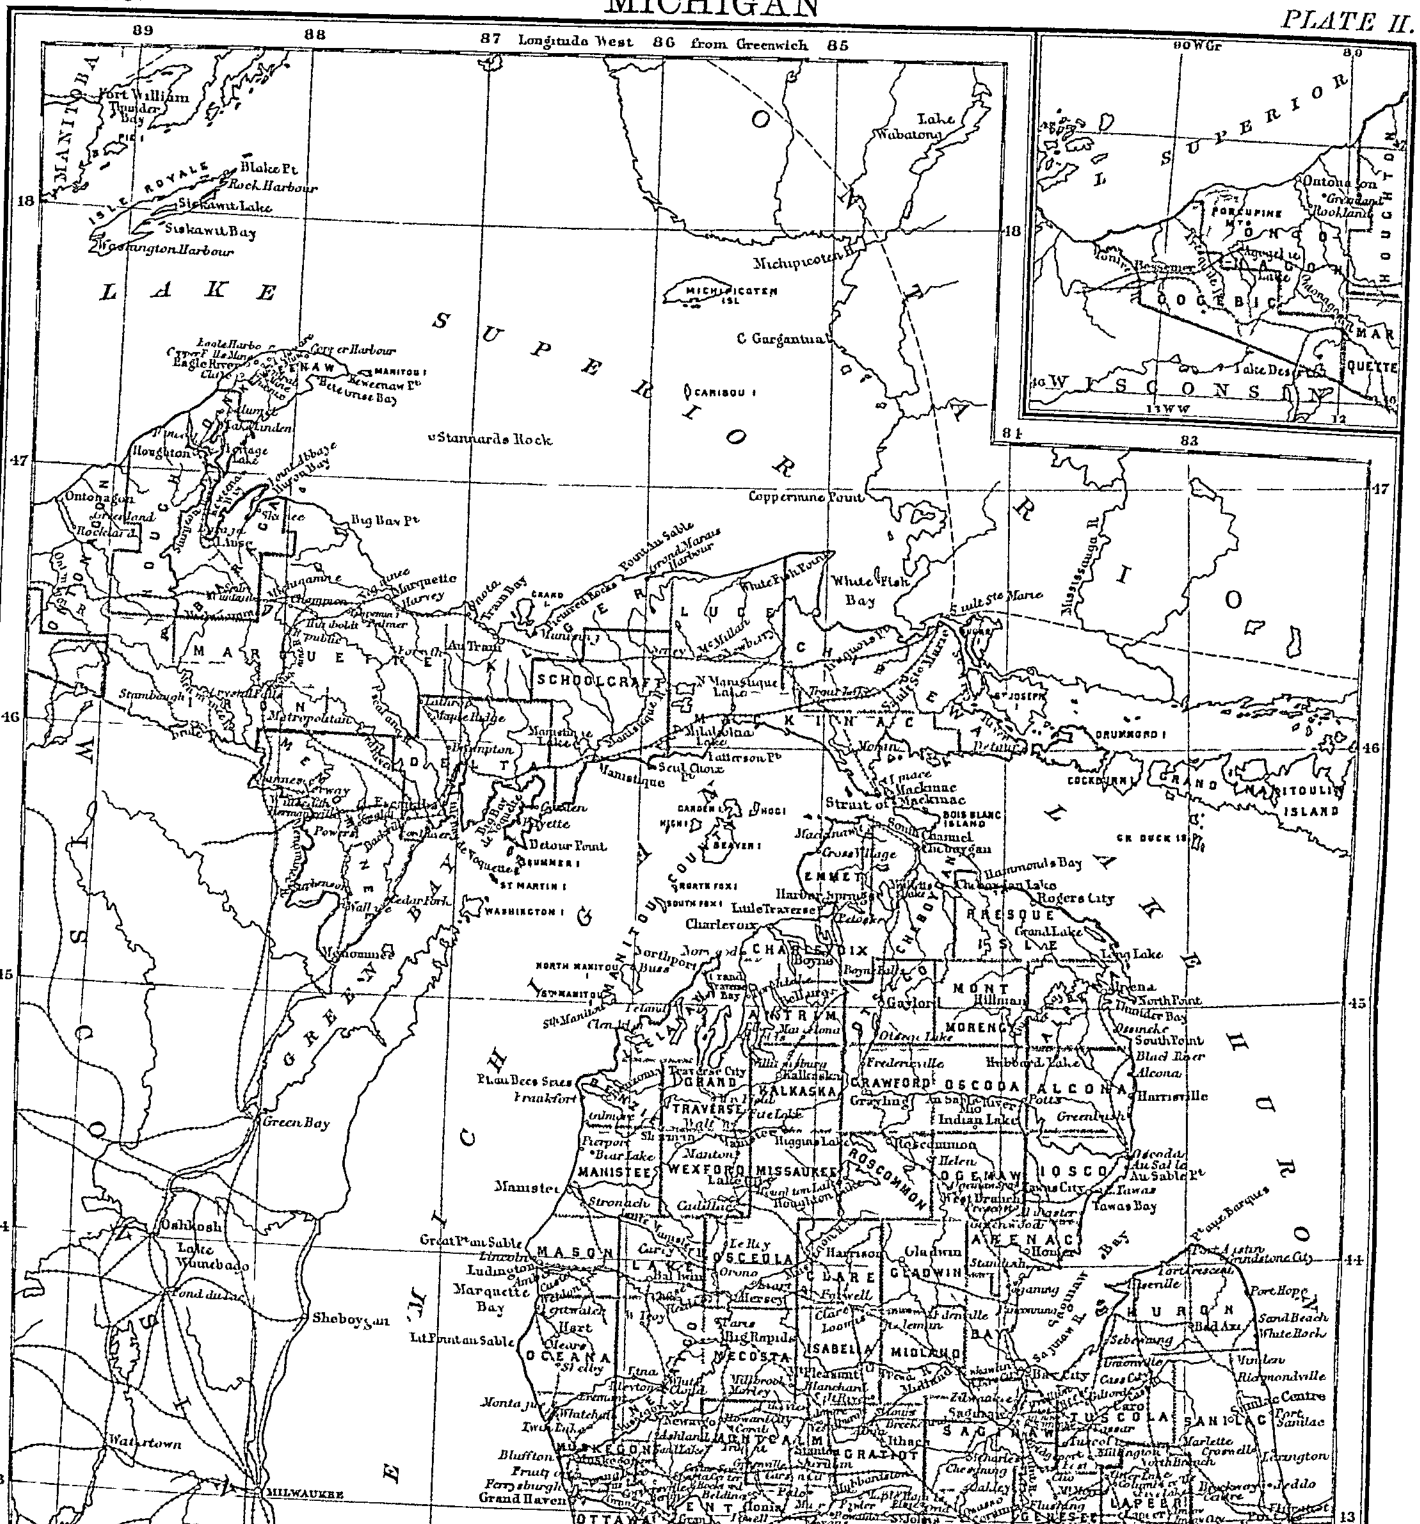
This remarkable series, every volume of which was at once a work of imagination and of research, was not even yet finished, but the later volumes exhibit a certain falling off. The ambitious *Bible de l'Humanité* (1864), an historical sketch of religions, has but little merit. In *La Montagne* (1868), the last of the natural history series, the tricks of staccato style are pushed even farther than by Victor Hugo in his less inspired moments, though—as is inevitable in the hands of such a master of language as Michelet—the effect is frequently grandiose if not grand. *Nos Fils* (1869), the last of the string of smaller books published during the author's life, is a tractate on education, written with ample knowledge of the facts and with all Michelet's usual sweep and range of view, but with visibly declining powers of expression. But in a book published posthumously, *Le Banquet*, these powers reappear at their fullest. The picture of the industrious and famishing populations of the Riviera is (whether true to fact or not) one of the best things that Michelet has done. To complete the list of his miscellaneous works, two collections of pieces, written and partly published at different times, may be mentioned. These are *Les Soldats de la Révolution* and *Légendes Démocratiques du Nord.*

The publication of this series of books, and the completion of his history, occupied Michelet during both decades of the empire. He lived partly in France, partly in Italy, and was accustomed to spend the winter on the Riviera, chiefly at Hyères. At last, in 1867, the great work of his life was finished. As it is now published it fills nineteen volumes. The first of these deals with the early history up to the death of Charlemagne, the second with the flourishing time of feudal France, the third with the 13th century, the fourth, fifth, and sixth with the Hundred Years' War, the seventh and eighth with the establishment of the royal power under Charles VII. and Louis XI. The 16th and 17th centuries have four volumes apiece, much of which is very distantly connected with French history proper, especially in the two volumes entitled *Renaissance* and *Réforme.* The last three volumes carry on the history of the 18th century to the outbreak of the Revolution. The characteristics which this remarkable history shares with Michelet's other works will be noted presently. At present it may be remarked that, as the mere division of subjects and space would imply, it is planned on very original principles. Michelet was perhaps the first historian to devote himself to anything like a picturesque history of the Middle Ages, and his account is still the most vivid though far from the most trustworthy that exists. His inquiry into manuscript and printed authorities was most laborious, but his lively imagination, and his strong religious and political prejudices, made him regard all things from a singularly personal point of view. Circumstances which strike his fancy, or furnish convenient texts for his polemic, are handled at inordinate length, while others are rapidly dismissed or passed over altogether. Yet the book is undoubtedly the only history of France which bears the imprint of genius, and in this respect it is not soon likely to meet a rival.

Uncompromisingly hostile as Michelet was to the empire, its downfall and the accompanying disasters of the country once more stimulated him to activity. Not only did he write letters and pamphlets during the struggle, but when it was over he set himself to complete the vast task which his two great histories had almost covered by a *History of the Nineteenth Century.* He did not, however, live to carry it further than Waterloo, and the best criticism of it is perhaps contained in the opening words of the introduction to the last volume—"l'âge me presse." The new republic was not altogether a restoration for Michelet, and his professorship at the Collége de France, of which he contended that he had never been properly deprived, was not given back to him. He died at Hyères on the 9th of February 1874, and an unseemly legal strife between his representatives took place as to his funeral.

The literary characteristics of Michelet are among the most clearly marked and also among the most peculiar in French literature. A certain resemblance to Lamennais has been already noted, and to this may be added an occasional reminiscence of the manner of Bossuet. But in the main Michelet, even in the minor details of style, is quite original and individual. His sentences and paragraphs are as different as possible in construction and rhythm from the orderly architecture of French classical prose. A very frequent device of his (somewhat abused latterly) is the omission of the verb, which gives the sentence the air of a continued interjection. Elsewhere he breaks his phrase, not finishing the regular clause at all. In these points and many others the resemblance to his contemporary Carlyle is very striking; and, different as were their points of view, their manners of seeing were by no means unlike. History to Michelet is always picturesque; it is a series of tableaux. Allusion has been already made to the singular per-

MICHIGAN



ENCYCLOPÆDIA BRITANNICA NINTH EDITION

spective in which these tableaux are drawn, a perspective so strange that a reader unacquainted with the actual size and relation of the objects represented is certain to be deceived. Nothing indeed is further from Michelet's purpose than deceit. Although a strong republican, an ardent anti-sacerdotalist, and a patriot of fanatical enthusiasm, he is always scrupulously fair as far as he understands what he is doing. For instance, his hatred for England and Englishmen is one of the most comically intense passions in literature. He is never tired of exclaiming against their diabolical pride, their odious jealousy of France, their calculating covetousness, and so forth. In his excited imagination the long drama of European history is a kind of conflict of Ormuzd and Ahriman, in which France, it is needless to say, plays the first part and England the second. Yet he is never unfair to English fortitude and coolness, never (after the childish fashion of some of his countrymen) slurs over English victories, and often expresses genuine admiration (mixed, it is true, with a shudder or two of aversion) for the masterful ways and constantly advancing prosperity of the English people. So, with all his dislike to the priesthood, he never is chary of praise to pope or monk whenever it can fairly be given, and, with all his republicanism, he is never weary of worshipping the heroism of a great king. But his poetical fashion of dealing with events, his exaggeration of trivial incidents into great facts of history, his fixed ideas, especially in reference to the intellectual and social condition of mediæval times, the evils of which he enormously exaggerates, and his abiding prejudices of a general kind combine to distort his accounts in the strangest fashion. A laborious person might pick out of contemporary authors a notable collection of erroneous views of which Michelet is not so much the author as the suggester, for it is when his brilliant exaggerations are torn from their context and set down in some quite other context as sober gospel that they are most misleading to those who do not know the facts, and most grotesque to those who do. This is especially the case in regard to literature. Michelet began his great work too early to enjoy the benefit of the resurrection of old French literature which has since taken place; and though his view of that literature partakes of the amorous enthusiasm which colours his view of everything French, it is astoundingly incorrect in detail. The most remarkable passage of all perhaps is the passage in his *Renaissance* relating to Rabelais, Ronsard, and Du Bellay, a passage so widely inconsistent not only with sound criticism but with historic fact that the author (a very rare thing with him) makes a kind of half apology for it elsewhere. Of the work of the age of chivalry proper, the chansons de gestes, the Arthurian romances, the early lyrics and dramas, he evidently knew but little, and chose to subordinate what he did know to his general theories of the time. Even much later his praise and blame, though transparently honest, are quite haphazard. Unless, therefore, the reader be gifted with a very rare faculty of applying the "grain of salt" to what he reads, or unless he be well acquainted with the actual facts before coming to Michelet's version of them, he will almost certainly be misled. But despite this grave drawback (which attends all picturesque history) the value of Michelet merely as an historian is immense. Not only are his separate tableaux, the wonderful geographical sketch of France in the beginning of the book, the sections devoted to the Templars, to Joan of Arc, to the Renaissance, to the Camisards, almost unequalled, but the inspiriting and stimulating effect of his work is not to be surpassed. If his reconstruction is often hazardous and conjectural, sometimes definitely and demonstrably mistaken, and nearly always difficult to adjust entirely to the ascertained facts, it is always possible in itself, always instinct with genius, and always life-like. There are no dead bones in Michelet; they are if anything only too stirring and lively. These criticisms apply equally to the minor books, though these are necessarily fuller of the author's somewhat wearisome propaganda, and less full of brilliantly painted facts. The great fault of Michelet as of not a few other modern authors is the comparatively improvised and ephemeral character of too much of his work. His immense volume is, much of it, mere brilliant pamphleteering, much more mere description equally brilliant but equally liable to pass. Nevertheless he is (especially in French, the language *par excellence* of measured and academic perfection) so characteristic and singular a figure in his turbid eloquence and fitful flashing insight that he is never likely to lose a place, and a notable one, in literary history.

Almost all Michelet's works, the exceptions being his translations, compilations, &c., are published in uniform size and in about fifty volumes, partly by Marpon and Flammarion, partly by Calmann Lévy. (G. SA.)

MICHELL, John, an eminent English man of science of the 18th century. He received his university education at Queen's College, Cambridge. His name appears fourth in the Tripos list for 1748–49; and in 1755 he was moderator in that examination. He was a fellow of his college, and became successively Woodwardian professor of geology (in 1762) and rector of Thornhill in Yorkshire. He was elected a member of the Royal Society in the same year as Henry Cavendish (1760). He died in 1793. In 1750 he published at Cambridge a small work of some eighty pages, entitled *A Treatise of Artificial Magnets, in which is shown an easy and expeditious method of making them superior to the best natural ones.* Besides the description of the method of magnetization which still bears his name, this work contains a variety of acute and accurate magnetic observations, and is particularly distinguished by a lucid exposition of the nature of magnetic induction. He is now best known as the original inventor of the torsion balance, which afterwards became so famous in the hands of its second inventor Coulomb. Michell described it in his proposal of a method for obtaining the mean density of the earth. He did not live to put his method into practice; but this was done by Henry Cavendish, who made, by means of Michell's apparatus, the celebrated determination that now goes by the name of Cavendish's experiment (*Phil. Trans.*, 1798).

Michell's other contributions to science are—"Conjectures concerning the Cause and Observations upon the Phenomena of Earthquakes," *Phil. Trans.*, 1760; "Observations on the Comet of January 1760 at Cambridge," *Ib.*, 1760; "A Recommendation of Hadley's Quadrant for Surveying," *Ib.*, 1765; "Proposal of a Method for measuring Degrees of Longitude upon Parallels of the Equator," *Ib.*, 1766; "An Inquiry into the Probable Parallax and Magnitude of the Fixed Stars," *Ib.*, 1767; "On the Twinkling of the Fixed Stars," *Ib.*, 1767; "On the Means of Discovering the Distance, Magnitude, &c., of the Fixed Stars," *Ib.*, 1784.

MICHELOZZI, Michelozzo (1391–1472?), was a Florentine by birth, the son of a tailor, and in early life a pupil of Donatello. He was a sculptor of some ability in marble, bronze, and silver. The statue of the young St John over the door of the Duomo at Florence, opposite the Baptistery, is by him; and he also made the beautiful silver statuette of the Baptist on the altar-frontal of San Giovanni. Michelozzi's great friend and patron was Cosimo I. dei Medici, whom he accompanied to Venice in 1433 during his short exile. While at Venice, Michelozzi built the library of San Giorgio Maggiore, and designed other buildings there. The magnificent Palazzo dei Medici at Florence, built by Cosimo, was designed by him; it is one of the noblest specimens of Italian 15th-century architecture, in which the great taste and skill of the architect has combined the delicate lightness of the earlier Italian Gothic with the massive stateliness of the Classical style. With great engineering skill Michelozzi shored up, and partly rebuilt, the Palazzo Vecchio, then in a ruinous condition, and added to it many important rooms and staircases. When, in 1437, through Cosimo's liberality, the monastery of San Marco at Florence was handed over to the Dominicans of Fiesole, Michelozzi was employed to rebuild the domestic part and remodel the church. For Cosimo I. he designed numerous other buildings, mostly of great beauty and importance. Among these were a guest-house at Jerusalem, for the use of Florentine pilgrims, Cosimo's summer villa at Careggi, and the strongly fortified palace of Cafagiuolo in Mugello. For Giovanni dei Medici, Cosimo's son, he built a very large and magnificent palace at Fiesole. In spite of Vasari's statement that he died at the age of sixty-eight, he appears to have lived till 1472. He is buried in the monastery of San Marco, Florence. Though skilled both as a sculptor and engineer, his fame chiefly rests on his architectural works, which claim for him a position of very high honour even among the greatest names of the great 15th-century Florentines.

MICHIGAN, one of the States of the American Union, Plate II.
situated in the region of the great lakes. It lies between 41° 42′ and 47° 32′ N. lat., and 82° 24′ and 90° 31′ W. long., the centre of the State being 670 miles north of west from New York, the nearest point on the seaboard. The area is 58,915 square miles. The State consists of two

natural divisions, known as the Upper and the Lower Peninsula. The Upper or Northern Peninsula is bounded on the N., E., and S. by Lakes Superior, Huron, and Michigan, and on the W. by the river St Mary and the State of Wisconsin. The Lower Peninsula is bounded on the W., N., and E. by Lakes Michigan, Huron, St Clair, and Erie, and the St Clair and Detroit rivers, and on the S. by the States of Ohio and Indiana. The general contour of the Lower Peninsula approaches that of a horse-shoe, with an average width of about 200 miles from east to west and a length of about 300 miles from north to south. Its surface gradually rises in gentle undulations from the surrounding lakes to an elevation of about 400 feet above Lake Huron, no point reaching an altitude of more than 600 feet. The Upper Peninsula is much more rugged in contour and surface, at some points reaching an elevation of about 1100 feet. The territory was originally covered with forests, with only here and there a small open prairie. It abounds in fine inland lakes, with areas varying from a few acres to several miles. The rivers are not large enough to be navigable, but they afford ample water-power, and are particularly valuable for floating down the logs of the lumbering districts. The coast-line of the State is not less than about 1600 miles in length; and along the whole of this distance vessels of 2000 tons may pass without losing sight of land.

Geological Formation.—The Lower Peninsula occupies the central part of a great basin, the borders of which extend to the east as far as London, Ontario, and to the west as far as Madison, Wisconsin. Within these limits the traveller starting in any direction from the centre of the State encounters successively the outcropping edges of older and older strata. The whole series has been likened to a nest of wooden dishes; it embraces not only the Laurentian and Huronian systems but also the numerous groups that go to make up the Silurian, the Devonian, the Carboniferous, and the Quaternary systems. These several formations are covered almost universally with a drift of finely comminuted and triturated rock, borne thither by moving glaciers and floating icebergs, or washed to its present position by currents of water, while the surface was still submerged. This loose material varies in thickness, sometimes extending to a depth of 200 or 300 feet. While the lower formations contain almost inexhaustible deposits of copper, iron, gypsum, and salt, the surface soil is pre-eminently fertile, uniting all the mineral constituents necessary for the most luxuriant growth of plants. There are limited areas of light and somewhat sterile drift soil; but even these have shown themselves under proper treatment to be capable of yielding a rich vegetation. For the most part the drift soil is composed of a mixture of clay with sand and gravel. It is easily cultivated, is retentive of moisture, and is sufficiently porous to prevent the injury of crops by excessive rains.

Climate and Natural Products.—The mean temperature of Lansing, the capital of the State, as determined by observations extending through eighteen years, is 46°·71 Fahr., or about the same as that of Berlin. During the summer months the mean temperature is nearly the same as that of Vienna; in the winter it is nearly that of Stockholm. The annual rainfall during the eighteen years previous to 1882 was about 31 inches. This is very evenly distributed throughout the year, though a little more than half the amount falls in the five months from May to October. The average snowfall in the centre of the State is about 4 feet, though it is seldom that more than 12 inches lie on the ground at any one time. The winter temperature is much modified by the open water of the adjacent lakes. The severe winds are commonly from the west and north-west; but in sweeping across the open waters of Lake Michigan they are so far softened as to make the climate much milder than that found in the same latitude on the western side of the lake. This peculiarity is specially favourable to the growth of fruits. Peaches are grown successfully along the 45th parallel, and figs thrive in the open air in lat. 42½°. The modifying influence of the lake winds also gives great variety to the flora. The predominant woods are oak, maple, beech, elm, ash, cherry, hickory, walnut, basswood, and pine. All these grow luxuriantly in the vast forests of the State, and afford an abundant supply of the best timber. There are 165 species of trees and shrubs indigenous to Michigan; and the entire flora of the State makes a list of 1634 species.

Cereals and Fruits.—The most important crop of Michigan is wheat, and the average yield per acre, as shown by the latest census, is greater than that of any other State in the Union. The acres sown in 1879 were reported as 1,822,749, and the amount produced as 35,532,543 bushels. These figures show that Michigan is fourth in rank of the wheat-producing States, the number of bushels grown being exceeded by the crops of Illinois, Ohio, and Indiana. In 1879 the yield in bushels of the other principal cereals is shown by the following figures:—Indian corn, 32,461,452; oats, 18,190,793; barley, 1,204,316; rye, 294,918; buckwheat, 413,062; clover seed, 313,063; pease, 538,332. The crop of potatoes in the same year was 8,025,475 bushels, and the hay amounted to 1,051,115 tons. Of the fruits grown in the State apples are the most important, and these are believed to be unsurpassed in excellence in any country in the world. The sales in 1880 were 4,834,936 bushels, a considerable quantity going to the markets of Europe. Next in importance is the peach crop, annually gathered from more than fifty of the counties of the State. In 1880 the peach orchards were reported as covering 12,908 acres, and the fruit sold as amounting to 413,418 bushels. The long coast-line of Lake Michigan affords easy access to market even for the most perishable fruits. Besides the facilities thus afforded, the railroads that now thread the State, with an aggregate length in March 1882 of 4332 miles, afford abundant means of rapid transportation. As the fruit belt extends from north to south more than 200 miles, the danger of disastrous competition in the markets is obviated by prolongation of the season of ripening. At the meeting of the State Horticultural Society held in 1881 it was reported that the average value of the peach crop per acre was above $125. The ten volumes of the *Transactions* of the State Horticultural Society published since its organization in 1870 show that the development of fruit culture within the last decade has been much more rapid than in any other State.

Lumber.—The timber produce in Michigan is of superior quality, and the amount is so great that about two-thirds of the best lumber sold in New York, Philadelphia, and Boston go out from its mills. The logs are borne along the lakes, rivers, and small watercourses to the booms of mills situated at convenient points, where the timber is sawed and shipped for the different markets of the world. Of these manufacturing districts those known as the Saginaw, the Grand River, and the Muskegon valleys are the most important. The Saginaw receives the waters of the Tittabawasse, the Cass, the Flint, the Shiawassee, the Bad, the Pine, the Chippewa, the Tobacco, and their numerous tributaries, draining a vast region that still yields an undiminished supply of pine. The forests of the western parts of the State are easily accessible by the Grand River and its tributaries, while those still farther north find a natural outlet through the numerous streams that flow to Lake Michigan. On the banks of these watercourses are

some of the largest and finest mills of the world. In 1854, when the first effort was made to collect statistics of this industry, it was found that there were only sixty-one mills in operation, and that the entire annual product was only 108,000,000 feet. Eighteen years later, in 1872, it was estimated that the annual product was not less than 2,560,000 feet of oak, 12,700,000 of staves, 300,000,000 lath, 400,000,000 shingles, and 2,500,000,000 of sawed pine. The number of saw-mills had already reached about 1500, the number of persons employed 20,000, and the capital represented $25,000,000. In 1881 the manufacture of pine lumber amounted to 3,919,500,000 feet, the value of which exceeded $60,000,000. The aggregate value of the forest products of the State was estimated in 1881 to have reached more than $1,000,000,000. *Forestry Bulletin*, No. 6, issued December 1, 1881, estimated the amount of standing white pine of merchantable quality at 35,000,000,000 feet, and the amount of standing hard wood at 700,000,000 cords. Besides these amounts, the same authority estimates the amount of hemlock at 7,000,000,000 feet, with 7,000,000 cords of bark, and an aggregate of 70,000,000 of cedar and tamarack. It is probable that before many years the hard wood produced by the State will approach in value the figures representing the value of the pine now sent to the markets of the world. It is probable that Michigan for many years to come will maintain its precedence as a lumber-producing State.

Mineral Resources.—Of the mineral products of Michigan the most important is iron. As early as 1842 the report of the first State geologist, Dr Douglas Houghton, called attention to the presence of hæmatite ore, though for a considerable time after this it was not found in such quantities as to make it certain that mining could be made profitable. Before 1860, however, it became known that iron in the Upper Peninsula not only existed in vast quantities, but also that it was of superior quality. From that time iron-mines were rapidly developed, until in 1881 they had come to exceed in value, though not in amount, even the products of Pennsylvania. In 1880 the product was 1,834,712 tons, with a value at the mines of $6,034,648, as against the yield in Pennsylvania of 2,185,675 tons, with a value of $5,517,079. The product of Michigan in 1882 was 2,948,307 tons of ore, with a market value of about $25,000,000. The Michigan minerals are of extraordinary richness,—62·9 per cent. being the average of the first-class ores, while the furnace books often show a much higher yield.

Next in importance to the iron-mines are those of copper. These are also situated in the Northern Peninsula, in the mountain range of trappean rocks which crown the point of land extending northwards into Lake Superior. This secondary peninsula or cape, known as Keweenaw Point, rises to an average height of about 600 feet above the lake, the highest pinnacles reaching nearly double that altitude. This point contains what are believed to be the richest copper-mines ever discovered; the metal is not found as an ore, but as virgin copper almost chemically pure. It has only to be separated from its rocky matrix, when it is ready for the market. The largest of the copper-mines, that at Calumet, has built up an industry which employs 2000 men, and its total product of refined copper in 1882 was no less than 50,770,719 ℔, or one-eighth of the annual production of copper in the world. In quality the copper of the Lake Superior district is such that it commands the highest price at home and abroad. Its tenacity is remarkable, and therefore it is eagerly sought after for cartridges by all the great military powers. In 1882 the copper-mines paid dividends amounting to $2,900,000,—making an aggregate of $28,248,000 since they were opened.

Within a few years the salt-works of Michigan have also come to exceed those of any other State in the Union. The first well was sunk in 1859–60, but in 1882 the production was found to have exceeded that of the famous works in New York, and to have amounted in that year to no less than 3,204,921 barrels. The extraordinary development of this industry is due to several causes. A careful system of inspection by State authority has kept its salt unsurpassed in purity. The salt basin is not only accessible by navigable waters, so as to have the advantage of cheap transportation, but the wells are situated in the great lumber-producing districts, and the manufacture is thus carried on at very small expense, in connexion with the saw-mills. The power is furnished by the same engines, the exhausted steam is used for the evaporation of brine during the day, and during the night evaporation is still carried on by means of refuse wood and saw-dust, while the staves for barrels are made from rejected timber. By this system the best quality of salt is obtained at a minimum expense. The chief reservoir of salt is the series of sandstones and shales constituting the Waverly group. This salt-producing rock covers no less than about 8000 square miles, and it is safe to presume that the supply is inexhaustible. The average depth of the wells is about 800 feet, but in some localities wells sunk to nearly 2000 feet have been remunerative. Important salt-works have recently been developed in the western part of the State.

There are also certain other minerals of considerable importance. Deposits of gypsum, easily accessible, practically inexhaustible in quantity, and superior in quality, are found in several localities both in the eastern and in the western parts of the Lower Peninsula. In the outskirts of Grand Rapids the deposit crops out at the surface, and at an average depth of from 40 to 70 feet extends over an area of 10 or 12 square miles. The rock is easily quarried, and is either ground for use as a fertilizer or calcined into plaster of Paris. The deposits of coal are supposed to cover about 8000 square miles, but as yet the product at any one point has not been very considerable. In quality the coal is highly bituminous, and is not sufficiently pure to be useful for smelting or for the manufacture of gas. For these reasons the stock of coal in the State is practically untouched. If future explorations and experiments should make these deposits available, a new era in the manufacture of iron will be the result. At present the coal for smelting the Lake Superior ores is brought chiefly from Ohio and Pennsylvania. Quarries of limestone and of sandstone have been opened in various parts of the State. The brown stone of the Upper Peninsula is of excellent quality, and is capable of receiving a high finish. The supply is inexhaustible, and the accessibility of the quarries by water gives promise of a thriving industry. The grindstones taken from the Huron county quarries are of superior quality, and the slates found in unlimited quantities on the shores of the Huron Bay are unsurpassed in point of durability and colour. Clays and sands of commercial value are found in great abundance. Though the manufacture of glass is yet in its infancy, sands in large quantities have been discovered in Monroe county suitable for the manufacture of plate glass of excellent quality. Brick and tile clays are found in all parts of the State. Though native silver has been found in small quantities in the Upper Peninsula, the systematic mining of this metal has not yet been carried on with successful results. The *Report* of the commissioner of mineral statistics for 1882 shows that, except as to coal, Michigan is the foremost of all the States in mineral wealth.

Fisheries.—The geographical position of Michigan explains the fact that its fresh-water fisheries are the most productive in the United States. The most important varieties of fish are lake-trout,

sturgeon, bass, pickerel, herring, brook-trout, grayling, and white-fish. General laws for the protection of fish have been passed; and a fish commission has been maintained for some years for the purpose of propagating the best varieties and planting them in waters adapted to their natural development. Up to the close of 1880 the commissioners had planted about 80,000,000 young white-fish, 1,000,000 silver eels, 1,000,000 lake-trout, 2,000,000 salmon, and 500,000 brook-trout, besides smaller numbers of shad, grayling, pike, and bass. Excellent results have followed, especially in the multiplication of white-fish, salmon, and eels. In 1879 the total "take" was 24,013,100 lb, of which 12,902,250 lb were white-fish, the most valuable lake-fish known to epicures and to commerce. During winter large quantities preserved by freezing are taken to Eastern markets, where they are readily sold at a high price.

Educational Institutions.—As early as 1785 the law of congress which provided for the sale of lands north of the Ohio river reserved for the support of public schools "section 16" of each township. This fundamental law devoted to educational purposes one-thirty-sixth of all the lands of that vast domain known as the north-western territory. The "ordinance of 1787," by which this territory was organized, further provided that "schools and the means of education shall for ever be encouraged." In 1826 this congressional action was supplemented by a grant to Michigan of two townships of land for the founding and support of a university. When Michigan became a State in 1837, its educational policy took definite form. The constitution provided, not only that the grant of "section 16" should be devoted exclusively to the support of schools of the primary grade, but also that the State and not each township should be the custodian of the lands so appropriated. The constitution expressly provided that the proceeds from the sale of "school lands" should be held by the State as a perpetual fund, the interest of which should be annually applied to the support of primary schools. The lands devoted to school purposes in Michigan under these provisions amounted to 1,077,209 acres, of which, in September 1881, 675,000 acres had been sold. On the sum realized by these sales, $3,095,679, the State pays interest at 7 per cent., and the resulting income, amounting to $216,645, is annually distributed to the schools. This source is supplemented from local taxes, so that in 1881 the total sum realized from all sources for the primary schools was $3,644,778.

The schools organized under State law are known as graded and ungraded. In the small districts where the schools are under the charge of but one or two teachers, grading is impracticable. Of ungraded districts there were in 1881 6120, attended by 219,570 children, while the graded schools were 404 in number, with an attendance of 152,043. The school census includes all children between the ages of five and twenty, amounting in 1881 to 518,317, of whom there was an average attendance of 391,401. To all children of school age the public schools are free, though a fee may be required for advanced studies in the high schools. The immediate administration of the schools is entrusted to school officers elected annually by the tax-payers of the individual districts. The State constitution requires that a free school shall be in session at least three months of every year in each district. In districts of more than 30 and less than 800 children, the law requires at least five months of school; while in districts of more than 800 children, the session must be not less than nine months in length. In the graded schools the division is into primary schools, grammar schools, and high schools, each of these divisions retaining the scholar ordinarily four years. At the end of the course the student is ready for the university, to which, under certain restrictions provided by the university itself, he is admitted on diploma from the high school. The university of Michigan, situated at Ann Arbor, was first opened for instruction in 1841. It now (1883) consists of the department of literature, science, and the arts, the department of medicine, the department of law, the college of homœopathic medicine, the school of pharmacy, the college of dental surgery, and the school of political science. Connected with the medical departments are the State hospitals. In 1881–82 there were 86 officers of instruction and 1534 students. The total income for the year 1879–80 from Federal grant, State grants, and fees was $231,339. The general control of the university is placed in the hands of eight regents elected by popular suffrage at the biennial spring elections, two regents being chosen at each election. The normal school, situated at Ypsilanti, and generously supported by the State, may be said to complete the school system.

Charitable and Reformatory Institutions.—A school for the deaf, dumb, and blind, instituted under an Act passed in 1848, is situated at Flint, about 60 miles north-west of Detroit; in February 1882 it had 249 pupils. In 1879 a distinct school for the training of the blind was established at Lansing. The "State public school for dependent and neglected children" is devoted to the systematic education of such children as otherwise would have to be maintained in the county poorhouses. The pupils are divided into "families" of about thirty each, and are cared for in separate cottages, each cottage being under the charge of a "cottage manager." The school receives dependent children of sound health, and free from contagious disease; and it is made the duty of the officers having charge of the poor to send all such children between the ages of three and twelve to it. This institution, the pioneer of its kind, and one of the most useful of charitable schools, is situated at Coldwater, 132 miles south-west of Detroit. In February 1882 there were 320 children and 21 officers and teachers. The "Reform School" at Lansing is designed to reclaim juvenile offenders who have been convicted of some offence. A farm of 224 acres connected with the school is, in considerable part, tilled by the boys. The number of inmates in February of 1882 was 325. A similar school at Adrian has recently been instituted for girls. There are State asylums for the insane at Kalamazoo (715 patients) and Pontiac (499 patients). The legislature of 1881 provided for the establishment of an additional asylum in one of the northern counties of the Lower Peninsula.

Population.—In 1837 the State had 174,647 inhabitants. The numbers according to the different census returns from 1840 are given in the following table:—

Census.	Total	Males.	Females.	Density per Square Mile.
1840	212,267	113,788	98,479	3·77
1850	397,654	209,897	187,757	7·07
1860	749,113	394,694	354,419	12·11
1870	1,184,059	617,745	566,314	20·01
1880	1,636,937	862,678	774,259	27·80

At the last census 388,508 of the inhabitants were of foreign birth, 97,346 being natives of the United Kingdom, 89,085 Germans, and 16,445 Scandinavians. In point of population the State, which was twenty-third in 1840, now stands ninth in the Union.

The following are the principal cities in the State, with population at the census of 1880:—Detroit, 116,340; Grand Rapids City, 32,016; Bay City, 20,693; East Saginaw City, 19,016; Jackson City, 16,105; Muskegon City, 11,262; Saginaw City, 10,525; Port Huron, 8883; Flint City, 8410; Lansing (the State capital), 8319; Ann Arbor, 8061; Adrian City, 7849; Battle Creek, 7063; Manistee, 6930; West Bay City, 6397; Alpena City, 6153; Ishpeming, 6039.

History and Government.—The State of Michigan is part of the territory that was first settled by the French, and until the fall of Canada into the hands of the British after the middle of the 18th century was under the government of New France. The territory was explored by Jesuit missionaries in the 17th century; but, although it was known at an early period that the lands were of exceptional excellence, very little progress was made in developing the resources of the territory until after the completion of the first half-century of the American Union. The surveyors employed by the general government to inspect the lands and report as to their fitness for settlement by the soldiers of the war of 1812 appear to have derived their impressions almost exclusively from the low lands in the south-eastern corner of the territory. The report, accordingly, was not favourable; and consequently the tide of immigration that had already begun to set in flowed steadily past Michigan into the territories farther west. It was largely for this reason that the early development of Indiana, Illinois, Iowa, and Wisconsin was somewhat more rapid than that of Michigan. But gradually the false impressions concerning the soil and climate were dispelled; and within the past few years the increase of the population and the growth of wealth have been very rapid. In 1851 the valuation of the State for purposes of taxation (which excludes much valuable property) was $30,976,270; in 1861, $172,055,808; in 1871, $630,000,000; at 1881, $810,000,000. The State constitution, adopted in 1837 at the time of admission to the Union, has been modified in some minor particulars; but in most respects it remains unchanged. The governor is elected for two years, with no restriction as to re-election. The legislature meets biennially in the first week of January, and usually continues in session till May. The supreme court consists of four judges chosen by popular vote for terms of eight years, one being elected every second year. Judges have been so frequently re-elected that the office may be said to be practically a permanent one, with a provision for termination in case of need. The State is divided into twenty-two judicial districts, in each of which a circuit court sits for the trial of causes of original jurisdiction, and of causes appealed from the justice courts. The judges of the circuit courts are also elected by popular suffrage. On political questions voting is open to all naturalized citizens of the male sex more than twenty-one years of age unless prevented by some natural disqualification. At school meetings the right of suffrage is extended so as to include tax-payers of either sex.

Authorities.—Frederick Morley, *Michigan and its Resources*, compiled under authority of the State, 2d ed., Detroit, 1882; *Walling's Atlas of Michigan, with an Account of the Topography, Climate, and Geology of the State*, by Alex. Winchell, LL.D.; James V. Campbell, *Outlines of the Political History of Michigan*; *Reports of the Secretary of the State Pomological Society of Michigan from* 1871 *to* 1880; *Report of the Commissioner of Education for* 1880: *Forty-fifth*

Annual Report of the Superintendent of Public Instruction of the State of Michigan for the year 1881; *Reports of the Geological Survey of the State of Michigan*, 1869-80, 4 vols.; *Special Report of Commissioner of Mineral Statistics*, March 1883; *Forestry Bulletins* for 1881. (C. K. A.)

MICHIGAN, LAKE. See ST LAWRENCE.

MICHIGAN CITY, a town of the United States, in Laporte county, Indiana, on the south-east shore of Lake Michigan, 40 miles east-south-east of Chicago. As a lake-port and a junction for several railroads, it is a place of considerable prosperity. It is the largest lumber-market in the State, and one of the largest in the west, and has numerous manufacturing establishments. The northern State prison (with 577 convicts at the close of 1880) is one of the principal buildings. The population increased from 3985 in 1870 to over 10,000 in 1883.

MICHMASH (מִכְמָשׂ, מִכְמָס), the scene of one of the most striking episodes in Old Testament history (1 Sam. xiv., comp. vol. xii. p. 403), was a place in Benjamin, about 9 Roman miles north of Jerusalem (*Onom.*, ed. Lag., p. 280). Though it did not rank as a city (Josh. xviii. 21 *sq.*), Michmash was recolonized after the exile (Neh. xi. 31), and, favoured by the possession of excellent wheat-land (*Mishna*, Men. viii. 1), was still a very large village (Μαχμάς) in the time of Eusebius. The modern Makhmás is quite a small place.

The historical interest of Michmash is connected with the strategical importance of the position, commanding the north side of the Pass of Michmash, which made it the headquarters of the Philistines and the centre of their forays in their attempt to quell the first rising under Saul, as it was also at a later date the headquarters of Jonathan the Hasmonæan (1 Mac. ix. 73). From Jerusalem to Mount Ephraim there are two main routes. The present caravan road keeps the high ground to the west near the watershed, and avoids the Pass of Michmash altogether. But another route, the importance of which in antiquity may be judged of from Isa. x. 28 *sq.*, led southwards from Ai over an undulating plateau to Michmash. Thus far the road is easy, but at Michmash it descends into a very steep and rough valley, which has to be crossed before reascending to Geba.[1] At the bottom of the valley is the Pass of Michmash, a noble gorge with precipitous craggy sides. On the north the crag is crowned by a sort of plateau sloping backwards into a round-topped hill. This little plateau, about a mile east of the present village of Makhmás, seems to have been the post of the Philistines, lying close to the centre of the insurrection, yet possessing unusually good communication with their establishments on Mount Ephraim by way of Ai and Bethel, and at the same time commanding the routes leading down to the Jordan from Ai and from Michmash itself.

MICKIEWICZ, ADAM (1798–1855), Polish poet, was born in 1798, near Nowogrodek, in the present government of Minsk, where his father, who belonged to the schlachta or lesser nobility, had a small property. The poet was educated at the university of Vilna; but, becoming involved in some political troubles there, he was forced to terminate his studies abruptly, and was ordered to live for a time in Russia. He had already published two small volumes of miscellaneous poetry at Vilna, which had been favourably received by the Slavonic public, and on his arrival at St Petersburg he found himself admitted to the leading literary circles, where he was a great favourite both from his agreeable manners and his extraordinary talent of improvisation. In 1825 he visited the Crimea, which inspired a collection of sonnets in which we may admire both the elegance of the rhythm and the rich Oriental colouring. The most beautiful are *The Storm*, *Bakchi-serai*, and *Grave of the Countess Potocka*.

In 1828 appeared his *Konrad Wallenrod*, a narrative poem describing the battles of knights of the Teutonic order with the heathen Lithuanians. Here, under a thin veil, Mickiewicz represented the sanguinary passages of arms and burning hatred which had characterized the long feuds of the Russians and Poles. The objects of the poem, although evident to many, escaped the Russian censors, and it was suffered to appear, although the very motto, taken from Machiavelli, was significant: "Dovete adunque sapere come sono duo generazioni da combattere . . . bisogna essere volpe e leone." After a five years' exile in Russia the poet obtained leave to travel; he had secretly made up his mind never to return to that country or Poland so long as it remained under the government of the Muscovites. Wending his way to Weimar, he there made the acquaintance of Goethe, who received him cordially, and, pursuing his journey through Germany, he entered Italy by the Splügen, visited Milan, Venice, and Florence, and finally took up his abode at Rome. There he wrote the third part of his poem *Dziady*, the subject of which is the religious commemoration of their ancestors practised among Slavonic nations, and *Pan Tadeusz*, his longest poem, by many considered his masterpiece. A graphic picture is drawn of Lithuania on the eve of Napoleon's expedition to Russia in 1812. In 1832 Mickiewicz left Rome for Paris, where his life was for some time spent in poverty and unhappiness. He had married a Polish lady, Selina Szymanowska, who became insane. In 1840 he was appointed to the newly founded chair of Slavonic languages and literature in the Collége de France, a post which he was especially qualified to fill, as he was now the chief representative of Slavonic literature, Poushkin having died in 1837. He was, however, only destined to hold it for a little more than three years, his last lecture having been given on the 28th of May 1844. His mind had become more and more disordered under the influence of religious mysticism. His lectures became a medley of religion and politics, and thus brought him under the censure of the Government. A selection of them has been published in four volumes. They contain some good sound criticism, but the philological part is very defective, for Mickiewicz was no scholar, and he is obviously only well acquainted with two of the literatures, viz., Polish and Russian, the latter only till the year 1830. A very sad picture of the declining days of Mickiewicz is given in the memoirs of Herzen. At a comparatively early period the unfortunate poet exhibited all the signs of premature old age; poverty, despair, and domestic affliction had wrought their work upon him. In 1849 he founded a French newspaper, *La Tribune des Peuples*, but it only existed a year. The restoration of the French empire seemed to kindle his hopes afresh; his last composition is said to have been a Latin ode in honour of Napoleon III. On the outbreak of the Crimean War he was sent to Constantinople to assist in raising a regiment of Poles to take service against the Russians. He died suddenly there in 1855, and his body was removed to France and buried at Montmorency.

Mickiewicz is held to have been the greatest Slavonic poet, with the exception of Poushkin. Unfortunately in other parts of Europe he is but little known; he writes in a very difficult language, and one which it is not the fashion to learn. There were both pathos and irony in the expression used by a Polish lady to a foreigner, "Nous avons notre Mickiewicz à nous." He is one of the best products of the so-called romantic school. The Poles had long groaned under the yoke of the classicists, and the country was full of legends and picturesque stories which only awaited the coming poet to put them into shape. Hence the great popularity among his countrymen of his ballads, each of them being connected with some national tradition. Besides *Konrad Wallenrod* and *Pan Tadeusz*, attention may be called to the poem *Grazyna*, which describes the adventures of a Lithuanian chieftainess against the Teutonic knights. It is said by Ostrowski to have inspired the brave Emilia Plater, who was the heroine of the rebellion of 1830, and after having fought in the ranks of the insurgents, found a grave in the forests of Lithuania. A fine vigorous Oriental piece is *Farys*. Very good too are the odes to Youth and to the historian Lelewel; the former did much to stimulate the efforts of the Poles to shake off their Russian conquerors. It is enough to say of Mickiewicz that he has obtained the proud position of the representative poet of his country; her customs, her superstitions, her history, her struggles are reflected in his works.

[1] So Isa. x. 28 describes the invader as leaving his heavy baggage at Michmash before pushing on through the pass.

MICKLE, WILLIAM JULIUS (1734–1788), son of the minister of Langholm, Dumfriesshire, holds a respectable place among the imitative minor poets of the 18th century. He wrote a poem on *Knowledge*—carefully versified, pointing a moral on the vanity of intellectual pride—at the age of eighteen, entered into business as a brewer at his father's request and against his own inclinations, soon became bankrupt, went to London on outlook for work as a man of letters, solicited patronage in vain, earned a living hardly by writing for magazines, made some impression in 1765 by "a poem in the manner of Spenser" called the *Concubine* (afterwards *Syr Martyn*), was appointed corrector to the Clarendon Press, and finally took a place among the leading poets of that very barren time by a translation of the *Lusiad* of Camoens into heroic couplets (specimen published 1771, whole work 1775). So great was the repute of the work that when Mickle—appointed secretary to Commodore Johnstone—visited Lisbon in 1779 the king of Portugal gave him a public reception. As a translator of Camoens Mickle has been superseded, but he aimed, not at close rendering of the original, but at making a poem which should be worthy of a permanent place in English literature. This ambition he was not capable of fulfilling, though he had great fluency and vigour. It may be doubted whether the fashionable forms which he imitated were the best suited to his natural gifts. He shows delight in lively action, a sense of dramatic effect, and, in the *Concubine*, the substance of which might have been conceived by Crabbe, considerable fulness of detail in coarse realistic painting. Certainly, if the Scottish poem *There 's nae luck aboot the hoose* was Mickle's, he mistook his medium. Scott read and admired Mickle's poems in his youth, and, besides founding *Kenilworth* on the ballad of *Cumnor Hall*, was a good deal influenced by him in style. Mickle's prose is lively and vigorous.

MICROMETER, an instrument generally applied to telescopes and microscopes for measuring small angular distances with the former or the dimensions of small objects with the latter.

Before the invention of the telescope the accuracy of astronomical observations was necessarily limited by the angle that could be distinguished by the naked eye. The angle between two objects, such as stars or the opposite limbs of the sun, was measured by directing an arm furnished with fine "sights" (in the sense of the "sights" of a rifle) first upon one of the objects and then upon the other, or by employing an instrument having two arms each furnished with a pair of sights, and directing one pair of sights upon one object and the second pair upon the other. The angle through which the arm was moved, or, in the latter case, the angle between the two arms, was read off upon a finely graduated arc. With such means no very high accuracy was possible. Archimedes concluded from his measurements that the sun's diameter was greater than 27′ and less than 32′; and even Tycho Brahe was so misled by his measures of the apparent diameters of the sun and moon as to conclude that a total eclipse of the sun was impossible.[1] Maestlin in 1579 determined the relative positions of eleven stars in the Pleiades (*Historia Cœlestis Lucii Baretti*, Augsburg, 1666), and Winnecke has shown (*Monthly Notices R. A. S.*, vol. xxxix. p. 146) that the probable error of these measures amounted to about ±2′.[2]

[1] Grant, *History of Physical Astronomy*, p. 449.

[2] This is an astonishing accuracy when the difficulty of the objects is considered. Few persons can see with the naked eye—much less measure—more than six stars of the Pleiades, although all the stars measured by Maestlin have been seen with the naked eye by a few individuals of exceptional powers of eye-sight.

The invention of the telescope at once extended the possibilities of accuracy in astronomical measurements. The planets were shown to have visible disks, and to be attended by satellites whose distance and position angle relative to the planet it was desirable to measure. It became, in fact, essential to invent a "micrometer" for measuring the small angles which were thus for the first time rendered sensible. There is now no doubt that William Gascoigne, a young gentleman of Yorkshire, was the first inventor of the micrometer. Crabtree, a friend of his, taking a journey to Yorkshire in 1639 to see Gascoigne, writes thus to his friend Horrocks. "The first thing Mr Gascoigne showed me was a large telescope amplified and adorned with inventions of his own, whereby he can take the diameters of the sun and moon, or any small angle in the heavens or upon the earth, most exactly through the glass, to a second." The micrometer so mentioned fell into the possession of Mr Richard Townley of Lancashire, who exhibited it at the meeting of the Royal Society held on the 25th July 1667.

Gascoigne's micrometer.

The principle of Gascoigne's micrometer is that two pointers, having parallel edges at right angles to the measuring screw, are moved in opposite directions symmetrically with and at right angles to the axis of the telescope. The micrometer is at zero when the two edges are brought exactly together. The edges are then separated till they are tangent to the opposite limbs of the disk of the planet to be measured, or till they respectively bisect two stars, the angle between which is to be determined. The symmetrical separation of the edges is produced and measured by a single screw; the fractions of a revolution of the screw are obtained by an index attached to one end of the screw, reading on a dial divided into 100 equal parts. The whole arrangement is elegant and ingenious. A steel cylinder (about the thickness of a goose-quill), which forms the micrometer screw, has two threads cut upon it, one-half being cut with a thread double the pitch of the other. This screw is mounted on an oblong box which carries one of the measuring edges; the other edge is moved by the coarser part of the screw relatively to the edge attached to the box, whilst the box itself is moved relatively to the axis of the telescope by the finer screw. This produces an opening and closing of the edges symmetrically with respect to the telescope axis. Flamsteed, in the first volume of the *Historia Cœlestis*, has inserted a series of measurements made by Gascoigne extending from 1638 to 1643. These include the mutual distances of some of the stars in the Pleiades, a few observations of the apparent diameter of the sun, others of the distance of the moon from neighbouring stars, and a great number of measurements of the diameter of the moon. Dr Bevis (*Phil. Trans.*, 1773, p. 190) also gives results of measurements by Gascoigne of the diameters of the moon, Jupiter, Mars, and Venus with his micrometer.

Delambre gives[3] the following comparison between the results of Gascoigne's measurements of the sun's semi-diameter and the computed results from modern determinations:—

	Gascoigne.	*Conn. d. Temps.*
October 25 (O.S.)	16′ 11″ or 10″	16′ 10″·0
,, 31 ,, ...	16′ 11″	16′ 11″·4
December 2 ,, ...	16′ 24″	16′ 16″·8

Gascoigne, from his observations, deduces the greatest variation of the apparent diameter of the sun to be 35″; according to the *Connaissance des Temps* it amounts to 32″·3.[3] These results prove the enormous advance attained in accuracy by Gascoigne, and his indisputable title to the credit of inventing the micrometer.

Huygens, in his *Systema Saturnium* (1659), describes a micrometer with which he determined the apparent

[3] Delambre, *Hist. Ast. Moderne*, vol. ii. p. 590.

diameters of the principal planets. He inserted a slip of metal, of variable breadth, at the focus of the telescope, and observed at what part it exactly covered the object under examination; knowing the focal length of the telescope and the width of the slip at the point observed, he thence deduced the apparent angular breadth of the object. The Marquis Malvasia in his *Ephemerides* (Bologna, 1662) describes a *micrometer* of his own invention. At the focus of his telescope he placed fine silver wires at right angles to each other, which, by their intersection, formed a network of small squares. The mutual distances of the intersecting wires he determined by counting, with the aid of a pendulum clock, the number of seconds required by an equatorial star to pass from web to web, while the telescope was adjusted so that the star ran parallel to the wires at right angles to those under investigation.[1] In the *Phil. Trans.*, 1667, No. 21, p. 373, Auzout gives the results of some measures of the diameter of the sun and moon made by himself, and this communication led to the letters of Mr Townley and Dr Bevis above referred to. The micrometer of Auzout and Picard was provided with silk fibres or silver wires instead of the edges of Gascoigne, but one of the silk fibres remained fixed while the other was moved by a screw. It is beyond doubt that Huygens independently discovered that an object placed in the common focus of the two lenses of a Kepler telescope appears as distinct and well-defined as the image of a distant body; and the micrometers of Malvasia, Auzout, and Picard are the natural developments of this discovery. Gascoigne was killed at the battle of Marston Moor on the 2d July 1644, in the twenty-fourth year of his age, and his untimely death was doubtless the cause that delayed the publication of a discovery which anticipated, by twenty years, the combined work of Huygens, Malvaison, Auzout, and Picard in the same direction.

Spider webs. As the powers of the telescope were gradually developed, it was found that the finest hairs or filaments of silk, or the thinnest silver wires that could be drawn, were much too thick for the refined purposes of the astronomer, as they entirely obliterated the image of a star in the more powerful telescopes. To obviate this difficulty Professor Felice Fontana of Florence (*Saggio del real gabinetto di fisica e di storia naturale*, 1755) first proposed the use of spider webs in micrometers,[2] but it was not till the attention of Troughton had been directed to the subject by Rittenhouse that the idea was carried into practice.[3] In 1813 Wollaston proposed fine platinum wires, prepared by surrounding a platinum wire with a cylinder of silver, and drawing out the cylinder with its platinum axis into a fine wire.[4] The surrounding silver was then dissolved by nitric acid, and a platinum wire of extreme fineness remained. But experience soon proved the superiority of the spider web; its perfection of shape, its lightness and elasticity, have led to its universal adoption.

Beyond the introduction of the spider line it is unnecessary to mention the various steps by which the Gascoigne micrometer assumed the modern forms now in use, or to describe in detail the suggestions of Hooke,[5] Wren, Smeaton, Cassini, Bradley, Maskelyne, Herschel, Arago, Pearson, Bessel, Struve, Dawes, &c., or the successive productions of the great artists Ramsden, Troughton, Fraunhofer, Ertel, Simms, Cooke, Grubb, Clarke, and Repsold. It will be sufficient to describe those forms with which the most important work has been done, or which have survived the tests of time and experience.

Position angles. Before astronomical telescopes were mounted parallactically, the measurement of position angles was seldom attempted. Indeed, in those days, the difficulties attached to such measures, and to the measurement of distances with the filar micrometer, were exceedingly great, and must have taxed to the utmost the skill and patience of the observer. For, on account of the diurnal motion, the direction of the axis of the telescope when directed to a star is always changing, so that, to follow a star with an altazimuth mounting, the observer requires to move continuously the two handles which give slow motion in altitude and azimuth.

Herschel's instrument. Sir William Herschel was the first astronomer who measured position angles; the instrument he employed is described in *Phil. Trans.*, 1781, vol. lxxi. p. 500. It was used by him in his earliest observations of double stars (1779-83); but, even in his matchless hands, the measurements were comparatively crude, because of the difficulties he had to encounter from the want of a parallactic mounting. In the case of close double stars he estimated the distance in terms of the disk of the components. For the measurement of wider stars he invented his lamp-micrometer, in which the components of a double star observed with the right eye were made to coincide with two lucid points placed 10 feet from the left eye. The distance of the lucid points was the tangent of the magnified angles subtended by the stars to a radius of 10 feet. This angle, therefore, divided by the magnifying power of the telescope gives the real angular distance of the centres of a double star. With a power of 460 the scale was a quarter of an inch for every second.

The Modern Filar Micrometer.

When equatorial mountings for telescopes became more general, no filar micrometer was considered complete which was not fitted with a position circle.[6] The use of the spider line or filar micrometer became universal; the methods of illumination were improved; and micrometers with screws of previously unheard-of fineness and accuracy were produced. These facilities, coupled with the wide and fascinating field of research opened up by Sir William Herschel's discovery of the binary character of double stars, gave an impulse to micrometric research which has continued unabated to the present time. A still further facility was given to the use of the filar micrometer by the introduction of clockwork, which caused the telescope automatically to follow the diurnal motion of a star, and left the observer's hands entirely at liberty.[7]

Classification of micrometers. The modern filar micrometer has now assumed forms of five types.

Type A.—Micrometers in which there are two webs, each movable by a fine screw with a divided head. This is the usual English form of filar micrometer.

Type B.—Micrometers in which one web is movable by means of a fine screw with a divided head, and the other by a screw without a divided head. The latter screw, in ordinary use, is only employed to change the coincidence-reading of the two webs, for eliminating the errors of the micrometer screw. This is the ordinary German form of micrometer as originally made by Fraunhofer and since by Merz, and employed by the Struves and other principal Continental astronomers down to the present day.

Type C.—A similar form of micrometer to B, except that the coincidence-point cannot be changed,—there being no second screw to alter the position of the fixed web.

Type D.—A micrometer somewhat similar in general construction to form B, except that, in addition to means of changing the zero point, there is a screw head by which a fine movement can be given to the whole micrometer box, in the direction of the axis of the micrometer screw. This is the modern form of micrometer as constructed by Repsold.

Type E.—Micrometers fitted with two eye-pieces for measuring angles larger than the field of view of an ordinary eye-piece.

Troughton's filar micrometer. The micrometer of type A is due to Troughton; it is represented in figs. 1, 2, 3. Fig. 1 is a horizontal section in the direction of the axis of the telescope. The eye-piece *ab* consists of two plano-convex lenses *a*, *b*, of nearly the same focal length, and with the two

[1] *Mém. Acad. des Sciences*, 1717, p. 78 *sq.*

[2] In 1782 (*Phil. Trans.*, vol. lxxii. p. 163) Sir W. Herschel writes:—"I have in vain attempted to find lines sufficiently thin to extend them across the centres of the stars, so that their thickness might be neglected." It is a matter of regret that Fontana's suggestion was unknown to him.

[3] Quekett in his *Treatise on the Microscope* ascribes to Ramsden the practical introduction of the spider web in micrometers. The evidence appears to be in favour of Troughton.

[4] *Phil. Trans.*, 1813, pp. 114-118.

[5] Dr Hooke made the important improvement on Gascoigne's micrometer of substituting parallel *hairs* for the parallel edges of its original construction (Hooke's *Posthumous Works*, p. 497).

[6] Herschel and South (*Phil. Trans.*, 1824, part iii. p. 10) claim that the micrometer by Troughton, fitted to their 5-feet equatorial telescope, is the first position micrometer constructed capable of measuring position angles to 1′ of arc.

[7] So far as we can ascertain, the first telescope of large size driven by clockwork was the 9-inch equatorial made for Struve at Dorpat by Fraunhofer; it was completed in 1825. The original idea appears to be due to Passement (*Mém. Acad.*, Paris, 1746). In 1757 he presented a telescope to the king, so accurately driven by clockwork that it would follow a star all night long.

convex sides facing each other. They are placed at a distance apart less than the focal length of *a*, so that the wires of the micrometer, which must be distinctly seen, are beyond *b*.[1] The eye-piece slides into the tube *cd*, which screws into the brass ring *ef*, through two openings in which the oblong frame, containing the micrometer slides, passes. These slides are shown in fig. 2, and consist of brass forks *k* and *l*, into which the ends of the screws *o* and *p* are rigidly fitted. The slides are accurately fitted so as to have no sensible lateral shake, but yet so as to move easily in the direction of the greatest length of the micrometer box. Motion is communicated to the forks by female screws tapped in the heads *m* and *n*

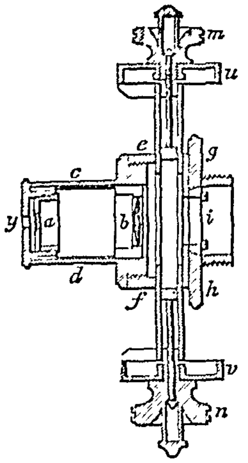


Fig. 1.

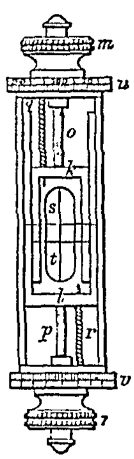

Fig. 2.

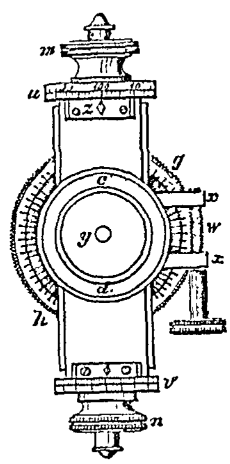

Fig. 3.

acting on the screws *o* and *p* respectively. Two pins *q*, *r*, with spiral springs coiled round them, pass loosely through holes in the forks *k*, *l*, and keep the bearings of the heads *m* and *n* firmly pressed against the ends of the micrometer box. Thus the smallest rotation of either head communicates to the corresponding slide motion, which, if the screws are accurate, is proportional to the amount through which the head is turned. Each head is graduated into 100 equal parts on the drums *u* and *v*, so that, by estimation, the reading can easily be carried to $\frac{1}{1000}$th of a revolution. The total number of revolutions is read off by a scale attached to the side of the box, but not seen in the figure.

Two spider webs are stretched across the forks, one (*t*) being cemented in a fine groove cut in the inner fork *k*, the other (*s*) in a similar groove cut in the outer fork *l*. These grooves are simultaneously cut *in situ* by the maker, with the aid of an engine capable of ruling fine straight lines, so that the webs when accurately laid in the grooves are perfectly parallel. A wire *st* is stretched across the centre of the field, perpendicular to the parallel wires. Each movable web must pass the other without coming in contact with it or the fixed wire, and without rubbing on any part of the brass-work. Should either fault occur (technically called "fiddling") it is fatal to accurate measurement. One of the most essential points in a good micrometer is that all the webs shall be so nearly in the same plane as to be well in focus together under the highest powers used, and at the same time absolutely free from "fiddling." For measuring position angles a brass circle *gh* (fig. 3), fixed to the telescope by the screw *i*, has rack teeth on its circumference that receive the teeth of an endless screw *w*, which, being fixed by the arms *xx* to the oblong box *mn*, gives the latter a motion of rotation round the axis of the telescope; an index upon this box points out on the graduated circle *gh* the angular rotation of the instrument.

The English micrometer still retains the essential features of Troughton's original construction above described. The later English artists have somewhat changed the mode of communicating motion to the slides, by attaching the screws permanently to the micrometer head and tapping each micrometer screw into its slide. Instead of making the shoulder of the screw a flat bearing surface, they have given the screw a spherical bearing resting in a hollow cone (fig. 4) attached to the end of the box. The French artists still retain Troughton's form. Simms (Troughton's successor) and Cooke (of York), for symmetry and more effectual elimination of "the loss of time" (called by the Germans "todter Gang," and sometimes in English "back-lash"), have provided two pins with spiral springs,

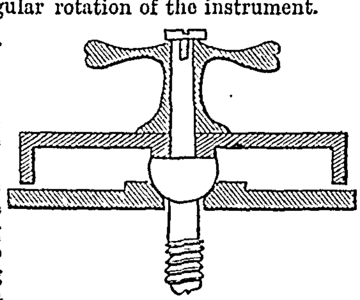

Fig. 4.

like *q* and *r* (fig. 2), one on each side of the screw which moves each slide.

Grubb of Dublin, with the intention of avoiding the variation of pressure exerted by the spiral springs when the slide is at different distances from the head of the screw, has adopted the following plan. Where the screw enters the slide he has a nut *n* attached to a strong spring *pp* (fig. 5), the pressure of which exerts a constant tension in the axis of the screw, tending to bring the threads into close contact, in opposite directions, with their bearings in the nut *n* and the slide *q*. The pressure of this spring is regulated by the screws *s*, *s*, tapped into the thickened ends of the springs. For maintaining the spherical shoulder of the screw in close and constant pressure on its conical bearing he has attached a conical bearing to the spring *p′p′* (fig. 6). The pressure of this on the upper part of the spherical shoulder is regulated by the screws *s′*, *s′*, passing through elongated holes in the spring *p′p′*, and tapped into the end of the box.

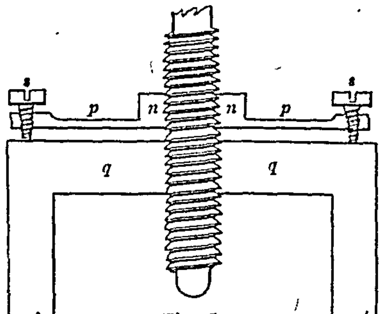

Fig. 5.

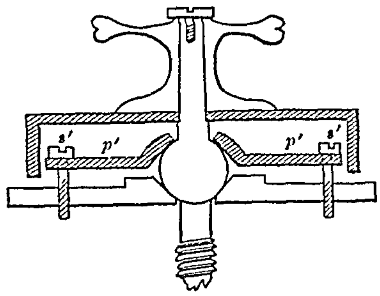

Fig. 6.

The screws of micrometers are generally made with 50 or 100 threads to the inch. Troughton's method of reading the number of whole revolutions by a silver scale is inconvenient, because $\frac{1}{100}$th or even $\frac{1}{50}$th of an inch is too small a quantity to read easily with the naked eye, especially with the faint illumination that it is desirable to use when measuring faint objects. Different methods, including the "comb" (see below) and various kinds of "counters," have been introduced with more or less success; but recently the Repsolds of Hamburg have contrived a plan at once so simple and so efficient that it will be unnecessary to describe those methods which this plan is certain to supersede (see below, type D). Grubb has introduced a modification in the form of the slides with a view to avoid the friction of one slide against the other. On the inner side of the brass plate which forms the bottom of the box (*i.e.*, the side opposite to the eye-piece) four V-shaped furrows are placed (fig. 7); and at each end of the slides are projections (fig. 8, end view) which fit into these furrows. The slides are kept down in their places by springs attached to them, which press upon the inner side of the lid of the box.

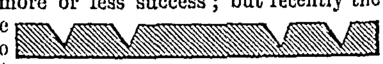

Fig. 7.

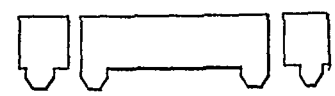

Fig. 8.

Troughton's mode of giving rotation to the position circle is now abandoned. A much quicker motion in position angle than can be obtained without slow motion is often desirable, since, in observing very close double stars, the uncertainty of each pointing may amount to several degrees in the most accurate measurements. The plan of a pinion working in a toothed wheel is often employed, but that also is too slow. Most modern micrometers are now fitted with a clamp and slow motion screw (see fig. 9, type B). This permits observation of position angles of very close objects by simple rotation of the box with the hand; while the slow motion, after clamping, permits the more delicate movements that are required in measuring the position angle of objects farther apart.

The Cookes and Grubb have for years almost invariably transferred the position circle from the micrometer to the telescope tube. The whole eye-end with its focussing arrangements rotates, and its rotation can be measured by a circle attached to the butt end of the tube. There is considerable convenience in this arrangement. One position circle only is required for all the micrometers that may be employed with the instrument; and the orientation of reticulated diaphragms, or the adjustment of the direction of the slit of a spectroscope, may also be accomplished by the same means. But, after a very extended experience of all the various types of existing mountings, the present writer does not hesitate to express a decided preference for a position circle attached to the micrometer and a rigid attachment of the eye-end to the telescope tube,—having never seen an eye-end attached to a position circle on the butt end of the telescope-tube in which, after the wear and tear of a few years,

[1] This is known as Ramsden's eye-piece; it was made originally by him.

some looseness or shake could not be detected. This is a fatal fault, especially in those delicate observations of difference of declination which have latterly formed so prominent a feature in refined micrometric research. On the other hand, in some good old micrometers at the Royal Observatory, Cape of Good Hope, that are fitted with attached *position circles*, there is no trace of shake or wear after fifty years of work.

Fraunhofer's filar micrometer

The micrometer of type B represented in fig. 9[1] is the original Merz micrometer of the Cape Observatory, made on Fraunhofer's model. S is the head of the micrometer screw proper, *s* that of the screw moving the slide to which the so-called "fixed web" is attached, *s'* that of a screw which moves the eye-piece E. C is the clamp and M the slow motion in position angle. L, L are tubes attached to a larger tube N; the latter fits loosely on a strong hollow cylinder which terminates in the screw V. By this screw the whole apparatus is attached to the telescope. The

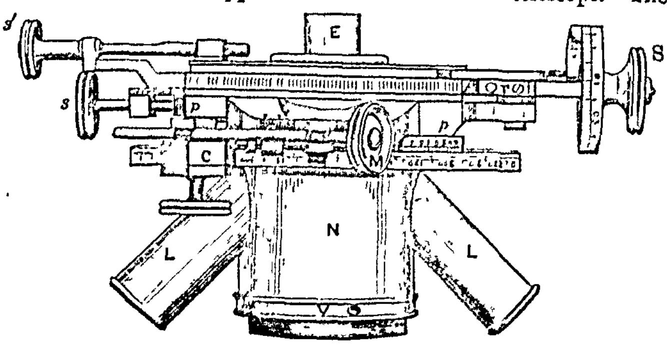

Fig. 9.

nozzles of small lamps are inserted in the tubes L, L, for illuminating the webs in a dark field; the light from these lamps is admitted through apertures in the strong hollow cylinder above mentioned (for illumination, see below). In this micrometer the three slides moved by S, *s*, and *s'* are simple dovetails. The lowest of these slides reposes upon a foundation-plate *pp*, into one end of which the screw *s* is tapped. In the middle of this slide a stiffly fitting brass disk is inserted, to which a small turn-table motion may be communicated by an attached arm, acted on by two fine opposing screws accessible to the astronomer; and by their means the "fixed wire" may be rendered strictly parallel with the movable wire.

The micrometer screw is mounted on the slide which carries the movable web. Fig. 10 shows a plan of this slide; the divided drum of the screw is omitted for sake of clearness. The screw S has a shoulder at κ, carefully fitted and ground to a bearing so as to work sweetly in a hole in the very strong spring $\sigma\sigma$; the other extremity of the screw is formed into a pivot, which fits a hole in the brass piece $\beta\beta$. The end of this pivot—hardened, polished, and slightly rounded—rests on the flat surface of an agate α, which is imbedded in the end of the slide, and kept firmly in its place by the brass piece $\beta\beta$. By careful adjustment of the screws θ, θ sufficient pressure may be left upon κ to slightly bend the strong spring $\sigma\sigma$ and thus eliminate all end-shake without preventing easy action of the screw. The screw passes at the same time through the bush B (shown in plan and elevation, fig. 10) attached to *pp* (fig. 9); and there is a fine saw cut, which can be narrowed by the small screw τ, to close the bush upon the micrometer screw with a view of preventing "loss of time." The spider web ω is cemented on the further side of the thin plate $\nu\nu\nu$, the varnish being applied in the countersunk holes shown by the dotted circles μ, μ. The slide is countersunk to about half its thickness within the area indicated by *oooo*, in order to allow the adapter of the eye-piece to come sufficiently close to the webs. The eye-piece was originally moved by a pinion working in a rack *r* (fig. 9); but the screw *s'* applied by Simms was found by Maclear to be more convenient for the purpose. Beyond this, and the graduation of the edge of the circle with more strongly cut divisions than those originally engraved on the face of the circle, the instrument remains and is figured in its original form. Pistor and Martius (Berlin) have also made excellent instruments of the above type. There is a celebrated micrometer of their make, with which, in the hands of Brunnow at Dunsink (Dublin), some of the most perfect and refined investigations ever made in practical

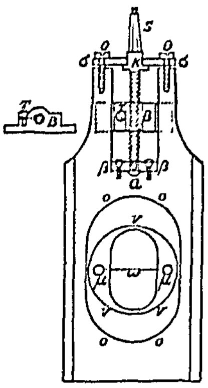

Fig. 10.

Dunsink micrometer.

astronomy have been executed. In this micrometer the screw *s* is mounted on its own slide and has a divided head precisely like the screw S (fig. 9). The plate *pp* is elongated towards *s*, and the corresponding bush B is attached to this elongation. The screw *s'* is shifted to another part of the eye-piece slide, so that it does not interfere with the increased diameter of the screw *s*. Fraunhofer's micrometer in this form belongs to type A, but is quoted under type B for convenience of description.

It is not necessary to give a figure representing type C. Such micrometers have been generally constructed on Troughton's type (figs. 1, 2, 3) with the omission of one of the screws, and with one or more of the modifications described in detail under type A. Some have also been made similar otherwise to the Fraunhofer construction, by omitting the screw *s* with its corresponding slide and attaching the fixed wire to a circular plate in *pp*.

Clark's filar micrometer.

Good instruments have been made on type C by Clark (Cambridge, Massachusetts), by Steinheil (Munich), and by the great French artists Secretan, Froment, Brunner, Eichens; and good work has been done with them. But it is necessary that the errors of the screw should be very carefully determined, since, in type C, such errors cannot be eliminated by employing different parts of the screw to measure the same angle. There is a noteworthy description of micrometer that forms a link between types C and D, of which the most famous example (by Clark) is attached to the great Washington telescope. It is essentially a micrometer of type C, with a slide (or fork) and a screw of the English form of construction. But the instrument is provided with a screw as at *s* (fig. 9), which, instead of changing the position of the fixed wire, moves the whole micrometer box in the direction of the axis of the measuring screw. Thus the fixed wire can be set exactly on one star by the screw *s* while the other star is immediately afterwards bisected by the movable wire, and that without disturbing the reading for coincidence of the wires. No one, unless he has previously worked without such an arrangement, can fully appreciate the advantage of bringing up a star to bisection by the fixed wire by moving the micrometer box with a delicate screw-motion, instead of having to change the direction of the axis of a huge telescope for the same purpose. When it is further remembered that the earlier telescopes were not provided with the modern slow motions in right ascension, and that the Struves, in their gigantic labours among the double stars, used to complete their bisections on the fixed wire by a pressure of the finger on the side of the tube, one is puzzled whether most to wonder at the poor adaptation of means to ends or the marvellous patience and skill which, with such means, led to such results.[2] It should be added that Dawes practically adopted a modification of Clark's micrometer by using a slipping piece, and bolting one of the heads of his micrometer (*Mem. R. A. S.*, vol. xxxv. p. 139). His slipping piece gave motion to the micrometer by two slides, one in right ascension the other in declination, so that "either of the webs can be placed upon either of the components of a double star with ease and certainty."

All micrometers used, in conjunction with a microscope, for reading the divisions of transit circles, heliometer scales, &c., are of the type C. The reading micrometer is shown in fig. 11. C is the objective, D the micrometer box, E the graduated head of the screw, G the milled head by which the screw *cc* is turned, A an eye-piece sliding in a tube B, *aa* (fig. 12) the slide,

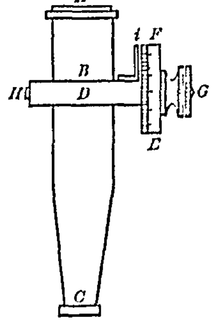

Fig. 11.

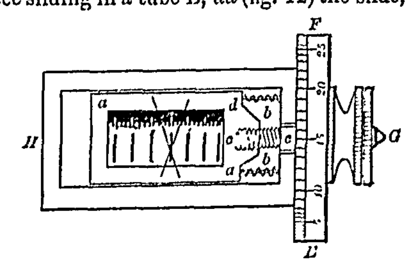

Fig. 12.

and *b*, *b* the spiral springs. The focal length of the objective and the distance between the optical centre of the lens and the webs are so arranged that images of the divisions are formed in the plane of the webs, and the pitch of the screw is such that one division of the scale corresponds with some whole number of revolutions of the screw.

There is what is technically called a "comb" inserted in the micrometer box at *d* (fig. 12),—its upper surface being nearly in the plane of the wires. This comb does not move with reference to the box, and serves to indicate the whole revolution of which a fraction is read on the head. In fig. 12 a division is represented bisected by cross webs, and five revolutions of the screw correspond with one division of the scale. In all modern reading micrometers the cross webs of fig. 12 are replaced by parallel webs embracing the division

[1] When it is remembered that the measurements of the Struves, Dembowski, Secchi, the Bonds, Maclear, and of most modern Continental astronomers have been made with Fraunhofer or Merz micrometers, it is not too much to say that fig. 9 represents the instrument with which three-fourths of the astronomical measurements of the last fifty years have been made.

[2] The late Professor Watson used to say, quaintly and with truth, "After all, the best part of the micrometer is the man at the small end!"

(fig. 13). The means for changing the length of the tube and the distance of C from the scale are omitted in the figure. These appliances are required if the "run" has to be accurately adjusted. By "run" is meant the difference between the intended whole number of screw-revolutions and the actual measure of the space between two adjacent divisions of the scale in turns of the screw divided by the number of intended revolutions. In delicate researches two divisions of the scale should always be read, not merely for increased accuracy but to obtain the corrections for "run" from the observations themselves.

Fig. 13.

Repsold's reading micrometer.

Fig. 14 represents an important type of reading micrometer by the Repsolds. Here the web-frame is mounted on the screw itself. The limiting plane of motion is at *p*, where the end of the micrometer screw bears upon the hardened, flattened end of the screw *s*, and is kept in bearing against this plane by the spiral spring *q*. Rotation

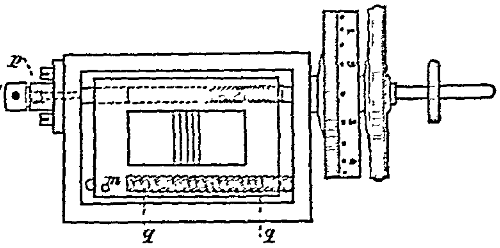

Fig. 14.

of the wire-frame is prevented by the small stud *m* which passes through the web-frame and projects slightly on both sides of it, just barely touching the inner surfaces of the top and bottom of the micrometer box. The web-frame thus rests solely on the screw and on the point *m*, and therefore follows it absolutely and accurately.

Micrometer errors.

The comparative merits of the various micrometers are discussed by Lord Lindsay and Mr Gill (*Dunecht Publications*, vol. ii. pp. 53–55, 1877). If the screw of the Repsold micrometer is bent, so that, for example, the end of the frame next the screw-head is raised and that next the end *p* lowered, a twist will be given to the web-frame, and the centre of the wire will be moved nearer to the micrometer head than it should be, while the reverse effect will follow when the head has been turned through 180°. The effect of a similar error on the other micrometers described would be of a much less amount. They are, however, liable to errors of another character. If, as in Troughton's original micrometer, the shoulder is square, the hole in the end of the box may be left sufficiently wide to allow for a small error in the parallelism of the screw-matrix with the motion of the slide, but the smallest bend in the screw causes the shoulder no longer to bear flat, but to ride on its edge, thus introducing an extremely uncertain form of error. If the shoulder is spherical, fitting into a hollow cone on the end of the box, as in the micrometers of Simms, Cooke, and Grubb, an almost inconceivable accuracy of construction is implied in drilling the matrix of the screw in the slide so that its axis and that of the cone shall be in the same straight line, and both parallel to the motion of a point in the slide. Any departure from perfect accuracy in this respect has the effect of bringing different portions of the spherical shoulder to bear on different parts of the cone for different revolutions, and introduces errors of a character by no means easy to deal with. In addition to these objections there always is the greater objection of employing as a delicate contact-measuring surface one that is exposed where oil is used. Dust and oil will arrange themselves in layers of variable and uncertain thickness and defeat all attempts to secure absolutely consistent results. In Repsold's micrometer the *point d'appui* is a small hardened and polished bearing, requiring little lubrication, and perfectly protected from dust; the errors of the screw (some of them exaggerated, certainly) are faithfully reproduced, and consequently determinable, and beyond this the work to be done by the screw is reduced to a minimum,—no slide-friction having to be overcome. If we are to regard as the most perfect instrument, "not that which has absolutely the smallest errors, but that which reproduces its errors with the most perfect consistency," undoubtedly Repsold's form of micrometer is best.

In order to avoid the exaggeration of the screw-errors produced by the non-symmetrical position of the screw in Repsold's micrometer, Stone, in December 1879, exhibited at the Royal Astronomical Society, and described (*Monthly Notices*, p. 270), a modification of Repsold's instrument. But, both in his statement of the comparative merits of the Troughton and Repsold micrometers and in the new form which he figures, Stone overlooks a strong point in the Repsold form, and in that proposed by Lord Lindsay and Gill three years previously,[1]—namely, the avoidance of all friction of the slide, and the elimination of all error or strain that may occur from a want of parallelism in the axis of the matrix and the motion of the slide.

Lindsay-Gill micrometer.

The Lindsay-Gill micrometer will be better understood from the following description. In fig. 15 S*s* is the micrometer screw; its cylindrical axis is nicely ground to fit a hole in the side of the box at *a*;[2] the same axis, but ground to a somewhat smaller cylinder, fits neatly but smoothly a hole in the web-frame at *b*. A screw, cut on the same axis, is tapped into the web-frame at *s*, and the axis terminates in a pivot which fits a hole in a brass plate *cc*. The end of the pivot—hardened and slightly rounded —rests on a flat agate[3] bearing *a*, which is imbedded in the plate B, and securely held *in situ* by pressure of the plate *cc*. The plate B is firmly attached to the bottom of the box. *q*, *q* are spiral springs mounted on pins. Both springs and pin pass freely through the web-frame at *p*, *p*, and the pins (but not the springs) pass freely through the frame at *n*, *n*.[4] The parallel webs for observing the division (fig. 13) are mounted on the forked end of the frame at *ww*.

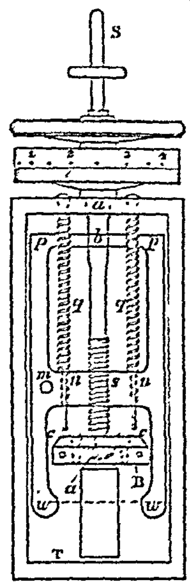

Fig. 15.

The web-frame is narrower and thinner than the breadth and height of the interior of the box, and is only prevented from rotating by the delicate touch of the projecting ends of the pin *m* on the inner surfaces of the top and bottom of the box. It appears that a frame so mounted fulfils all theoretical conditions of accuracy. It is perfectly free to follow the motion of the screw and accurately to reproduce its errors, notwithstanding any reasonable faults of workmanship; and no permissible shake or fouling of the bearing at *a* can produce sensible error in the distance between the bearing surface of the agate plane and the spider webs. The motion is produced with the minimum of friction; and the "feel" of the screw is therefore as delicate and perfect as it is possible to make it.

Repsold's micrometer.

The micrometer of type D shown in fig. 16 has recently been made by the Repsolds for the Cape Observatory. As this instrument combines all their most recent modifications, we describe it in detail. Fig. 17 represents the same micrometer with the upper side of the box removed. The letters in the description refer to both figures.

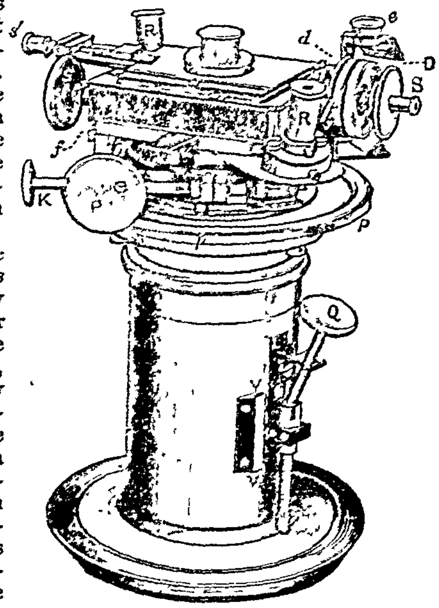

Fig. 16.

S is the head of the micrometer screw, *s* that of the screw by which the micrometer box is moved relative to the plate *f* (fig. 16), *s'* that of the screw which moves the eye-piece slide. K is the clamp in position angle, P the slow motion screw in position angle; *pp* is the position circle, R, R its two readers. The latter are in fact little microscopes carrying a vernier etched on glass, in lieu of a filar micrometer. These verniers can be read to 1′, and estimated to 0′·2. D is the drum-head which gives the fraction of a revolution, *d* that which gives the whole number of revolutions, I is the index or pointer at which both drums are read. This index is shown in fig. 17, but only its mode of attachment (X, fig. 17) in fig. 16. The teeth of the pinion *z*, fig. 17, are cut on the axis of the micrometer screw. The drum *d* and its attached tooth-wheel are ground to turn smoothly on the axis of the screw. The pinion *z* and the toothed wheel *d* are connected by an intermediate wheel and pinion Y; the numbers of teeth in the wheels and pinions are so proportioned that twenty-four revolutions of the micrometer screw produce one revolution of the drum and wheel *d*. (This is the description of Repsold's counter referred to under type A.) The divisions of both drums are conveniently read, simultaneously, by

[1] *Dunecht Publications*, vol. ii., footnote p. 55, Dunecht, 1877.

[2] There would be some advantage in allowing the screw's axis to pass with a little shake through the hole in the end of the box at *a*, and then, extending the length of the larger cylinder, transfer the bearing from *a* to a well-fitting hole in a piece fixed like B to the bottom of the box. This form would also give some facilities of construction, and all the oiled surfaces would be perfectly protected.

[3] Sapphire is better; the agate bearing of such a screw has been found very sensibly worn.

[4] If it is desired to prevent possible contact of these pins with the frame, the ends of the pins may be made to enter guiding holes in *cc*.

the lens e; at night the lamp which illuminates the webs and the position circle also illuminates the drum-heads (see on illumination below). $aaaa$ is the web-frame (fig. 17), $\beta\gamma$ is a single rod consisting of two cylinders accurately fitting in the ends of the micrometer box, the larger cylinder being at β. There is a hole in the web-frame which smoothly fits the larger cylinder at β', and another which similarly fits the smaller cylinder at γ'. A spiral spring, coiled round the cylinder γ, resting one end on the shoulder formed by the difference of the diameters of the cylinders β and γ and the other on the inside of the web-frame, presses the latter continuously towards γ. Contact of the web-frame of the micrometer with the side of the box at γ would therefore take place, were it not for the micrometer screw. This screw fits neatly in the end of the box at ϵ, passes loosely through the web-frame at ϵ', is tapped into the frame at ζ', and its end rests on a flat hardened surface at ζ. Rotation of the web-frame about $\beta\gamma$ is prevented by the heads of the screws at m; the head of the screw on the lower side of the frame reposes on the plane $\nu\nu$, that on the upper side (fig. 17) touches lightly on the inner surface of the lid of the box. Such rotation can obviously be controlled within limits that need not be further considered. But freedom of rotation in the plane of the paper

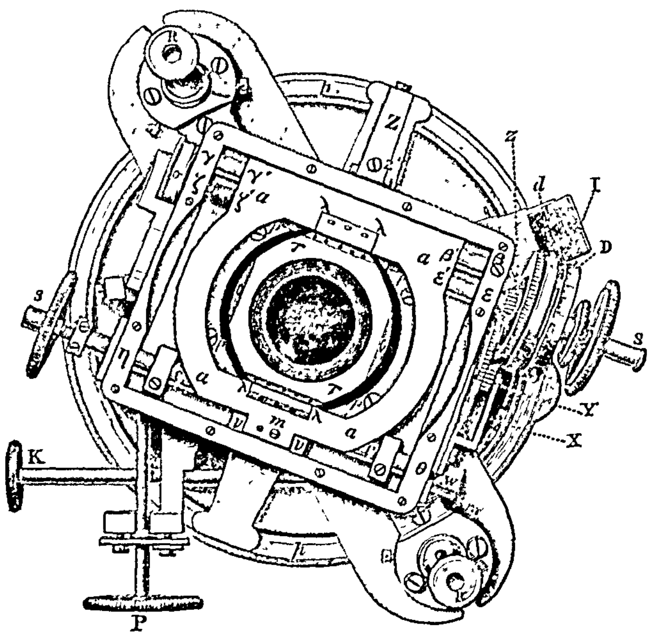

Fig. 17.

(fig. 17) is only prevented by good fitting of the holes β', γ'; and, since the weight of the slide is on one side of the screw, misfit here will have the effect of changing the reading for coincidence of the movable with the fixed web in reverse positions of the micrometer. With the Cape micrometer a systematic difference has been found in the coincidence point for head above and head below amounting to 0''·14. This corresponds, in the Cape instrument, with an excess of the diameters of the holes over those of the cylinders of about $\frac{1}{16000}$th of an inch,—a quantity so small as to imply good workmanship, though it involves a systematic error which is very much larger than the probable error of a single determination of the coincidence point. The obvious remedy is to make all measures on opposite sides of the fixed web before reversing in position angle,—a precaution, however, which no careful observer would neglect. In measuring differences of declination, where the stars are brought up by the diurnal motion, this precaution cannot be adopted, because it is necessary always to bisect the preceding star with the fixed web. But in $\Delta\delta$ measures index error can always be eliminated by bisecting both stars with the same web (or different webs of known interval fixed on the same frame), and not employing the fixed web at all. Had the spring q been placed as in fig. 14, and the cylinders β and γ been made to bear like the pivots of a transit on segmental bearings in the frame at β' and γ', it is probable that the difference in coincidence points would not have existed. Such a modification appears advisable, unless this construction, by leaving the end m less free, should make the "feel" of the screw less sweet and perfect. The discordance in zero when known to exist is really of no consequence, because the observations can be so arranged as to eliminate it.

The box is mounted on a strong hollow steel cylinder CC (fig. 17) by holes η, θ in the ends of the box, which fit the cylinder closely and smoothly. The cylinder is rigidly fixed in the studs C, C, and these are attached to the foundation plate f. The cylinder contains towards η a sliding rod, and towards θ a compressed spiral spring. There is thus a thrust outwards of the spring upon the hollow cap W (attached outside the box), and a thrust of the rod upon the end of the screw s. The position of the box relative to the plate f, in the direction of measurement, depends therefore on the distance between the end of the screw s and the fixed stud C. A screwing in of s thus causes the box to move to the left, and *vice versa*. Rotation of the box round CC is prevented by downward pressure of the spring Z on a projection attached to the side of the box. The amount of this pressure is regulated by the screw z'.

The short screw whose divided milled head is σ shifts the zero of the micrometer by pushing, without turning, the short sliding rod whose flat end forms the *point d'appui* of the micrometer screw at ζ. The pitch of the screw σ is the same as that of the measuring screw (50 threads to the inch), and its motion can be limited by a stop to half a revolution.

The five fixed webs are attached to the table $\tau\tau$, which is secured to the bottom of the box by the screws ρ. The three movable webs are attached to the projections $\lambda\lambda$ on the frame aa. The plane surfaces $\tau\tau$ and $\lambda\lambda$ are composed of a bronze of very close texture, which appears capable of receiving a finish having almost the truth and polish of an optical surface. It seems also to take a very clean V cut, as the webs can be laid in their furrows with an astonishing ease and precision. These furrows have apparently been cut *in situ* with a very accurate engine; for not the slightest departure from parallelism can be detected in any of the movable webs relative to the fixed webs. Extraordinary care has evidently been bestowed in adjusting the parallelism and distance of the planes τ and λ, so that the movable wires shall almost, but not quite, touch the surface τ. The varnish to fix the webs is applied, not on the surface τ as is usual, but on a bevel for the purpose,[1] the position of the webs depending on their tension to keep them in their furrows. The result is that no trace of "fiddling" exists, and the movable and fixed webs come sharply together in focus with the highest powers. Under such powers the webs can be brought into apparent contact with such precision and delicacy that the uncertainty of measurement seems to lie as much in the estimation of the fraction of the division of the head as in the accuracy of the contact. It is a convenient feature in Repsold's micrometer that the webs are very near the inner surface of the top of the box, so that the eye is not brought inconveniently close to the plate when high powers are used.

Micrometers of the type E have been invented by Alvan Clark and Grubb. Clark's micrometer was exhibited at the June meeting of the Royal Astronomical Society in 1859 (*Monthly Notices R. A. S.*, vol. xix.). It is capable of measuring angles up to about one degree. It is "furnished with two eye-pieces, composed of small single lenses, mounted in separate frames, which slide in a groove and can be separated to the required distance. A frame carrying two parallel spider lines, each mounted separately with its own micrometer screw, slides in a dovetailed groove in front of the eye-pieces; and by a free motion in this frame each web can be brought opposite its own eye-lens. In using this micrometer, the first step is to set the position-vernier to the approximate position of the objects to be measured. Then the eye-lenses are separated till each is opposite its own object. The frame containing the webs and their micrometer screws is then slid into its place; and the webs, having been separated nearly to their proper distance by their free motion in the frame, are placed precisely on the objects by their fine screws, the observer's eye being carried rapidly from one eye-lens to the other a few times, till he is satisfied of the bisection of each of the objects by its own web. The frame is then removed for reading off the measure by means of an achromatic microscope, on the stage of which it is placed." The advantages which Clark claims are these:— Clark's micrometer for large angles.

"1. Distances can be observed with great accuracy up to about one degree, and the angles of position also.

"2. The webs, being in the same plane, are perfectly free from parallax, and are both equally distinct, however high the magnifying power may be.

"3. The webs are also free from distortion and from colour.

"4. A different magnifying power may be used on each of the objects,—which may be advantageous in comparing a faint comet with a star."

It appears to us that the method of removing a slide in order to measure the interval between the webs is liable to objection, not only because of the risk to the webs, but because the taking of measurements of such a different character with a different instrument is inconvenient and troublesome. It is true that the intervals between the webs could be measured by an assistant, and two or more different slides be employed to save time; but astronomers will probably generally prefer the method introduced by Grubb described below. It is understood that Clark has since improved this instrument by an ingenious arrangement of prisms, which permits both webs, even though separated one degree in a large telescope, to be seen in the same eye-piece. The arrangement is not described, and is said to be, as yet, somewhat troublesome to arrange previous to measurement, though when arranged it gives very good results.

Grubb (*Scientific Proceedings of Royal Dublin Society*) thus describes

[1] The marks of varnish so applied will be seen in fig. 17.

Grubb's duplex micrometer.

what he calls his "duplex micrometer," shown in perspective in fig. 18:—"A plate of glass about $2\frac{1}{2}$ inches square is ruled with twenty-one lines in one direction $\frac{1}{10}$th inch apart, and two lines in the other direction 2 inches apart. The extreme lines of the set therefore form a perfect square of 2 inches. These lines are ruled with exceeding accuracy and care, but provision is left for ascertaining any errors that remain either as to distance or want of perfect squareness. Along one side of the square is mounted a micrometer frame in the ordinary way, actuated by a screw of one hundred threads to the inch. This micrometer frame carries eleven lines corresponding exactly to each alternate line in the glass reticule, so that when the first spider line is made coincident with the first diamond line on the glass the last spider line will be coincident with the last line on the glass, and each of the spider lines will be coincident with all the odd numbers of diamond lines, 1, 3, 5, 7, 9, 11, 13, 15, 17, 19, 21. Over this glass plate is placed a brass cap in which two eye-pieces are mounted, one sliding in a groove at right angles to the other,—so that, while one has its journey backwards and forwards on the horizontal line, the other has its journey on the vertical line, according to how the cap is placed, for this cap is capable of rotation to meet various circumstances.

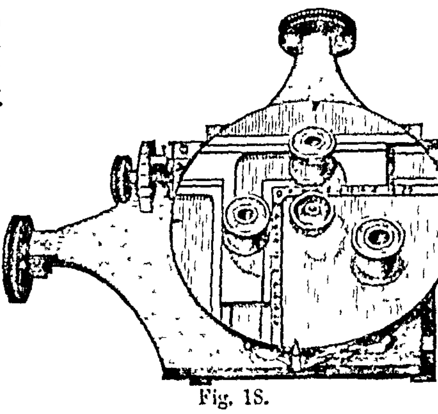

Fig. 18.

"*How to Use the Instrument.*—1. The two stars are brought on the horizontal line, and the distance measured from centre to centre along that line. This distance is measured by counting the number of spaces on the glass, adding the residue as measured by the micrometer screw. Thus the screw is never used for larger measures than $\frac{1}{10}$th inch, and therefore errors of screw and temperature errors are much reduced. In bisecting, one star is brought into the field of one eye-piece, and a bisection is made with one of the diamond lines by moving the micrometer by one or other of its slipping piece screws. Then the other eye-piece is moved till the second star is seen, and a bisection is made with the nearest spider line by moving the micrometer head. Then the eye can be moved back to the first eye-piece, and the bisection checked, and again back to the other eye-piece. When it is seen that both are satisfactory the measure can be read off. 2. The micrometer is turned round till the horizontal line becomes parallel to the path of apparent motion of the star. This is easily found by stopping the clock and allowing the star to run along the horizontal wire. Now the other star will be found to cross the vertical line somewhere, while the first star is on the horizontal line. This second star is then bisected on the vertical line, while the first star is bisected by one of the spider lines; thus the difference in right ascension is found. We then have two sides of a right-angled triangle and of course all the elements are known.

"*To Ascertain the Errors* (*if any*) *of the Distance of the Lines.*—Of course, the usual plan of taking transits can be adopted, and to ascertain if the lines be perfectly at right angles a special additional eye-piece is provided, so that transits can be taken across each diagonal of the square."

This instrument has great advantage over Clark's in case of adjustment and use, and has done good work at the University Observatory, Oxford (*Mem. R. A. S.*, vol. xlvii. pp. 5–12). Professor Pritchard claims too much when he estimates its work as equal in accuracy with that of the heliometer—at least the published results do not confirm such a view. But it is a very valuable instrument for measuring objects too faint for the limited aperture of most heliometers, and which at the same time are farther apart than the field of view of an ordinary eye-piece.

The accuracy of the duplex micrometer would be very greatly increased if Clark's idea (above mentioned) of viewing both widely separated webs in one eye-piece of high power could be reduced to a convenient practical form.

Method of Webbing the Filar Micrometer.

The webbing of a micrometer is a process that should be familiar to all practical astronomers. English opticians usually proceed as follows. A spider (the variety is marked by a cross on the back, and is found in English gardens about decayed wood) is caught, and placed on a wire fork. The insect immediately attaches a web to the wire and begins to lower itself by a web to the ground. This web is wound up on the fork till ten or twelve turns, separated by a convenient space, have been secured. A brush with varnish is then passed along the prongs; the webs are thus securely fixed to the fork. The parallel prongs of the fork must be sufficiently far apart to allow the web-frame of the micrometer to pass between them. The frame to be webbed is placed on a flat dull black surface between the prongs of the fork, the latter being carefully arranged so that one of the webs lies nearly in the furrow ruled in the frame for its reception. As the web-frame is generally thicker than the fork, the web will now be stretched across the former, with a certain amount of tension, and is brought into the furrow with a finely pointed piece of soft wood. If the surface of the frame is well polished, and the furrows sharply cut, without "burr," the web should leap sharply and decidedly into its place. Each end of the web is then secured by a drop of shellac varnish, which should be allowed to harden thoroughly before the frame is touched. The webs can be very readily so handled against a black background, with the aid of a hand lens of 2 or 3 inches focus. In experienced hands this method gives good results, but the following, which is generally followed on the Continent, is preferable.

A web, about 2 inches longer than the width of the frame, is unwound from a cocoon,[1] and small pieces of lead are attached to its extremities by beeswax. One end of the web, with its attached lead, is laid on a piece of cork floating in a tumbler of water; the other end is allowed to hang down in the water, where it becomes thoroughly saturated and untwisted. It is then laid across the fork, and dropped into its furrows in the manner above described, the little lead weights exerting a definite tension. Varnish[2] is immediately applied to secure the webs, and the frame is not touched till it is dry.

The bevel-edge of the web-frame introduced by Repsold (type D) offers great facilities for accurate webbing, and should be employed in all future micrometers.

Illumination of Micrometers.

When micrometer observations are made by night it is necessary to have some mode of rendering the webs visible,—either by rays of light at right angles to the axis illuminating the webs, or by rays nearly coincident with the axis of the telescope. In the former case we get bright webs in a dark field, in the latter dark webs on a bright field.

In the older telescopes bright web illumination is produced by small lamps with nozzles that enter the tubes L, L (fig. 9). The illumination is regulated in colour and intensity by wedges of coloured or darkened glass passing through slides in the nozzles. But it is inconvenient to have lamps so near the observer's eye, and it is at least very difficult to obtain a perfectly dark field when the wires are illuminated in this way.

The Clarks, in their micrometer of the great Washington telescope, have made the end of box T (fig. 15) transparent, and light is thrown on the webs from a lamp held by an assistant. Holden has very recently applied a lamp ingeniously hung so as to preserve its verticality and the constant direction of its light in a similar way, adding a plain silvered mirror inside the box and opposite the lamp, so as to illuminate the webs symmetrically. In the Clarks' and Holden's methods it is only the webs at right angles to the screw that are illuminated.

For illumination of the field, in very old telescopes, light was thrown on a small ivory reflector fixed outside the object-glass in the axis of the telescope by an arm fitting on the cell of the lens. This involved the aid of an assistant to direct lamplight on the ivory reflector, or the very frequent change of a lamp support. Afterwards the light from an attached lamp was introduced through a hole in the telescope-tube and thrown upon an elliptical plane (generally dull-gilt) having its centre part cut away sufficiently to avoid interruption of the cone of rays from the object-glass. Many ingenious modes of suspending the lamp have been invented for the purpose of securing a constant direction of its light coupled with verticality of the lamp. One of the best of these, due to Cooke, is shown in fig. 19. L is the lamp, P a prism to reflect

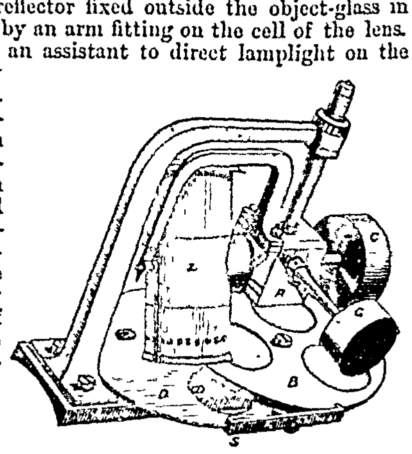

Fig. 19.

[1] It is asserted that webs from cocoons are more elastic, better shaped, and more durable than those obtained during an effort of the insect to escape. The best webs we have seen were from a cocoon obtained in Holland, but we have been unable to ascertain the name of the variety of spider.

[2] Argelander used to apply two drops of varnish at each end of his webs. He first fixed each extremity by a drop of shellac varnish, and after that had dried he applied a drop of copal varnish nearer the centre of the frame; the latter took a long time to harden, but gave ultimately a much stronger attachment.

its light into the tube, D a disk to regulate the quantity of light, B a disk with glasses to regulate the colour of the light, S a spring to clamp the disks, C the counterpoise of the lamp, G a poise to preserve the horizontality of the axis CL. But astronomers owe to the genius of Grubb the introduction of a more efficient and convenient system, viz., the performance of all necessary illumination of an astronomical telescope by a single lamp, and the perfect control of the illumination of the field or webs, and the regulation of these as to intensity or colour by simple motions from the eye-end. It is impossible to speak too highly of Grubb's efforts in this direction; he has broken the ground in this department of astronomical engineering, and rendered the working of so huge an instrument as the Vienna telescope of 27 inches aperture not only convenient, but easier for a single observer than that of a very small telescope of the older constructions.

But in the illumination of the field wires and scales of a micrometer Grubb's original method has recently been surpassed by one which is due to the Repsolds. We shall therefore describe the latter.

Fig. 20 represents the eye-end of a telescope. The reader will recognize the micrometer (figs. 16 and 17) previously described. L is a paraffin lamp fitting by a bayonet joint into a copper cover *c*. This effectually defends its glass chimney against accident, and protects the lamp from wind. The simple means by which this lamp is made to preserve its verticality in all positions of the telescope is evident from the figure. By this lamp alone the bright wire or bright field illumination is given at pleasure, and with any desired intensity, simply by movement of the small pin *p*.

The position circle and the head of the micrometer are also illuminated, as well as the declination circle, by the same lamp. AB is a cylindrical box, ending in a truncated cone towards A. It is shown, mid-section, in a plane passing through the telescope axis, in fig. 21, where all details unnecessary to the explanation of the illumination are omitted, and proportion of parts is sacrificed to clearness. P is a prism (fig. 21) that rotates with the lamp and reflects its light into AB. The flame of the lamp is in the focus of the lens *ll*, so that the rays become parallel after passing through it. There is a sliding motion to perfect this adjustment. There is a well-polished flat annular reflector of speculum metal *rr* (fig. 21), which reflects light upon the double mirror M (fig. 20), whence it is diverted to the two opposite points on the declination circle that are read by micrometer microscopes from the eye-end (the latter are omitted for sake of clearness).

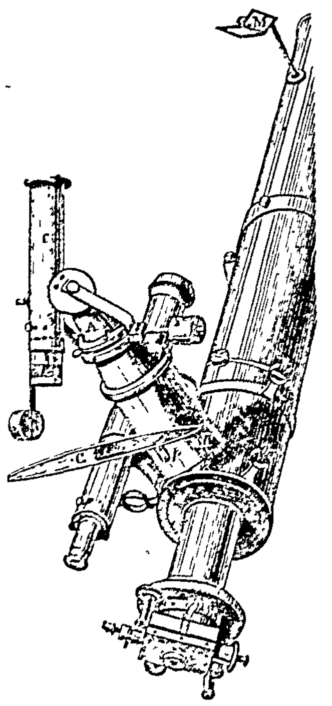

Fig. 20.

The little handle at p' and the dotted lines $p'z$ represent an iris-diaphragm, very ingeniously constructed, mounted on a plate of transparent glass. There is a flat ring of brass, carrying four pins, which is turned by the handle p', in a plane at right angles to P*n*. These pins work in spiral slots cut in four slides. Thus rotation of the ring causes the four slides to approach or recede from a centre. When the handle p' is in the middle of its range, the slides together form a disk as large as the hole in the diaphragm *dd*, and thus prevent all light from entering the telescope tube. When p' is pushed to one side of its range the slides move outwards leaving a square opening in the centre so that the light falls on the prism *n*,

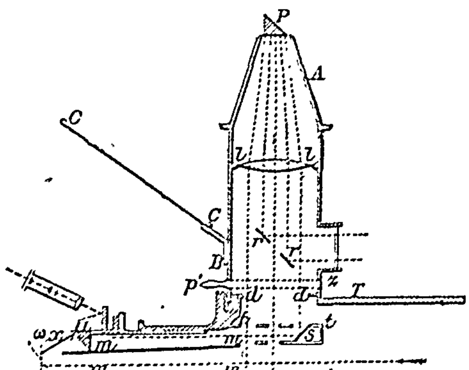

Fig. 21.

whence it is diverted to a silvered reflector cemented on the middle of the inner surface of the object-glass, and is then reflected back along the axis of the telescope to illuminate the field at ω. When p' is pushed to the other side of its range the slides approach and overlap at the centre, excluding light from *n* and allowing it to fall upon the reflector *s* instead. From *s* the light is thrown upon the webs ω, ω by reflexion from a white papier maché surface laid on the inside of a thin hollow brass truncated cone *xx*. The edge of this cone forms the circle seen within $\tau\tau$ in fig. 17. All stray light is prevented by the light-guard tube *mm*, which is attached to and moves with the rotating part of the micrometer. The result is to produce a symmetrical illumination of the whole system of webs in a perfectly dark field. It is also obvious that by placing p' at an intermediate position between the centre and the extremes of its range any desired modification of bright wire or bright field illumination can be obtained at pleasure.

The light falling on the papier maché hollow cone is intercepted at three points by prisms, one of which μ is shown in section. These prisms are inserted in the cylinder which carries the foundation plate of the micrometer box and rotate with it. Two of them divert light upon the reflectors (seen from different points of view in figs. 16, 17, 20). The third prism after two reflexions (figs. 16, 20) illuminates the micrometer head. The whole arrangement is in the highest degree elegant, and we have found it most simple and convenient in practice. The screen C (figs. 20 and 21)—made of thin copper and attached to AB—effectually protects the observer's eye from stray light from the lamp.

It has been found essential, in bright field illumination, when the highest accuracy is desired, to have the illuminating rays parallel with the telescope axis.

In the best telescopes of the future some plan like that of Repsold's, above described, will doubtless be adopted. It is probable also that with the introduction of condensers, in conjunction with the incandescent carbon light in vacuum, electricity will ultimately supersede the oil or paraffin lamp in illuminating astronomical instruments. A small "Swan lamp" can be placed anywhere, is unaffected by wind, and gives off comparatively little heat. These are most valuable qualities for the purpose in question.

The astronomer-royal (Mr Christie) has recently used luminous paint to render the measuring pointer of the Greenwich spectroscope visible at night. This paint, after exposure during the day to sunlight, shines at night with a dull phosphorescence sufficient to make the micrometer pointer, to which it is applied, faintly visible, and, it is stated, with very satisfactory results.

On the use of the filar micrometer consult Struve, *Mensuræ Micrometricæ*, St Petersburg, 1837; Brunnow, *Practical and Spherical Astronomy*; Chauvenel, *Practical and Spherical Astronomy*; Brunnow, *Astronomical Observations and Researches made at Dunsink*, Dublin, 1870, 1873, 1879; Ball, *ibid.*; Kaiser, *Leiden Observations*; and the papers of Dembowski in the *Astronomische Nachrichten*.

Double-Image Micrometers.

The discovery of the method of making measures by double images is stated to have been first suggested by Roemer about 1678. Roemer.
But no such suggestion occurs in the *Basis Astronomiæ* of Horrebow (Copenhagen, 1735), which contains the only works of Roemer that remain to us. It would appear that to Savary is due the first invention of a micrometer for measurement by double image. His heliometer (described in a paper communicated to the Royal Society in 1743, and printed, along with a letter from Short, in *Phil. Trans.*, 1753, p. 156) was constructed by cutting from a complete lens *abcd* the equal portions *aghc* and *acfe* (fig. 22). The segments *gbh* and *efd* so formed were then attached to the end of a tube having an internal diameter represented by the dotted circle (fig. 23). The width of each of the portions *aghc* and *acfe* cut away from the lens was made slightly greater than the focal length of lens × tangent of sun's greatest diameter. Thus at the focus two images of the sun were formed nearly in contact as in fig. 24. The small interval between the adjacent limbs was then measured with a wire micrometer.

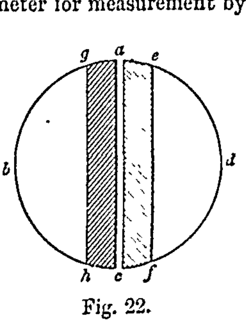

Fig. 22.

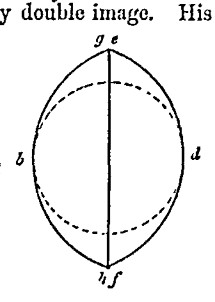

Fig. 23.

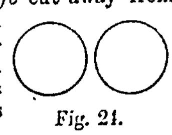

Fig. 24.

Savary also describes another form of heliometer, on the same Savary.
principle, in which the segments *aghc* and *acfe* are utilized by cementing their edges *gh* and *ef* together (fig. 25), and covering all except the portion indicated by the unshaded circle. Savary expresses preference for this second plan, and makes the pertinent remark that in both these models "the rays of red light in the two solar images will be next to each other, which will render the sun's disk more easy to be observed than the violet ones." This

he mentions "because the glasses in these two sorts are somewhat prismatical, but mostly those of the first model, which could therefore bear no great charge" (magnifying power).

A third model proposed by Savary consists of two complete lenses of equal focal length, mounted in cylinders side by side, and attached to a strong brass plate (fig. 26). Here, in order to fulfil the purposes of the previous models, the distance of the centres of the lenses from each other should only slightly exceed the tangent of sun's diameter × focal length of lenses. Savary dwells on the difficulty both of procuring lenses sufficiently equal in focus and of accurately adjusting and centring them.

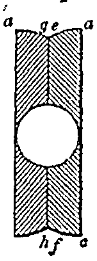

Fig. 25.

Bouguer. In the *Mém. Acad. de Paris*, 1748, Bouguer describes an instrument which he calls a heliometer. Lalande in his *Astronomie* (vol. ii. p. 639) mentions such a heliometer which had been in his possession from the year 1753, and of which he gives a representation on Plate XXVIII., fig. 186, of the same volume. Bouguer's heliometer was in fact similar to that of Savary's third model, with the important difference that, instead of both object-glasses being fixed, one of them is movable by a screw provided with a divided head. No auxiliary filar micrometer was required, as in Savary's heliometer, to measure the interval between the limbs of two adjacent images of the sun, it being only necessary to turn the screw with the divided head to change the distance between the object-glasses till the two images of the sun are in contact as in fig. 27. The differences of the readings of the screw, when converted into arc, afford the means of measuring the variations of the sun's apparent diameter.

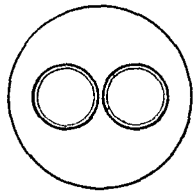

Fig. 26.

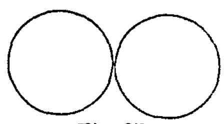

Fig. 27.

Dollond. On the 4th April 1754 Dollond communicated a paper to the Royal Society of London (*Phil. Trans.*, vol. xlviii. p. 551) in which he shows that a micrometer can be much more easily constructed by dividing a single object-glass through its axis than by the employment of two object-glasses. He points out—(1) that a telescope with an object-glass so divided still produces a single image of any object to which it may be directed, provided that the optical centres of the segments are in coincidence (*i.e.*, provided the segments retain the same relative positions to each other as before the glass was cut); (2) that if the segments are separated in any direction two images of the object viewed will be produced; (3) that the most convenient direction of separation for micrometric purposes is to slide these straight edges one along the other as the figure on the margin (fig. 28) represents them: "for thus they may be moved without suffering any false light to come in between them; and by this way of removing them the distance between their centres may be very conveniently measured, viz., by having a vernier's division fixed to the brass work that holds one segment, so as to slide along a scale on the plate to which the other part of the glass is fitted."

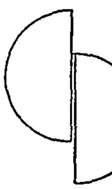

Fig. 28.

Dollond then points out three different types in which a glass so divided and mounted may be used as a micrometer:—

"1. It may be fixed at the end of a tube, of a suitable length to its focal distance, as an object-glass,—the other end of the tube having an eye-glass fitted as usual in astronomical telescopes.

"2. It may be applied to the end of a tube much shorter than its focal distance, by having another convex glass within the tube, to shorten the focal distance of that which is cut in two.

"3. It may be applied to the open end of a reflecting telescope, either of the Newtonian or the Cassegrain construction."

Dollond adds his opinion that the third type is "much the best and most convenient of the three"; yet it is the first type that has survived the test of time and experience, and which is in fact the modern heliometer

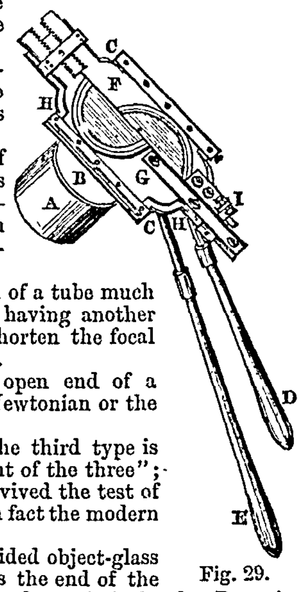

Fig. 29.

Fig. 29 illustrates Dollond's divided object-glass heliometer of the third type. A is the end of the reflecting telescope, upon which the adapter B is fitted. B carries a wheel (not seen in the figure) formed of a ring racked at the outer edge, and fixed to the brass plate CC, so that a pinion moved by the handle D may turn it into any position. Two plates F, G, with the attached semi-lenses, move in slides fixed to the plate CC,—simultaneous motion, in contrary directions, being communicated to them by turning the handle E, which drives a concealed pinion that works in the two racks seen in the highest part of the figure. The amount of separation of the semi-lenses is measured by a scale 5 inches long, subdivided to $\frac{1}{10}$th of an inch, and read by a vernier on the plate F to $\frac{1}{500}$th of an inch. In practical use this micrometer has never given satisfactory results (see Mosotti in the *Efemeride* of Milan for 1821). It must be remembered, however, that when Dollond gave preference to this type he had not invented the achromatic object-glass; his preference was fully justified under these circumstances. So far as we know no heliometer with a divided achromatic object-glass was ever made by the elder Dollond on the principle of his first type. His son, however, made what he called an object-glass micrometer, which was a great improvement on the elder Dollond's second type.

In the older construction the brass mountings of the semi-lenses obstructed the light entering the telescope in proportion to their separation, and the images were so coloured as to prevent the use of any but very low powers. In the later construction the movable segments are formed from a negative achromatic lens of much larger aperture than the object-glass of the telescope with which the micrometer is employed; and, for convenience in mounting, the segments *gbh* and *cdf* (fig. 22) are removed. In the fine example of this instrument at the Royal Observatory, Cape of Good Hope, the movable lenses consist of segments of the shape *gach* and *eacf* (fig. 22) cut from a complete negative achromatic combination of 8¼ inches aperture and about 41 feet focal length, composed of a double concave flint lens and a double convex crown. This is applied to an excellent achromatic telescope of 3½ inches aperture and 42 inches focal length. The instrument is represented in fig. 30; the same letters indicate the analogous parts of fig. 29. The frame CC, moved by teeth on its outer edge, carries one of the halves G of the lens, and a similar frame with teeth carries the other half F. A scale 8½ inches long is fastened like an edge-bar to the frame of the segment G, and each inch is subdivided into twenty parts, which are read off by a vernier to $\frac{1}{1000}$th of an inch, and, by estimation, this can easily be carried to $\frac{1}{2000}$th or $\frac{1}{3000}$th of an inch. The two movable frames are imbedded in a fixed plate HH, screwed to the adapter B, having a circular hole in its middle equal to the diameter of the object-glass. The slide of the segment G is moved by turning the milled head to the right of A, and the other segment F by means of a rack and pinion on the opposite side, the latter being turned from the eye-end by a handle not seen in the figure. A screw is provided for clamping the slide of the segment G, as it is intended that only the segment F shall be moved in making the final bisection. There is an index attached to the slide of G, reading on a rough scale engraved on the plate H, which is obviously intended for setting the optical centre of the segment G approximately as far from the optical axis of the telescope on one side as the optical centre of the segment F will be on the other side during the intended measurement. This arrangement not only permits the measurement of angles twice as great as would be possible if one segment were fixed, but is also important in increasing the symmetry of the measures. The vernier is placed at one end of the scale when the optical centres of the segments are in coincidence, and is provided with screws at I, which are intended for adjusting the zero of the scale. The younger Dollond has in this model retrograded, in some respects, from the admirable example of his father, who, as shown in fig. 29, not only gave the lenses automatic opposite motion symmetrically with respect to the axis of the telescope, but seems also to have provided for entire elimination of index error by making it possible to observe all angles on opposite sides of zero—a precaution possible in the later form only when very small angles are measured. Rotation of the micrometer in position angle is provided for as in the earlier form, but the instrument is not furnished with a position circle.

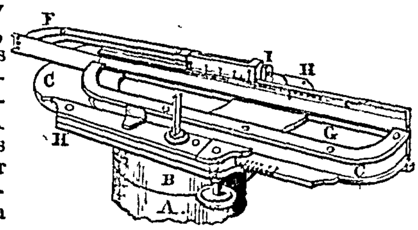

Fig. 30.

With one of these instruments of somewhat smaller dimensions (telescope 2½ inches aperture and 3½ feet focus) Triesnecker made a series of measurements at the observatory of Vienna which has been recently reduced by Dr Schur of Strasburg (*Nova Acta der Ksl. Leop.-Carol. Deutschen Akademie der Naturforscher*, xlv. No. 3). The angle between the stars ζ and *g* Ursæ maj. (708″·55) was measured on four nights; the probable error of a measure on one night was ± 0″·44. Jupiter was measured on eleven nights in the months of June and July 1794; from these measures Schur derives the values 35″·39 and 37″·94 for the polar and equatorial diameter respectively, at mean distance, corresponding with a compression 1/14·44. These agree satisfactorily with the corresponding values Triesnecker's measurements.

35″·21, 37″·60, 1/15·69 afterwards obtained by Bessel (*Konigsberger Beobachtungen*, xix. 102). From a series of measures of the angle between Jupiter's satellites and the planet, made in June and July 1794 and in August and September 1795, Schur finds the mass of Jupiter $= \frac{1}{1048 \cdot 55 \pm 1 \cdot 45}$, a result which accords perfectly with the received value of the mass derived from modern researches. The probable errors for the measures of one night are ±0″·577, ±0″·889, ±0″·542, ±1″·096, for Satellites I., II., III., and IV. respectively. It is probable that Triesnecker deduced the index error from his measures of the diameter of Jupiter, as, in 1794, the measures of diameter are made on the same nights with those of the measures of distance of the satellites, and it is possible that measures of diameter may have been made in 1795 but not published.

Considering the accuracy of these measures (an accuracy far surpassing that of any contemporary observations), it is somewhat surprising that this form of micrometer was never systematically used in any sustained or important astronomical researches, although a number of instruments of the kind were made by Dollond. Probably the last example of its employment is an observation of the transit of Mercury (November 4, 1868) by Mr Mann, at the Royal Observatory, Cape of Good Hope (*Monthly Notices R. A. S.*, vol. xxix. p. 197–209). The most important part, however, which this type of instrument seems to have played in the history of astronomy arises from the fact that one of them was in the possession of Bessel at Konigsberg during the time when his new observatory there was being built. In 1812 Bessel measured with it the angle between the components of the double star 61 Cygni and observed the great comet of 1811. He also observed the eclipse of the sun on May 4, 1818. In the discussion of these observations (*Konigsberger Beobacht.*, Abth. 5, p. iv) he found that the index error of the scale changed systematically in different position angles by quantities which were independent of the direction of gravity relative to the position angle under measurement, but which depended solely on the direction of the measured position angle relative to a fixed radius of the object-glass. Bessel attributed this to non-homogeneity in the object-glass, and determined with great care the necessary corrections. But he was so delighted with the general performance of the instrument, with the sharpness of the images, and the possibilities which a kindred construction offered for the measurement of considerable angles with micrometric accuracy, that he resolved, when he should have the choice of a new telescope for the observatory, to secure some form of heliometer.

Bessel's observations.

Nor is it difficult to imagine the probable course of reasoning which led Bessel to select the model of his new heliometer. Why, he might ask, should he not select the simple form of Dollond's first type? Given the achromatic object-glass, why should not it be divided? This construction would give all the advantage of the younger Dollond's object-glass micrometer and more than its sharpness of definition, without liability to the systematic errors which may be due to want of homogeneity of the object-glass; for the lenses will not be turned with respect to each other, but, in measurement, will always have the same relation in position angle to the line joining the objects under observation. It is true that the scale will require to be capable of being read with much greater accuracy than $\frac{1}{1000}$th of an inch—for that, even in a telescope of 10 feet focus, would correspond with 2″ of arc. But, after all, this is no practical difficulty,—for screws can be used to separate the lenses, and, by these screws, as in a Gascoigne micrometer, the separation of the lenses can be measured; or we can have scales for this purpose, read by microscopes, like the Troughton[1] circles of Piazzi or Pond, or those of the Carey circle, with almost any required accuracy.

Fraunhofer.

Whether Bessel communicated such a course of reasoning to Fraunhofer, or whether that great artist arrived independently at like conclusions, we have been unable to ascertain with certainty. The fact remains that before 1820[2] Fraunhofer had completed one or more of the five heliometers (3 inches aperture and 39 inches focus) which have since become historical instruments. In 1824 the great Konigsberg heliometer was commenced, and it was completed in 1829.

To sum up briefly the history of the heliometer. The first application of the divided object-glass and the employment of double images in astronomical measures is due to Savary in 1743. To Bouguer in 1748 is due the true conception of measurement by double image without the auxiliary aid of a filar micrometer, viz., by changing the distance between two object-glasses of equal focus. To Dollond in 1754 we owe the combination of Savary's idea of the divided object-glass with Bouguer's method of measurement, and the construction of the first really practical heliometers. To Fraunhofer, some time not long previous to 1820, is due, so far as we can ascertain, the construction of the first heliometer with an achromatic divided object-glass, *i.e.*, the first heliometer of the modern type.

Double-Image Micrometers with Divided Lenses.

Various micrometers have been invented besides the heliometer for measuring by double image. Ramsden's dioptric micrometer consists of a divided lens placed in the conjugate focus of the innermost lens of the erecting eye-tube of a terrestrial telescope. The inventor claimed that it would supersede the heliometer, but it has never done anything for astronomy. Dollond claims the independent invention and first construction of a similar instrument (Pearson's *Practical Astronomy*, vol. ii. p. 182). Of these and kindred instruments only two types have proved of practical value. Amici of Modena (*Mem. Soc. Ital.*, xvii. (1815) pp. 344–359) describes a micrometer in which a negative lens is introduced between the eye-piece and the object-glass. This lens is divided and mounted like a heliometer object-glass; the separation of the lenses produces the required double image, and is measured by a screw. Dawes has very successfully used this micrometer in conjunction with a filar micrometer, and finds that the precision of the measures is in this way greatly increased (*Monthly Notices*, vol. xviii. p. 58, and *Mem. R. A. S.*, vol. xxxv. p. 147).

In the improved form[3] of Airy's divided eye-glass micrometer (*Mem. R. A. S.*, vol. xv. pp. 199–209), the rays from the object glass pass successively through lenses as follows.

Lens	Distance from next Lens.	Focal Length.
a. An equiconvex lens	p	arbitrary $= p$
b. " "	2	3
c. Plano-convex, convex towards *b*	$1\frac{3}{4}$	1
d. Plano-convex, convex towards *c*	...	1

The lens *b* is divided, and one of the segments is moved by a micrometer screw. The magnifying power is varied by changing the lens *a* for another in which *p* has a different value. The magnifying power of the eye-piece is that of a single lens of focus $= \frac{1}{2}p$

In 1850 Valz pointed out that the other optical conditions could be equally satisfied if the divided lens were made concave instead of convex, with the advantage of giving a larger field of view (*Monthly Notices*, vol. x. p. 160).

The last improvement on this instrument is mentioned in the *Report* of the R. A. S. council, February 1865. It consists in the introduction by Simms of a fifth lens, but no satisfactory description has ever appeared. There is only one practical published[4] investigation of Airy's micrometer that is worthy of mention, viz., that of Kaiser (*Annalen der Sternwarte in Leiden*, iii. pp. 111–274). The reader is referred to that paper for an exhaustive history and discussion of the instrument.[5] It is somewhat surprising that, after Kaiser's investigations, observers should continue, as many have done, to discuss their observations with this instrument as if the screw-value were constant for all angles.

Steinheil's ocular micrometer.

Steinheil (*Journal Savant de Munich*, 28th February 1843) describes a "heliomètre-oculaire" which he made for the great Pulkowa refractor, the result of consultations between himself and the elder Struve. It is essentially the same in principle as Amici's micrometer, except that the divided lens is an achromatic positive instead of a negative lens. Struve (*Description de l'Observatoire Central de Pulkowa*, pp. 196, 197) adds a few remarks to Steinheil's description, in which he states that the images have not all desirable precision,—a fault perhaps inevitable in all micrometers with divided lenses, and which is probably in this case aggravated by the fact that the rays falling upon the divided lens have considerable convergence. He, however, successfully employed the instrument in measuring double stars, so close as 1″ or 2″, and using a power of 300 diameters, with results that agreed satisfactorily amongst themselves and with those obtained with the filar micrometer. If Struve had employed a properly proportioned double

[1] The circles by Reichenbach, then almost exclusively used in Germany, were read by verniers only.

[2] The diameter of Venus was measured with one of these heliometers at the observatory of Breslau by Brandes in 1820 (*Berlin Jahrbuch*, 1824, p. 164)

circular diaphragm, fixed symmetrically with the axis of the telescope in front of the divided lens and turning with the micrometer, it is probable that his report on the instrument would have been still more favourable. This particular instrument has historical interest, having led Struve to some of those criticisms of the Pulkowa heliometer which ultimately bore such valuable fruit (see below).

Ramsden (*Phil. Trans.*, vol. xix. p. 419) has suggested the division of the small speculum of a Cassegrain telescope and the production of double image by micrometric rotation of the semi-specula in the plane passing through their axis. Brewster (*Ency. Brit.*, 8th ed., vol. xiv. p. 749) proposes a plan on a like principle, by dividing the plane mirror of a Newtonian telescope. Again, in an ocular heliometer by Steinheil double image is similarly produced by a divided prism of total reflexion placed in parallel rays. But practically these last three methods are failures. In the last the field is full of false light, and it is not possible to give sufficiently minute and steady separation to the images; and there are of necessity a collimator, two prisms of total reflexion, and a small telescope through which the rays must pass; consequently there is great loss of light.

Micrometers Depending on Double Refraction.

Rochon's micrometer. To the Abbé Rochon (*Jour. de Phys.*, liii., 1801, pp. 169–198) is due the happy idea of applying the two images formed by double refraction to the construction of a micrometer. He fell upon a most ingenious plan of doubling the amount of double refraction of a prism by using two prisms of rock-crystal, so cut out of the solid as to give each the same quantity of double refraction, and yet to double the quantity in the effect produced. The combination so formed is known as Rochon's prism. Such a prism he placed between the object-glass and eye-piece of a telescope. The separation of the images increases as the prism is approached to the object-glass, and diminishes as it is approached towards the eye-piece.

Arago (*Comptes Rendus*, xxiv., 1847, pp. 400–402) found that in Rochon's micrometer, when the prism was approached close to the eye-piece for the measurement of very small angles, the smallest imperfections in the crystal or its surfaces were inconveniently magnified. He therefore selected for any particular measurement such a Rochon prism as when fixed between the eye and the eye-piece (*i.e.*, where a sunshade is usually placed) would, combined with the normal eye-piece employed, bring the images about to be measured nearly in contact. He then altered the magnifying power by sliding the field lens of the eye-piece (which was fitted with a slipping tube for the purpose) along the eye-tube, till the images were brought into contact. By a scale attached to the sliding tube the magnifying power of the eye-piece was deduced, and this combined with the angle of the prism employed gave the angle measured. If p'' is the refracting angle of the prism, and n the magnifying power of the eye-piece, then p''/n will be the distance observed. Arago made many measures of the diameters of the planets with such a micrometer.

Dollond (*Phil. Trans.*, 1821, pp. 101–103) describes a double-image micrometer of his own invention in which a sphere of rock-crystal is substituted for the eye-lens of an ordinary eye-piece. In this instrument (figs. 31, 32) a is the sphere, placed in half-holes on

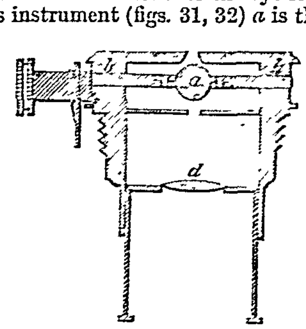

Fig. 31.

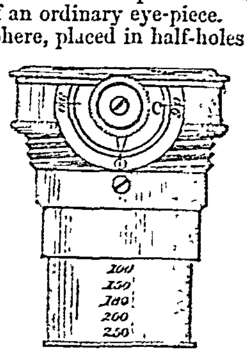

Fig. 32.

the axis bb, so that when its principal axis is parallel to the axis of the telescope it gives only one image of the object. In a direction perpendicular to that axis it must be so placed that when it is moved by rotation of the axis bb the separation of the images shall be parallel to that motion. The angle of rotation is measured on the graduated circle C. The angle between the objects measured is $= r \sin 2\theta$, where r is a constant to be determined for each magnifying power employed,[1] and θ the angle through which the sphere has been turned from zero (*i.e.*, from coincidence of its principal axis with that of the telescope). The maximum separation is consequently at 45° from zero. The measures can be made on both sides of zero for eliminating index error. There are considerable difficulties of construction, but these have been successfully overcome by Dollond; and in the hands of Dawes (*Mem. R. A. S.*, xxxv. p. 144 *sq.*) such instruments have done valuable service. They are liable to the objection that their employment is limited to the measurement of very small angles, viz., 13″ or 14″ when the magnifying power is 100, and varying inversely as the power. Yet the beautiful images which these micrometers give permit the measurement of very difficult objects as a check on measures with the parallel-wire micrometer.

[1] Dollond provides for changing the power by sliding the lens d nearer or farther from a.

The Modern Heliometer.

Königsberg heliometer. The Königsberg heliometer is represented in fig. 33. No part of the equatorial mounting is shown in the figure, as it resembles in every respect the usual Fraunhofer mounting. An adapter h is fixed on a telescope-tube, made of wood, in Fraunhofer's usual fashion. To this adapter is attached a flat circular flange h. The slides carrying the segments of the divided object-glass are mounted on a

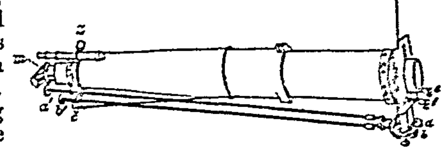

Fig. 33.

plate, which is fitted and ground to rotate smoothly on the flange h. Rotation is communicated by a pinion, turned by the handle c (concealed in the figure), which works in teeth cut on the edge of the flange h. The counterpoise w balances the head about its axis of rotation. The slides are moved by the screws a and b, the divided heads of which serve to measure the separation of the segments. These screws are turned from the eye-end by bevelled wheels and pinions, the latter connected with the handles a', b'. The reading micrometers e, f also serve to measure, independently, the separation of the segments, by scales attached to the slides; such measurements can be employed as a check on those made by the screws. The measurement of position angles is provided for by a graduated circle attached to the head. There is also a position circle, attached at m to the eye-end, provided with a slide to move the eye-piece radially from the axis of the telescope, and with a micrometer to measure the distance of an object from that axis. The ring which carries the supports of the handles a', b', c is capable of a certain amount of rotation on the tube. The weight of the handles and their supports is balanced by the counterpoise z. This ring is necessary in order to allow the rods to follow the micrometer heads when the position angle is changed. Complete rotation of the head is obviously impossible because of the interference of the declination axis with the rods, and therefore, in some angles, objects cannot be measured in two positions of the circle. The object-glass has an aperture of 6½ inches, and 102 inches focal length.

There are three methods in which this heliometer can be used.

First Method.—One of the segments is fixed in the axis of the telescope, and the eye-piece is also placed in the axis. Measures are made with the moving segment displaced alternately on opposite sides of the fixed segment.

Second Method.—One segment is fixed, and the measures are made as in the first method, excepting that the eye-piece is placed symmetrically with respect to the images under measurement. For this purpose the position angle of the eye-piece micrometer is set to that of the head, and the eye-piece is displaced from the axis of the tube (in the direction of the movable segment) by an amount equal to half the angle under measurement.
